Mines and Minerals

VOLUME XXXI

August, 1910, to July, 1911

122531
17/6/12

SCRANTON, PA.
INTERNATIONAL TEXTBOOK CO.
1911

INDEX

INDEX A—Authors, Subjects, and Titles of Articles

(Separate Indexes of "Book Reviews," "Personals and Obituaries," "Catalogs Received," and "Trade Notices" follow "Index A")

Page

A B C OF ELECTRICITY IN MINES..... 692
Accidental Taylor Air Compressor....... 458
Accident Investigations, Mine.......... 282
Accident Prevention, Mine.......... 276
Accidents, Liability for Industrial.......... 501
Accidents, Prevention of Mine.......... 611
Accidents to Working Men.......... 227
Acid Specific Gravity Tests, The.......... 62
Action of CO and H, or CO_2 and H on Iron Oxides.......... 454
Adams, Thomas K., James Blick, 486—Mine Fires.......... 274
Aerial Tramway, Utah Consolidated.......... 150
Aerolith Rescue Apparatus.......... 521
Air From a Hydraulic Compressor.......... 561
Air Compression, Hydraulic.......... 129
Air Compressor, An Accidental Taylor.......... 458
Air Compressor, Electric.......... 263
Air Compressors at Mines, Small.......... 477
Air Compressors, Turbine.......... 285
Air, Desiccation of Furnace.......... 723
Air Explosions, Disastrous.......... 683
Air Locomotives, Two-Stage.......... 365
Air-Nitrate Fertilizers.......... 320
Alabama Coal Mines, Convict Labor in.......... 679
Alabama Inspectors' Warning Card.......... 763
Alabama, Kellerman Mine.......... 204
Alabama, Mulga Mine Explosion.......... 40
Alabama, Natural Gas and Petroleum in.......... 175
Alaska, Bonanza Copper Mine.......... 441
Alaska Coal, Cost of Mining and Marketing.... 221
Alaska Copper Deposits, Chitina Valley.......... 315
Alaska Copper Mining, 1909.......... 318
Alaska Gold Production, 1909.......... 339
Alaskan Coal Business, Possible Effect of Panama Canal on.......... 175
Alaskan Coal Mining, No Progress in.......... 272
Alaskan Coals, Obstacles to Development of .. 657
Alaska Oil Field, Katalla.......... 731
Alaska's Coal Lands, Value of.......... 401
Alaska's Gold From Lode Mines, 1909.......... 326
Alaska, Transportation in.......... 409
Alaska, Valdez Creek Placer District.......... 572
Alchemist in Modern Industry, The.......... 688
Aldrich Pump Department.......... 506
Alkalinity, Determination of.......... 478
Alkalinity, Testing for Protective.......... 13
Alkalinity, Titrating for Protective.......... 479
Allis-Chalmers Co., The Largest Ore Crusher.. 432
Altar, Mexico, Mining Cement Gravel at.......... 229
Aluminum Bronze.......... 584
Aluminum for Prevention of Scale in Boilers... 719
American Blower Co., Test of Double-Inlet Sirocco Fan.......... 541
American Institute of Mining Engineers, One Hundredth Meeting.......... 754
American Institute Panama Meeting.......... 329
American Mining Congress..........226, 585
American Mining Congress, September, 1910 Meeting..........105, 231
American Safety Lamp and Mine Supply Co., Safety Lamps on Battleships.......... 535
American Society of Engineer Draftsmen 105
American Tin Mining in Bolivia.......... 568
American *vs.* European Coal Mines.......... 195
American Zinc, Lead and Smelting Co., Report of.......... 293
Amethyst Coloration of Glass.......... 573
Ammonium-Nitrate Explosives, Firing.......... 767
Analyses, Grading.......... 344
Announcement, Win G. Conley, Webster H. Taylor.......... 162
Anthracite and Bituminous Output, Pennsylvania.......... 485
Anthracite Cryptogram.......... 417
Anthracite, Thermochemistry of..........37, 166
Arizona, Los Pilares Mine.......... 106
Arizona, Miami Concentrating Mill.......... 1
Arkansas, Zinc and Lead in.......... 10
Asbestos.......... 469
Ashworth, James, Bellevue Explosion, Alberta, 399—Fernie Slack Bin Fire, 293—Protective Value of Humidity 188
Assay for Copper, Proof.......... 149
Assay of Copper Bullion, Combination.......... 240
Assay of Gold, Wet..........143, 423
Assayers in British Columbia, Examination for 769
Assays, Standardization of Bullion.......... 690
Aston, T. J., Rules for Mine Foremen.......... 293
Aston, W. C., Elizabeth Tunnel.......... 102
Atkinson, A. S., Restoring Dredged Ground... 422
Aubrey, Louis E., Fake Oil Companies.......... 424
Austin, C. C., Pumping at Bisbee, Ariz.......... 132
Australia, Restoring Dredged Ground.......... 422
Austria, Radium in.......... 6
Automatic Coal Sampler (Statt).......... 85
Automatic Transportation Co., New Transportation System.......... 39

BAILEY, E. E., COAL AND COKE SAMPLING, 89—Sampling Coal and Coke. .209, 190
Bailey, E. W., Can Water Vapor Be Resolved Into Its Gases in an Explosion, 225—Lamp Burning in Water, 166—Pumping.......... 38
Bailing Water at Coleman Shaft.......... 631
Balaklala Copper Co., Fume-Controlling Device 561
Baldwin Camp Lighting Outfit.......... 33
Banner Mine Explosion.......... 675
Barbour, Percy E., Developments in Cyanide Practice.......... 597
Bartlett & Snow Co., C. O., Self-Dumping Car Hauls.......... 536
Bath-House, Marianna Mine.......... 525
Battleships, Safety Lamps on.......... 535
Bavarian Graphite Industry.......... 504
Beard, J. T., Black Powder, 225—The Siphon in Mining, 427—Pumping and Siphoning Hot Water.......... 663
Bellevue Explosion, Alberta.......... 399
Belgium, Use of Breathing Appliance.......... 440
Bingham, Yampa Smelter at.......... 14
Bisbee, Ariz., Pumping at.......... 132
Black Powder..........165, 225
Blair's Zinc-Lead Pigment Plant.......... 698
Blakeley, Abram G., Gravity Determination of Coal.......... 499
Blast Furnaces, Circular Copper.......... 20
Blasting Holes Charging.......... 44
Blasting, Knox System.......... 36
Blasting, Principles of Electric.......... 393
Blasting Supplies.......... 222
Blatchley, Raymond S., Petroleum Mining Engineering.......... 4 2
Blick, James.......... 486
Blossburg Plant, Automatic Transportation Co. 39
Blowers in Coyote Mine, Gas.......... 361
Blowers, Turbine.......... 285
Blowpipe, The Oxygen.......... 163
Blumenstein, W. H., Rules for Handling Kanite.......... 681
Boiler Tests, Mechanical Stokers and Hand Firing.......... 42
Bolivia, American Tin Mining in.......... 568
Bonanza Copper Mine, Alaska.......... 441
Bonanza Mine.......... 315
Bonding in Mines, Rail.......... 673
Booth, W. H., Clay Shrinkage.......... 615
Boquillas Zinc Deposits.......... 479
Boring, Cost of Core.......... 323
Bowman, F. C., Power for Concentrating Mill.. 19
Brackett, F. Ernest, Bailing Water at Coleman Shaft.......... 631
Brady, F. Webster, Bunker Hill Coal Storage Plant.......... 166
Brattice Cloth, Use Care in Purchase of.......... 44
Brazil, Discovery of Coal in.......... 500
Brazil's Iron Ore Deposits.......... 57
Breaker, The Taylor Concrete.......... 272
Breathing Apparatus, European Laws Regarding.......... 413
Breathing Apparatus, New.......... 759
Breccia, Duty on.......... 213
Breccia, Tariff on.......... 380
Brier Hill, Pa., First-Aid Graduates.......... 491
British Coal Mining Notes.......... 666
British Columbia, Examination for Assayers in 769
Broadwater, C. C., Filter Presses.......... 682
Brokaw, Albert D., Surface Alterations of Gold Ores.......... 687
Broken Hill, N. S. W., Minerals.......... 439
Bronze, Aluminum.......... 584
B. T. U., How He Explained the.......... 82
Buffalo-Susquehanna Sagamore Mine.......... 645
Buker, H. W., Mining Iron Under the Sea..... 569
Bunker Hill Coal Storage Plant.......... 166
Bureau of Mines, The Director of.......... 162
Bureau of Mines Rescue Station.......... 68
Bureau of Mines, The United States.......... 79
Burton, Howard E., Leadville, Colo., Zinc Deposits.......... 436
Buskett, Evans W., Metal Mine Ventilation, 19—Tests for Copper Minerals.......... 430
By-Product Coke Ovens, Koppers.......... 185

CACTUS MINE, SOUTH UTAH MINE AND MILL.......... 592
Caging Machine, Mine Car.......... 413
Calama, Chile, Concentration at.......... 605
Calama Copper District, Chile.......... 473
Calcium Carbide Production in 1908.......... 369
Calcium Chloride, Desiccation of Furnace Air.. 723
Calculating the Tonnage of Ore Piles.......... 158

Page

Calculations, Portland Cement... 25
Calderwood, J. M., Hand Jig for Small Mines... 591
California, Electric Iron Smelting in... 221
California, Geology of the Coalinga Oil Fields... 4
California, Iron Ores of the Southwest... 574
Cameron Combination, Ingersoll-Rand... 462
Canada, William W., Mexican Territory of Quintana Roo... 425
Canadian Iron Ore Industry... 455
Canadian Mining Institute Meeting (March, 1911)... 596
Canal, The Panama... 241
Can Water Vapor be Resolved Into Its Gases in an Explosion... 225
Capacity of Revolving Screen... 181
Carbic Cakes... 174
Carbon Dioxide and Vegetation... 163
Carbon Dioxide in French Mines, Outbursts... 392
Carbon Monoxide, Tests for... 33
Care of Mine Mules... 650
Car Hauls, Self-Dumping... 536
Carraher, T. A., Oxygen Helmets Used at Mine Fire... 161
Carruth, J. A., New Mexico Gold Gravels... 117
Carter, T. Lane, Mining Industry of Nicaragua... 566
Catalog of Books Worth While... 612
Cement Calculations, Portland... 25
Cement Concrete Vats and Tanks... 364
Cement-Lined Pumps and Column Pipes... 506
Cement Mill, Coal Dust Explosion in a... 417
Cerium, Tariff on Alloy of Iron and... 23
Chance, Edwin M., Gravity Determination of Coal, 499—Thermochemistry of Anthracite... 166
Charging Blasting Holes... 44
Cheddite... 97
Chemistry of Coal Dust Explosions, Lievin, France... 264
Chemistry of the Cyanide Process... 689
Chemist's Place in Mining, The... 683
Chile, Calama Copper District... 473
Chilian Coal... 638
China, Tin Mining in... 131
Chitina Valley Copper Deposits... 315
Circular Copper Blast Furnaces... 20
Clancy Cyanide Process... 433
Classification of Fuels, Commercial... 397
Clay Shrinkage Under London... 615
Clifford, William, The Coefficient of Friction, 176—Warnings to Colliers... 562
Coahuila Coal Co., Explosion at Palau No. 2 Mine... 202
Coal and Coke Sampling...89, 190, 209
Coal and Coke Shipments, Pocahontas... 630
Coal and Other Exports... 526
Coal Consumption in the United States... 426
Coal Discovered in Territory of Magellan... 531
Coal Dust, Explosibility of... 369
Coal-Dust Explosion in a Cement Mill... 417
Coal-Dust Explosions...623, 746
Coal-Dust Explosions, Chemistry of, Lievin, France... 264
Coal, Export of... 494
Coal Fields of Iowa and Missouri... 80
Coal Field, The Illinois... 54
Coal, Gravity Determination of... 499
Coal in Boilers, Combustion of... 492
Coal in Brazil, Discovery of... 500
Coal in Chile... 638
Coal in Dan River District, North Carolina... 177
Coalinga Oil Field... 164
Coalinga Oil Field, Geology of... 4
Coaling Station in Southern Pacific... 700
Coal Lands, Value of Alaska's... 401
Coal-Loading Machine...66, 206
Coal Market, French... 766
Coal Mine Act, A Model (Canadian)... 546
Coal Mines of Dawson, New Mexico... 653
Coal Mine Transportation... 408
Coal Mining in India... 64
Coal Mining in Oklahoma... 193
Coal Mining Institute of America, December, 1910, Meeting... 407
Coal Mining Institute of America, June, 1911, Meeting... 38
Coal Mining News... 93
Coal Mining Notes...373, 404
Coal Mining Notes, British... 666
Coal Notes...48, 212, 281, 481, 649
Coal Pillars, Methods of Removing... 495
Coal Plants, Engineering of Modern... 57
Coal Production for 1910, United States... 417
Coal Production of the World, 1908... 538
Coal Sampler, Automatic (Statt)... 85
Coal Sampler, Mechanical... 169
Coal, Sampling... 98
Coal Seam, Working a Steep... 77
Coal Statistics, Illinois, 1910... 357
Coal Storage Plant, Bunker Hill... 166
Coal Trusts and Safe Mining (?)... 633
Cobalt, Air From Hydraulic Compressor... 561
Cobalt Ore Buying by Smelters... 705
Cobalt Ores, Hydrometallurgy of... 303
Cobalt Ores, Treatment of... 693
Cobalt, Ragged Chutes Air Compression... 129
Cobre Copper Mine... 235
Cobre Mines, Cuba... 449
Coefficient of Friction... 176
Cokedale, Colo., Explosion...547, 658
Cokedale Mine, Inspection Table at the... 752
Cokedale Plant, Falcone Oven Tile-Laying Machine... 287
Coke Oven Gas... 266
Coke Ovens in Mexico, Retort... 257
Coke Ovens, Koppers By-Product... 185
Coke, Sampling Coal and...190, 209
Coleman Shaft, Bailing Water at... 631
Coll, Aloysius, Mining Cement Gravel at Altar... 229
Colleges, Federal Aid for Mining... 743
Collieries, Power Production at... 33
Colliers, Warnings to... 562
Colliery Survey Notes, Rocky Mountain Fuel Co... 61
Colliery Warnings... 482
Collingridge, Bede, Testing for Protective Alkalinity... 13
Collins, Alonzo G., Siphon... 101
Colorado Coal Mine Commission... 418
Colorado Coal Mine Law, Proposed... 482
Colorado Fuel and Iron Co., Starkville Explosion... 261
Colorado Mine Law, The Proposed... 487
Colorado, Report of Coal Mine Inspector... 665
Colorado, Rio Blanco County... 328
Colorado School of Mines Thesis... 35
Combination Assay of Copper Bullion... 240
Combustion of Coal in Boilers... 492
Combustion of Explosives, Heat of... 429
Commercial Classification of Fuels... 397
Commission, Report of South African Mining Regulation... 337
Common Casting Copper... 421
Compensating Grades... 768
Compensation for Injury... 410
Competition Among Smelting Companies... 293
Competition, 1909, Transvaal Drill... 459
Compressor, Electric Air... 263
Concentrating Mill, Miami... 1
Concentrating Mill, Power for... 19
Concentration at Calama, Chile... 605
Concrete Breaker, The Taylor... 272
Concrete Floors, to Prevent Dusting of... 500
Concrete, Properties of... 636
Concrete Shafts in Iron Ore Mines... 740
Concrete Vats and Tanks, Cement... 364
Conical Mill, Fine Crushing With... 604
Conservation Undesirable... 384
Consolidated Fuel Co., Utah... 385
Contract, Selling Zinc Ore on... 550
Converter Flames, Copper... 718
Convict Labor in Alabama Coal Mines... 679
Copper Blast Furnaces, Circular... 20
Copper Bullion, Combination Assay of... 240
Copper, Common Casting... 421
Copper Converter Flames... 718
Copper Deposits, Chitina Valley... 315
Copper Deposits, Scientific Study of... 684
Copper District, Chile, The Calama... 473
Copper Minerals, Tests for... 430
Copper Notes, Lake Superior... 717
Copper, Proof Assay for... 149
Copper Refining, Laurel Hill Works, Brooklyn 690
Copper Smelting, Reverberatory... 557
Correction... 227
Correlation of Thacker Field... 83
Correspondence. Black Powder, 165, 225—Blick, James, 486—Can Water Vapor be Resolved Into Its Gases in an Explosion, 225—Clay Shrinkage, 615—Coal-Dust Explosions, 746—Determination of Meridian, 37, 682—Explosive Mixture, 225—Fernie Slack Bin Fire, 293—Filter Presses, 682—Haulage, 425—Howell-White Furnace, 225—Lamp Burning in Water, 166—Lamp Burns in Water, 37—Method of Laying Off a Curve, 165—Mining Around Gas Wells, 486—Mining in San Domingo, 745—Miscellaneous Questions, 293—Monazite, 101—Problem of Education, The, 745—Pumping, 37—Putting Out a Mine Fire, 101—Railroad Rates, 101—Recollections of William Smurthwaite, 165—Rolling Friction, 683—Rope Haulage, 563—Rules for Mine Foremen, 293—Safety in Mines, 562—Siphon, 101—Size of Shaft Pillar, 615—Steam in the Air-Current, 486—Steel Supports in Mines, 563—Storing Coal, 745—Surveying, 37, 166—Thermochemistry of Anthracite, 37, 166—To Find Percentage of Grade, 101—Ventilation, 101—Warnings to Colliers... 562
Coslettising, Rust-Proof Finish for Iron... 225
Cost of Core Boring... 323
Cost of Cyanide Process... 726
Cost of Mining and Marketing Alaska Coal... 221
Cost of Sinking a Mexican Mine Shaft... 275
Cottrell Fume Controlling Device... 561
Coxe & Fritz Laboratories... 35
Coyote Mine, Gas Blowers in... 364
Crawford, Robert, Power Production at Collieries... 33
Cresson Mine... 735
Crown Mines, Ltd... 691
Crusher, The Largest Ore... 432
Cryptogram, An Anthracite... 417
Cuba, El Cobre Mines... 449
Cuba, Iron Ores of Santiago... 245
Cuban Gold Mines... 240
Cuban Mining Development... 244

Mines and Minerals

Vol. XXXI—No. 1. SCRANTON, PA.—AUGUST, 1910—DENVER, COLO. Price, 25 Cents

MIAMI CONCENTRATING MILL

Written for Mines and Minerals, by R. L. Herrick

Features of Construction that Admit of Low Cost and Tend to Economy of Operation

The 2,000-ton concentrating mill of the Miami Copper Co., at Miami, in Gila County, Ariz., is now in course of construction. It is the design of H. Kenyon Burch, who constructed the Moctezuma concentrating mill at Nacozari, Sonora, Mex., which during the last year recovered 85 per cent. of the copper mineral in the ore, thus achieving a record for this kind of mill work. Preliminary to preparing plans for the Miami mill, Mr. Burch, bent on absorbing the good points in mills treating copper sulphide ores, visited Cananea, Mex., Anaconda, Mont., Garfield, Utah, and Ely, Nev. The Miami mill, therefore, embodies the best constructive features of previously built copper concentrating mills, besides original features and improvements by the designer. Fig. 1 shows the mill to be situated on a side hill, to the south of No. 4 main hoisting shaft, whose steel head-frame towers above the mill frame in the middle foreground. By constructing the mill on this steep hill, head room is obtained in the mill and a tailing dump in the gulches below, two advantages not always available. Adjacent to the No. 4 head-frame are the run-of-mine ore receiving bins of 1,000 tons capacity. Below the bins the coarse crushing machinery is to be placed, and between the coarse crushers and the crushed-ore bins is the mechanical sampler. One end of the building, in line with the fine crushing department, is to be devoted to a machine shop where repairs can be made. To move the heavy machinery in the fine grinding department to the repair shop, one 5-ton hand-moved crane and one 15-ton electrically operated power crane are installed. Heavy girders extend the length of the building for these cranes to operate on, so that in case of a breakdown, or if repairs are needed, the heavy parts of the machinery can be removed and new parts substituted with little delay. This is one of the original features of the plant, as the heavy machinery is either above or on the machine-shop floor.

Fig. 1. Miami Concentrator

Fig. 2. Rear of Miami Concentrator

The mill is divided into three units of two sections each. Fig. 2 shows the rear of the mill to have six circular concrete foundations on which will rest six steel ore bins, two for each section, and from which coarsely crushed ore will be fed to rolls that crush to $\frac{1}{8}$ inch in diameter. There are four floor levels to the main mill building, the uppermost being for screens and the fine rolls mentioned; the next lower floor is to be occupied by the Chilean mills; the third floor will carry the classifiers and Deister concentrating tables, and the fourth floor will be used for the conical settling tanks and Deister slime tables.

Above the third and fourth floors will be suspended narrow platforms, paralleling the tables, which will support the hydraulic classifiers and the launders that are to feed the tables. This arrangement is intended to promote dryness and cleanliness by preventing the splashings from falling to the table floor. The three products from the concentrating tables flow through separate pipes to their respective launders beneath the floor. There is a vault for each mill section centrally situated between the product ends of two lines of tables and in these the launders are placed. Fig. 4 shows the vault openings in the lowest retaining wall. The roof of the vault is the floor of the table room and is formed of iron in which are cemented thick pieces of glass. This floor is similar to a glass sidewalk and permits the daylight that enters from skylights above the tables to penetrate the vault beneath the floor. This is the original introduction of transparent floors into mill practice.

Another feature of importance in connection with the construction of this mill is the absence of elevators. The nearest approach to this kind of machinery is one inclined conveyer belt and several small centrifugal pumps. The flow of ore and pulp through the plant, with these exceptions, is accomplished by gravity.

The only hand work at this operation from the time the ore is broken in the mine stopes to the time the concentrate is going to its bin, consists in moving, loading, and starting levers and the adjustment of machinery. Shoveling and tramming are eliminated, making the mill the only one of its kind arranged in the world.

Construction Notes.—By taking advantage of the side-hill slope, which is hard cemented breccia of the Gila conglomerate, the mill terraces and tunnels are excavated from it. Little hard rock work was necessary and the concrete work consisted in facing up the excavations with retaining walls, etc. In this

way the elaborate concrete arched columns for foundations that have been a feature of several previously constructed concentrating mills were made unnecessary, with a consequent great saving. It is interesting to note that several score Apache "bucks" from the near-by Indian reservation condescended to work with pick and shovel on this foundation work and proved about as efficient as the Mexicans. The terrors of the Southwest a generation back were evidently tempted by the unusual chance to acquire the wampum for fire-water.

Fig. 5 shows the method of constructing the concrete retaining walls. Instead of building frames and tearing them down as fast as the wall was completed, the main walls were largely constructed by building sectional forms which were transported from place to place by means of a gin pole tackle. The illustration shows the forms in the foreground, the one immediately in front laid flat with its toe pointed vertically and about to be hauled into the correct position occupied by the adjacent form behind it. By using these forms built about 16 feet long, considerable time and expense were saved over the usual method, although the form method requires a greater employment of skilled labor and supervision to insure the avoidance of mistakes.

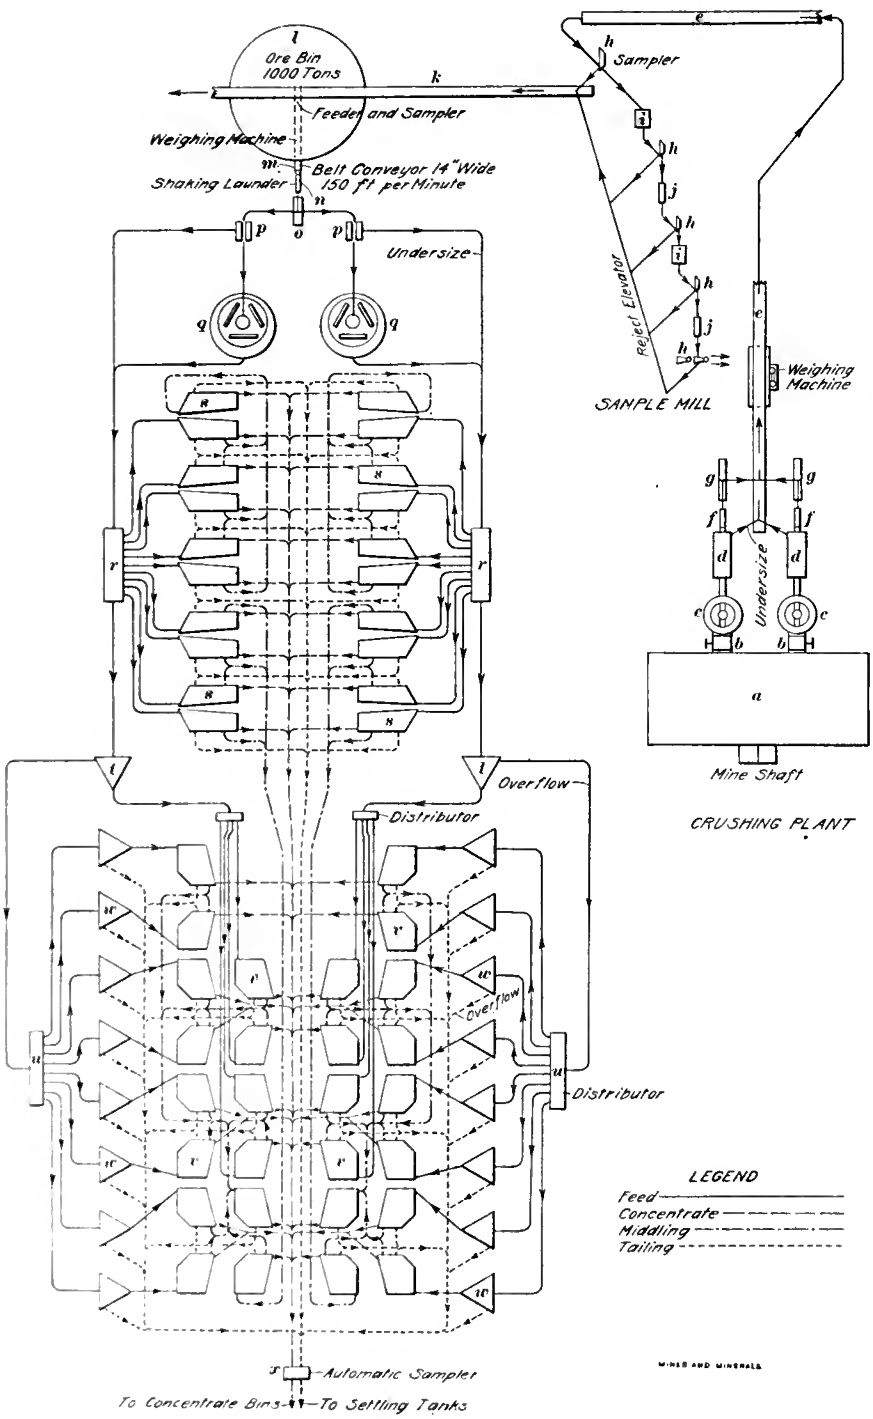

FIG. 3. FLOW SHEET, MIAMI CONCENTRATOR

The frame of the concentrator is of structural steel erected under contract by the Minneapolis Steel and Machinery Co. The sheathing will be corrugated iron with rubberoid or some similar roofing. With the exception of the wooden feed-launders and supporting platforms, nothing but concrete and steel enters into the construction of the entire plant.

The proposed mill treatment, as based upon the results achieved in the experimental mill, is approximately as indicated by the flow sheet, Fig. 3. The run-of-mine ore from bin *a* passes through the automatic ore feeder *b* to No $1\frac{1}{2}$ gyrating rock breakers *c*, whose average capacity is about 50 tons per hour through a 2-inch diameter ring. The material passes from the crushers to 4'×10' rotary screens *d*, which permit all that will pass through $\frac{3}{4}$-inch holes to go to a belt conveyer *e*. The oversize from the screens goes to the shaking launders *f* which feed the 54"×24" coarse rolls *g* that break the ore to $\frac{1}{2}$-inch cubes. From the coarse rolls the ore goes by gravity to the 30-inch wide conveyer belt *e* that travels at the rate of 300 feet per minute up an incline of 15° 30'. This delivers to the mechanical sampling department. On reaching the sampling mill the ore is cut out by samplers *h*, mixed by machines *i*, and crushed by rolls *j* until the final duplicate samples, weighing 40 pounds each, are obtained. The discard from the various samplers goes to the 30-inch wide conveyer belt *k*, and this, traveling at the rate of 250 feet per minute, delivers the ore by means of a tripper to one of the six large circular ore bins *l*. Reference to the flow sheet will show how the mill section is divided into two parts from here on. Fine rolls *o* of Mr. Burch's design, reduce the ore to $\frac{1}{8}$-inch cubes in the first application of wet crushing. The product is screened at *p* to 22 mesh or coarser, the screens' oversize going to Chilean mills *q*, the undersize to hydraulic classifiers *r*. The mills grind to 30 mesh and combine product with the screen undersize to the classifiers. The latter will probably be of the Richard vortex type, or the Swain individual classifier for each table. The coarse product of each classifier is split between nine Deister No. 2 concentrating tables *s* whose tailing goes direct to waste, and whose middling is treated on a tenth table. The fine slime product of the classifier, however, is settled in a conical tank *t* and the thickened pulp product distributed between four Deister slime tables *v*. The overflow from this first conical settling tank, however, flows to a distributor *u* which supplies eight conical settling tanks *w*, each individual tank serving to thicken the slime for one Deister slime table. All of these slime tables make a middling and tailing product in addition to concentrate. The

middling product from the 10 concentrating tables *s* on the floor above is combined and retreated on one Deister slime table which in turn gives its middling to a second slime table. The latter, in addition, treats the combined middling of the 12 previously mentioned slime tables and makes only concentrate and tailing.

The overflow water of the eight conical settling tanks *w* is combined with the tailing from the concentrating tables *s* and slime tables *v* and flows outside the mill to a system of concrete settling tanks. This will be similar to the system built by Mr. Burch at Nacozari, the clear overflow water from the tanks being pumped back to the head of the mill, and the sediment flushed to waste.

It will be noted that this proposed system provides for the accurate classification and uniform sizing of the pulp grains fed to every concentrating and slime table, thus insuring the early elimination of barren tailing and reducing the retreatment of middling to a minimum. By providing adequate capacity of settling tanks, every concentrator is likewise fed a pulp sufficiently thickened to insure the best results. And finally, by installing a tailing-settling system of adequate capacity, tanks of non-leaking concrete, etc., the continued reuse of the mill water is made possible, thus reducing its waste to a minimum, a noteworthy feature in such a desert country where the water expense is an important item.

Concentration Results.—While the ratio of concentration is not yet fully determined, it is likely that about 20 to 1 will be adopted. From the experimental mill tests it seems likely that the extraction will be somewhere between 75 and 80 per cent., or from an ore averaging 2.75 per cent. copper, the recovery will be from about 40 to 44 pounds of metal per ton milled.

This will give a product expected to contain about 40 per cent. copper, 35 per cent. silica, 6 per cent. iron, and the balance in sulphur and alumina.

With the depth of ore proved to the 620-foot level, thus giving it a thickness of 400 feet, and making 14,000,000 tons in sight, a production of 700,000 tons of ore annually can be maintained for at least 20 years. This does not take into consideration the possibilities of either prolonged life or enlarged production, based upon the other 150 acres of unexplored ground now thought to be mineralized.

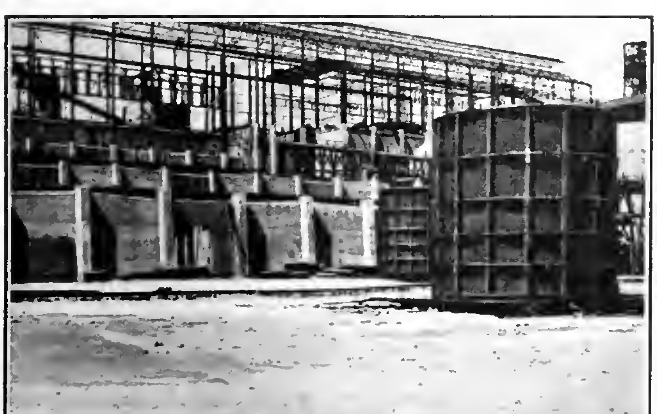

Fig. 4. Lower Portion of Miami Concentrator

Water Supply.—In addition to two valuable water rights of its own which will supply considerable water, the Miami company has secured from the Old Dominion company a supply of 1,000,000 gallons per day. This latter water will flow by gravity to the company ranch on the lower end of Miami wash at which point the pumping plant will be located. From here the water will be pumped through a 14-inch diameter cast-iron pipe to the storage tank located on the hill above the concentrating mill. Since the choice of mill site involved the problem of whether it was cheaper to pump water than to transport ore, it was solved in favor of the pumping.

Power Plant.—The power plant is situated at the foot of the hill, just east of the valley settlement of Miami. The containing building is constructed wholly of steel and concrete, and built for more power machinery than the present mill requires in order to provide for future installations. The boiler plant consists of three water-tube boilers burning fuel oil, each boiler of 600-horsepower nominal capacity with steam at 185 pounds pressure and 100 degrees of superheat. The steam engines, three in number, are of four-cylinder triple-expansion type, size 21″×40″×40″×40″×48″ stroke. Each engine is direct-connected to a 1,000-kilowatt, alternating-current generator producing three-phase current of 25 cycles at 6,600 volts pressure.

Fig. 5. Movable Forms for Concrete Work

The electric current will run the underground haulage system, the mill shops, and the lighting system, but compressed air will operate the mine drills and the hoisting engines.

The air-compressor plant consists of two machines, of the four-cylinder, triple-expansion, two-stage type, each with a capacity of 4,000 cubic feet of free air per minute compressed to 90 pounds per square inch pressure. This air will be piped a half mile from the power plant to No. 4 shaft where, by use of fuel oil, the air will be preheated before use in the hoisting engines.

SIMULTANEOUS INVENTIONS

That "nimble thoughts can jump both sea and land" is exemplified by the invention in Australia and the United States, granted almost simultaneously, of processes for the separation and recovery of zinc sulphides from intermixed sulphides or gangue. Scarcely had the full text of the process invented by Mr. H. J. Horwood, mine manager of the Broken Hill Proprietary, and which was published in our issues of November 10 and 17 last, been circulated throughout the world than the news of a similar patent taken out in the United States came to hand. The specifications of this patent are not available, but *The Mining Magazine* states that a patent covering exactly the same ground has been granted in the United States to H. A. Wentworth, who has assigned it to the Huff Electrostatic Separator Co., of Boston. This patent is numbered 938,732, and is dated November 2. The specification describes how complex sulphides are ground sufficiently fine, and subjected to a roast for a few minutes at a dull red heat. In this way the particles of pyrite and galena are covered with oxide or sulphate, while the blende remains unaffected. Subsequently the mixture is treated by a flotation process, whereby the blende is floated off while the iron and lead compounds sink. With the exception that the respective inventors differ as to the length of time required for the roast, the two processes are identical.—*Australian Mining Standard.*

GEOLOGY OF THE COALINGA OIL FIELD

Abstracted for Mines and Minerals

Location and Topography. A Description of the Distinguishing Rocks and Fossils

The Coalinga, Cal., oil field is in the southern part of Fresno County, the western part of Kings County, and is bounded on the south by the Kern County line. To fully understand the conditions in Coalinga it is necessary to have a reference map showing the ranges, townships, and the developed oil field. In a general way, however, from the southern extremity of the developed oil field, the foot-hills run due north for about 7 miles, then turn east for about 3 miles, and then again bend north. From the curve thus formed a spur of hills extends in a southerly direction for several miles.

This topographical arrangement in the Coalinga oil field is that of a plain some 6 miles square, surrounded on three sides by the hills, and bounded on the south by the railroad. The town of Coalinga is on the railroad and close to the foot-hills, and therefore near the southwest corner of this plain, which is smooth, and slopes very gently northwest to southeast.

Oil has been found on the lowest portion of the foot-hills, and extending out for a varying distance from them, on the north and west sides of this plain, as well as on the outer or valley face of the foot-hills where they turn to the north, and on the same side of the spur range. The "East Field" is that portion lying on the valley slope of the north limb; the "Southeast Extension" on the east or valley slope of the spur. The "West Field" lies on the inner portion of the hills west and south of the plain. The "South Field" is the prospective territory south of the railroad, following the hills for an indefinite distance.

The length of the developed field, extending from the railroad north, then east, then north again, is some 13 miles. The

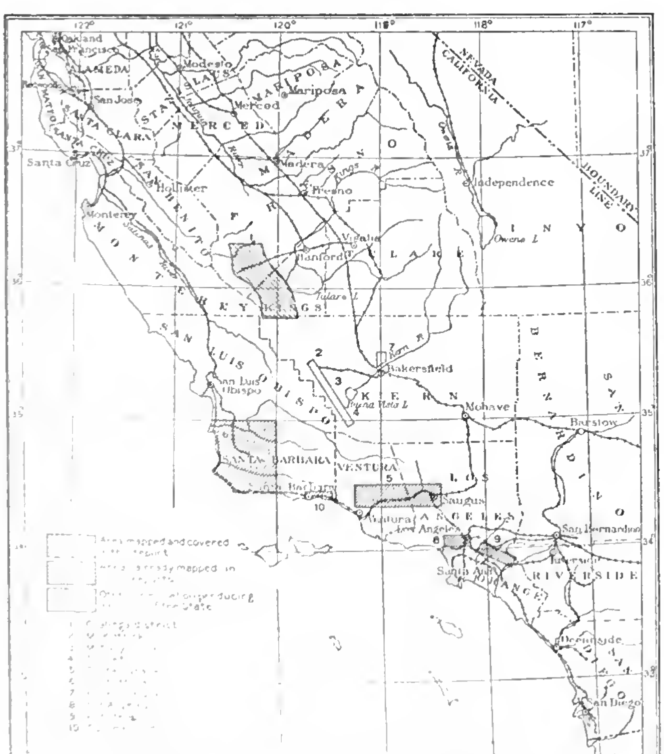

Fig. 1. Map Showing Location of Coalinga, Cal., Oil Field

extension to the ... has been proven up for a length of approximately a mile and a half. The width of the actually proven belt varies from ¾ of a mile at the lower extremity to about 2½ miles at the widest part, with an average of perhaps 2 miles.

Drilling is carried on in the foot-hills because the oil-bearing sand is there nearer the surface than it is in the plain, where it is over 4,000 feet deep.

The eastern slope of the mountains bordering the San Joaquin Valley is formed by a great thickness of strata dipping toward the valley.

The oldest rocks appear in the axis of the mountain and grade into younger rocks in the following order: Franciscan, Knoxville, Chico, Tejon, Vaqueros, Santa Margarita, Jacalitos, Etchegoin, Tulare, and late Quaternary alluvium and terrace deposits. With the exception of the magmatic rocks associated with the Franciscan, all formations are of sedimentary origin. The following table correlates the rocks of the coast range and the Coalinga oil district:

Era	Period	Epoch	Standard Coast Range Series Section	Coalinga District Series Section
Cenozoic	Quaternary	Recent	Alluvium	Alluvium
		Pleistocene	San Pedro —Unc.— —Unc.—	Stream deposits, valley fillings, and raised beaches —Unconformity—
	Tertiary	Pliocene	Merced	Tulare
			San Diego	—Unconformity—
		Miocene	San Pablo	Etchegoin —Unconformity—
			—Unconformity—	Jacalitos —Unconformity—
			Santa Margarita —Unconformity—	Santa Margarita (?) —Unconformity—
			Monterey	Lacking (with possible exception of a small part)
			—Unconformity— Vaqueros —Unconformity—	Vaqueros —Unconformity—
		Oligocene	San Lorenzo —Unconformity?—	Lacking
		Eocene	Tejon	Tejon —Unconformity—
			Martinez —Unconformity?—	
Mesozoic	Cretaceous		Chico —Unconformity— Horsetown —Unconformity—	Chico
			Knoxville —Unconformity—	Knoxville —Unconformity—
	Jurassic?		Franciscan —Unconformity— Granitic rocks, etc. —Unconformity—	Franciscan
	?		Schist and limestone	

The original rocks of the Franciscan series, which occupy the central portion of the Diablo Range are sandstone, shale, jasper, schists, and serpentine without fossils, being more or less metamorphosed. The Knoxville-Chico rocks comprise a thick succession of sandstone, shale, and conglomerate that may be recognized by the dark, thin-bedded, compact shale of the lower portion and the massive drab concretionary sandstone of the upper portion. From the Franciscan below to the Tejon above, the Knoxville-Chico formation is 12,800 feet thick. Owing to the insufficiency of evidence and the absence in the Middle Cretaceous epoch of the Horsetown series of the standard Coast Range series in the Coalinga district, the Knoxville and Chico series are not separated. Commencing with the lowest, and therefore earliest formation of the Knoxville-Chico rocks, the strata are about as follows:

1. Thinly bedded dark shale similar to that above, with some sandstone layers.
2. Massive iron-gray sandstone.
3. Thinly bedded dark shale and sandstone similar to that above, but without fossils.
4. Coarse massive conglomerate zone of locally variable thickness with large boulders of pre-Franciscan rocks. Probably basal conglomerate of the standard Chico.
5. Alternating thin, sharply defined beds of dark clay shale, sandy shale, iron-gray and brownish-gray sandstone and some beds of conglomerate and pebbly sandstone; marine

fossils of the Chico formation which is Upper Cretaceous, are found sparingly in the upper portion.

6. In the upper half of the upper division of the Knoxville-Chico series there are found purplish siliceous shale, dark clay shale, light-colored calcareous shale, white and yellow sandstone, and a minor zone of tawny concretionary sandstone. In the lower half mostly massive drab concretionary sandstone is found. The marine fossils shown in Fig. 2 are found sparingly throughout the upper half of the Knoxville-Chico.

The Tejon series of rocks above the Chico is named from Fort Tejon, in Kern County, Cal. It is of the Eocene epoch and attains a thickness of 1,850 feet in the Coalinga oil district. From the Chico up, the beds are:

1. Marine yellowish brown and gray fossiliferous sandstone and dark clay, with a local basal conglomerate.

2. Marine white and brown shale carrying diatoms and other minute shells of rhizopods called foraminifers. The distinctive feature of the formation is the increasing fine-grained texture from the sandy lower beds to the thin and tinted shales above. Fossils of the Tejon series are shown in Fig. 3. There are also a number of bivalves on the order of those found in the Vaqueros series of rocks.

The Vaqueros sandstone of the Lower Miocene epoch is said to attain a thickness of 900 feet in the Coalinga oil field. The upper member is a marine gray sandstone and sand with subordinate conglomerate, gravel, diatomaceous earth, and clay shale. The series is distinguished by the protruding tendency of the hard sandstone in its central portion known locally as the "reef beds." The lower number of the Vaqueros consist of marine white and brown diatomaceous earth and shale. The beds at the base of the Vaqueros series are said to be the chief oil-bearing sands of the Coalinga district. In many places they are saturated and discolored with petroleum. Wherever they overlap the Tejon stage and cover the Chico stage the lower beds lose their petroleum at a distance from the Tejon. This shows the oil horizon in the Coalinga district to belong to the Tejon and Vaqueros sands particularly, although upper sands may also contain oil. The fossils found in the Vaqueros formation, shown in Fig. 4, are not all bivalves, as an occasional gasteropod is found, as shown at *3*.

The Santa Margarita stage is said to be Middle Miocene and between 900 and 1,000 feet thick. On the eastern side of the Coalinga oil field there are a number of strata containing large fossil bivalves and a species of coral. Owing to this formation it is assumed that these beds are the Santa Margarita series, found in San Luis Obispo County, in the standard Coast Range. They are traceable as far south as the San Joaquin coal mine, and beyond that the beds are either lacking or are unfossiliferous. North of Waltham Creek the supposed Upper Middle Miocene is composed of marine fossiliferous sand, clay, gravel, and comminuted serpentine. South of Waltham Creek the Santa Margarita series are white, purple, and brown shales. The fossils belonging to this stage of the Miocene are shown in Fig. 5.

The Jacalitos stage of the early Upper Miocene epoch is said to be 3,800 feet thick in the Coalinga oil field. Jacalitos is named from a creek where the beds of this stage are exposed. The formation is composed of slightly consolidated marine fossiliferous beds of light-gray, greenish-gray, blue and brown sand, clay and fine gravel, interbedded with similar deposits indurated into sandstone, shale, and conglomerate, with some siliceous shale. The formation may be roughly distinguished as that portion of blue sand and sand rock above the brownish shale of the Santa Margarita and the large beds of blue sand of the Etchegoin formation above it.

A feature of the Jacalitos is the occurrence in it at intervals of hard rocks that project like saw teeth and which, by their resistence to weathering, protect the beds immediately above and below them, thus forming long parallel ridges. Another feature of the Jacalitos formation is the great number of sand and pebble beds full of fossil sea urchins, Fig. 6 *5*.

The Etchegoin formation is classed as the uppermost Miocene, and assigned a thickness of 3,800 feet in the Coalinga district. It derives its name from an abandoned sheep ranch about 20 miles northeast of Coalinga, and consists of slightly

consolidated, chiefly marine, fossil beds of gray and blue sand, black clay, light sandy clay, pebbly sand and gravel, with locally hardened beds of sandstone and occasional layers of siliceous and calcareous shale. The upper third is largely dark clay, the lower portion blue sand. This stage is distinguished by an abundance of sea urchins, Fig. 6 *5*, and barnacles, Fig. 5 *1*, as well as those shown in Fig. 7, which are bivalves and gasteropods.

The Etchegoin formation in the Coalinga district is overlain along the border of the San Joaquin Valley by thick beds of gravel, sand, clay, sandstone, conglomerate, and some limestone, which form the Tulare formation of the Pleistocene The formation is said to be 3,000 feet thick and is in the Pliocene of the Lower Pleistocene epoch. The lithological condition of this formation is given as unconsolidated but locally hardened unfossiliferous, light gray and yellowish sand, light and dark clay, coarse and fine gravel, and thin layers of purplish sandstone; in part of fresh water and marine origin. At the base are fresh-

water sand, sandstone, gravel, shell deposits, and limestone. In the Tulare formation are found shells shown in Fig. 8, which will be recognized as species of bivalves, periwinkles, and snails, approximately such as are to be found at this time. In places it is impossible to separate the Jacalitos, Etchegoin, and Tulare beds, and in the McKittrick district, southeast from Coalinga and west from Bakersfield, the three are combined and termed the McKittrick formation. The Tulare formation may be recognized most readily by the fresh water fossils and strange [illegible] its base, and by the boulder gravel, which is more [illegible] abundant than in any of the Tertiary formations.

RADIUM IN AUSTRIA

Thirteen grams of radium chloride have been produced at the Imperial Austrian radium factory located at St. Joachimsthal. It is estimated that this mineral has a value of $45,000 to $50,000 a gram, or more than half a million dollars for the entire amount. Pure metallic radium is never seen, but is always in combination. The bromide or chloride is extracted from pitchblende by repeated reductions. This latter mineral is taken from a worked-out silver mine near St. Joachimsthal, a small village in the Erzgebirge, about 12 miles northwest of Carlsbad.

The property belongs to the Austrian Government and the pitchblende has been mined during the last 50 years for the uranium, which is its principal mass, or about 50 to 90 per cent. of the whole.

Uranium is used in the manufacture of decorated glass and porcelain. Its yellow oxides are employed by glass manufacturers to give a delicate greenish-yellow tint to glass, and the black oxides are used as a pigment in porcelain painting. The colors are exported extensively and sell on the average for $12 a pound.

At present about 100 men are engaged in mining the pitchblende, which is found in small seams. They work in the mine 8 hours a day and the rest of the time cultivate small farms in the neighborhood.

The annual output of the mine is reported as about 400 hundredweight of pitchblende, equal to nearly 100 hundredweight of uranium ore. It requires approximately 10 tons of pitchblende to yield 1 gram of radium bromide, which is contained in the residue after the uranium is extracted. In the process 11,000 pounds of chemicals and 110,000 pounds of water are employed.

In order to obtain the radium bromide, more than a thousand crystalizations and reductions have been made at the factory. These require from a few hours to several days each, growing more difficult the nearer the approach to the radium chloride.—*United States Consular Report.*

BRAZIL'S IRON-ORE DEPOSITS

Consul-General George E. Anderson, of Rio de Janeiro, calls attention to certain advance figures on the known iron-ore deposits in Brazil.

Large Amount of High Grade Ores As Yet Undeveloped, Awaiting Means of Transportation

The report is furnished by Dr. Orville T. Herby, chief of the geological survey, of Brazil, as tentative conclusions on Brazil's available iron-ore supply. It is printed in Portugese for use of the International Geological Congress, which meets in Stockholm this year. Excerpts from the paper are taken.

Colonial records show that in 1590 iron was found south of Sao Paulo. Gold and silver being also reported in the same region, the Portugese Government sent in 1597, a colony from the mother country to promote the mining industry. One or two forges commenced to produce iron in about 1600, and this was the first to be manufactured in the Western Hemisphere; about 100 years later, the gold fields of Ouro Preto, the former capital of Minas Geraes, were discovered. This opened to exploration and permanent settlement the most extensive and important of the Brazilian iron fields, that of the Sierra do Espinhaco, or Backbone Range, forming the eastern rim of the basin of the Sao Francisco River. A large part of the gold mines of this and the neighboring district are actually in iron ore, though a century or more elapsed before any recorded efforts were made to turn it to use.

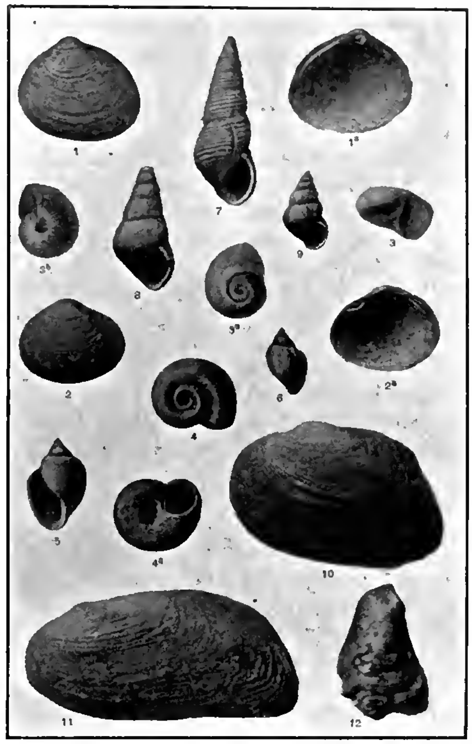

Fig. 8. Tulare Fossils

There is, however, a presumption that long before the definite establishment of the iron industry some metal may have been produced by the primitive African methods with which many of the slaves imported for the gold mines must have been familiar. Eschwege states that in 1811 most of the smithies produced their own iron, either directly in an ordinary blacksmith's forge, or in a primitive furnace constructed for the purpose.

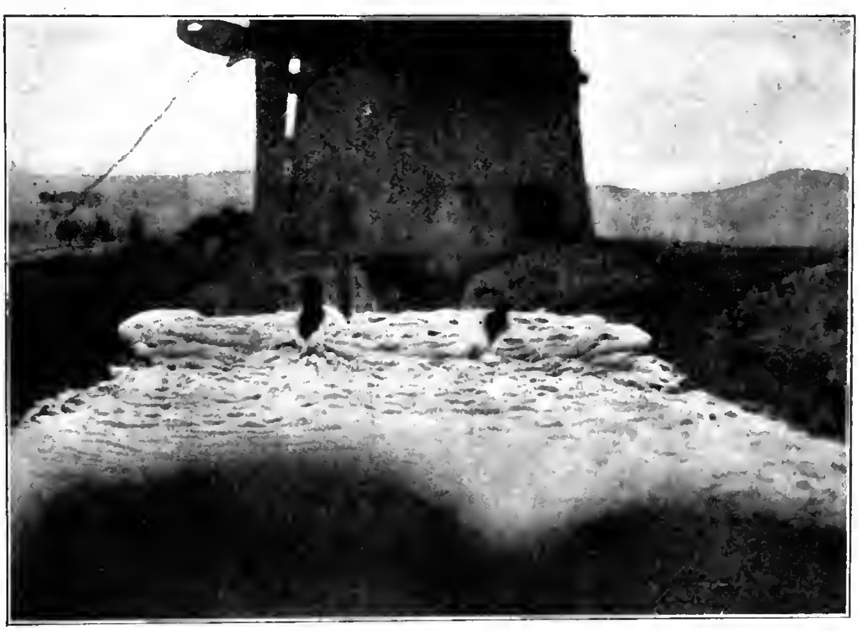

Fig. 9. Flowing Oil Well

Under the direction of Eschwege a company was formed to erect a direct-process plant near Ouro Preto which produced metal at the end of 1812 at the rate of about a hundredweight per day. The improvements here introduced were eagerly copied and in a short time the whole mining district of Minas Geraes was dotted with little furnaces. The number of these was estimated in 1864 as 120, many of which are still in operation.

In 1765 the production of iron was resumed at Ipanema in Sao Paulo, but again abandoned after a few years. An attempt made in 1800 to revive the industry, by means of a high furnace, was unsuccessful, and in 1810 a Swedish metallurgist under contract with the government constructed four direct-process furnaces which continued in operation until 1818, when two high furnaces constructed by the German engineer officer, Frederic von Vernhagen, then in the service of the Portuguese government, were put into operation. These continued in blast under government administration and with a daily production of 3 or 4 tons until 1895.

Between 1809 and 1814 an attempt was made to establish a high furnace at the Morro de Pilar in the neighborhood of Serro in Minas, but the enterprise was abandoned before reaching the productive stage, and until 1888 all the iron produced in Brazil, outside of Ipanema, was made by the direct process. In that year a high furnace with a daily capacity of four tons, afterwards raised to six, was put into blast at Esperanca near Itabira do Campo in the state of Minas Geraes, and this has continued to operate successfully, being now the only establishment of its kind in Brazil.

This inglorious history, extending over two centuries is suggestive of conditions unfavorable to the development of an iron industry, but it is sufficient to say that a deficiency of excellent ore is not one of them.

Iron ores are known in every state of Brazil and specimens of them figure in every national exposition, but for the most part definite information regarding the deposits is lacking. The greater part of the specimens exhibited are magnetites, highly titaniferous. With a single exception knowledge of the iron ore deposits of Brazil is lacking, and this exception does not furnish very definite information. A good number of specimens of hematites, representing numerous widely separated localities, have also appeared.

The districts regarding which definite information is at hand, belong to the states of Minas Geraes, Sao Paulo, Bahia, Goyaz, Parana, Santa Catharina, Rio Grande do Sul, and Matto Grosso The ores known in the first three and the last of these states are predominantly hematites; in the others,

predominantly magnetites. With a single exception, knowledge of these ore deposits is limited to the mere fact of their existence, their approximate geographical position, and the outward aspect of the ore picked up by unskilled observers.

The exception is the district situated in the eastern central part of the state of Minas Geraes, in the section of the Espinhaco Range that forms the divide between the Rio Doco and the Sao Francisco drainage systems extending over about two degrees of latitude with a width of about one degree of longitude. As already remarked, this is also the most productive of the gold fields of Brazil, and in consequence is one of the oldest and most densely populated of the interior regions. On this account and also on that of being on the road to the diamond fields of northern Minas Geraes, it has been more frequently visited and described by travelers than any other interior region. Notwithstanding this fact, it has been very imperfectly mapped and there is a singular lack of reliable and accurate information regarding its geological and economic features. A small party of the Servico Geologico e Mineralogico do Brazil, under the direction of Dr. Luiz Felippe Gonzaga do Campos, for the two past years has been occupied in mapping the district both topographically and geologically. The following brief account of the district is taken almost exclusively from a preliminary report now in course of preparation by Dr. Gonzaga do Campos.

The only all-rail means of access is by the Central Railroad of Brazil, which, starting from the port of Rio de Janeiro, enters the district at its southern border at kilometer 493, traverses it in a north and south direction for a distance of 90 kilometers to Sabara and extends a branch transversely across it which, when completed to Santa Barbara, will have an extension of 60 kilometers. The Leopoldina Railway, a narrow (1 meter) gage road belonging to an English company, starting from the same port, with a present extension of 630 kilometers will eventually tap the district at its northeast corner at Itabira do Matto Dentro with an extension of about 87 kilometers. The Victoria and Diamantina Railroad, also of meter gage and belonging to a French company, is now under construction from the port of Victoria, in the state of Espirito Santo, toward the same point (Itabira), which it can reach with an extension of about 630 kilometers. It is understood that the company proposes to complete this line as soon as possible and to equip it especially as an ore-carrying road. If this is done and if the port of Victoria, which is an excellent one, is properly equipped with handling facilities, one of the most important parts of the district will have a satisfactory outlet in the near future.

In its essential geological features the region is constituted by a basement complex of crystalline schists (gneiss, mica, amphibole, chlorite, and talcose schists), overlaid by a heavy series of partially metamorphosed sedimentary beds, profoundly folded and faulted. In this series, which consists principally of quartzites and clay slates with subordinate beds of limestone, a prominent member is the peculiar iron-bearing quartzite to which the name of "itabirite" has been applied. This name was originally proposed by Eschwege, in 1822, for the massive, pure iron ore of which the peak of Itabira do Campo, among others, is composed, and which is associated with a schistose rock composed of granular quartz and scaly hematite, which he discriminated as iron-mica schist. By common usage the name has come to be applied to the latter rock, and it is only in this sense that its retention can be justified as a convenient term that would otherwise have to be designated by an awkward and misleading descriptive name. Through variation in the proportions of the constituent elements, this type of rock grades off on one side to a purely quartzose, and on the other side to a purely hematitic phase. The phases sufficiently rich in iron to be commercially valuable may be conveniently designated as itabirite ores. This shows all possible gradations from an almost pure quartz rock with scattered flakes of hematite to a massive hematite free from quartz. The latter is in intercalated layers, varying from a few millimeters up to scores of meters in thickness, alternating with leaner quartzose portions. When limestones are with the series, they are also frequently associated with commercial ores of both iron and manganese.

The itabirite beds, become, when exposed to the weather, extremely friable, and as the region is one of heavy rainfall, they have been extensively denuded. In consequence of this, the massive portions, stand out as topographical features; the rain- and wind-swept slopes become covered with a rubble of iron ore due to the breaking up of the thinner intercalated layers, more or less completely freed from the associated siliceous elements by rain and wind action, and the bottom lands of the valleys become charged with deposits of iron sand separated by the natural sluicing of the streams. There are thus produced from the same series of beds three classes of ore; namely, (1) quarry ore, in the peaks and other natural exposures in situ of the massive portions of the rock; (2) rubble ore, on the denuded surfaces; and (3) sandy ore, in the valleys where sluicing action has taken place. To these must be added a fourth class, the so-called "canga" (contraction of Tapanhoacanga; i. e., "negro's head"), due to the cementation by limonite of the rubble ore into a hard stone conglomerate. It is probable also that still a fifth class might be recognized in the outcrops of quartz-hematite rock sufficiently friable to permit the separation of the metallic mineral by sluicing.

The crystalline areas of older rocks contain no iron ore, but in places, particularly in the southern part in the neighborhood of Queloz, there are important deposits of manganese that have been extensively mined. In the sedimentary area, on the contrary, iron ore of one kind or another is much more abundant and widespread. The outcrops on belts of the iron-bearing formation are so generally covered by superficial deposits of rubble ore and canga that by picking your route it is possible to traverse the area from one side to the other and along various lines without leaving, except for short intervals, one or another of the various kinds of ore deposits enumerated.

The deposit on the southwest extends to the mountain of Itatiaussu, which is known to be composed in large part of the iron-bearing formation and is reputed to contain large workable deposits of ore; that on the north includes the main ridge of the Espinhaco Range in the direction of Coniceicao and Serro, along which several iron mountains are known to occur, while the one on the northeast embraces the Candonga district, which is also reputed to be rich in iron ore.

From the above description it is evident that attempts to estimate the amount of ore in the district must be extremely fallacious. Practical geologists who have visited parts of the district hesitate to pronounce estimates that at first sight seem utterly preposterous.

The following estimates made by Dr. Gonzaga do Campos, of the Servico Geologico, will serve to give an approximate idea of what the ore may amount to when the district becomes better known. These estimates for nine of the deposits are as follows:

	Cubic Meters
Gava	72,000,000
Conceicao	80,000,000
Esmeril	19,000,000
Caue (Itabira peak)	33,000,000
Pitanguy	14,000,000
Sao Luiz	8,000,000
Peak of Itabira do Campo	8,000,000
Rio de Peixe	10,000,000
Cocaes	3,000,000
Total	247,000,000

Taking the specific gravity of these ores as 4, this volume represents 988,000,000 tons. In these estimates no account is taken of the presumed underground extension of the visible ore bodies.

No attempt has been made to estimate the volume of the rubble-ore deposits, which are both numerous and extensive throughout the district. So far only one such deposit has been actually measured by competent mining engineers, and this is

said to carry "20,800,000 tons of rubble ore, carrying 50 per cent. iron." From what is known of the district it seems quite safe to assume that there are scores of deposits of equal importance and that in the aggregate the volume of rubble ore is at least equal to that of the quarry ore.

As regards the canga, Dr. Gonzaga do Campos estimates that it covers about 10 per cent. of the area occupied by the iron-bearing formation, which is about 5,700 square kilometers. For the purposes of calculations, however, he takes 5 per cent. with a mean thickness of 2 meters which gives 570,000,000 cubic meters, which, calculated with a mean specific gravity of 3, gives 1,710,000,000 tons of ore, whose mean iron content will probably oscillate in the neighborhood of 50 per cent.

Most of the analyses are vague in that the phosphorus is given as "traces," without accurate determination, and no reference is made to titanium, leaving it doubtful whether this element had been sought. The oxide of iron is generally given as from 97 to 99.5 per cent., the remainder being almost exclusively silica. In two cases in which special tests were made for titanium none was found, and from this it seems safe to assume that as a class these ores are practically free from it.

The most reliable phosphorus determinations at hand, are from samples submitted to the Krupp works and to the United States Steel Corporation, both of which give the same result; namely, .0024 per cent.

From an industrial point of view, it seems tolerably safe to set the rubble ores down, as regards quantity and quality, as comparable with those of the quarry class.

The canga class of ore is naturally of lower grade than the others, owing to admixture of fragments of quartzose and argillaceous rocks, which it would be impracticable to separate in mining, and to the presence of water in the characteristic limonitic cement. Good observers estimate the mean iron contents of this class of ore at about 50 per cent. As already remarked, the apparent quantity of this class of ore is immense and, so far as can be judged by a simple ocular inspection, probably in excess of that of any other class.

Aside from the district above discussed and of its various prolongations that have not yet been examined, hematite ores are known to exist in various other districts of the state of Minas Geraes and in various other states of the republic.

The iron-ore formation seen many years ago by the writer at various points along the River Sao Francisco is believed to be identical with that of Minas Geraes, and some of the deposits may prove to be comparable with those above described as regards quantity and quality, but on this head nothing definite can be said, as the examination was of the most cursory character. That of Urucum in Matto Grosso occurs in association with manganese ores and with limestone, and in this respect offers a certain analogy with that of Minas Geraes, but it differs in the fact that the siliceous admixture, where it occurs, is in the form of jasper rather than that of granular quartz. The deposits are reputed, on good authority, to be extensive, but the quality judging from chance specimens that have come to hand, is not as high as in the Minas Geraes ores.

As already remarked, the magnetite is a very widespread mineral in Brazil, and many of the occurrences are reputed to be extensive. The most accessible and, so far as known, the most extensive, of these occurrences are situated in the coast region of Southern Sao Paulo, Parana, and Santa Catharina.

FAST TUNNEL DRIVING

Written for Mines and Minerals

In the April, 1909, issue of Mines and Minerals, was an article by R. L. Herrick in which he compared and tabulated the speed with which American and European tunnels were driven. In the April, 1910, issue he had an article on the Laramie-Poudre tunnel whose object is to divert the abundant waters of the Medicine Bow range of mountains to ditches to irrigate 200,000 acres of arid land in the vicinity of Fort Collins, Idaho. The length of the tunnel between portals will be 1,300 feet when completed.

During the month of May, 1910, the Laramie-Poudre tunnel, using No. 7 water Leyner drills, was driven from two headings a distance of 845 feet. The heading from the west end was advanced 332 feet, while the heading from the east portal was advanced a distance of 513 feet, thus breaking all Colorado records for a single heading in a calendar month.

In January, 1909, the Cripple Creek drainage tunnel was driven 435 feet, and in January, 1908, one of the headings in the Gunnison tunnel made 449 feet, and in October, 1908, the Elizabeth tunnel, near Los Angeles, was driven 466 feet. The rock in the Cripple Creek drainage tunnel and in the Laramie tunnel is very much the same, being very hard, firm granite in each; whereas in the Gunnison and the Elizabeth the rock was very much softer, and in the latter quite a large proportion of it was shale. The rock through which the Laramie tunnel is being run is so hard that 27 holes have to be drilled in the face of each heading and loaded with the most powerful modern explosives to break it successfully.

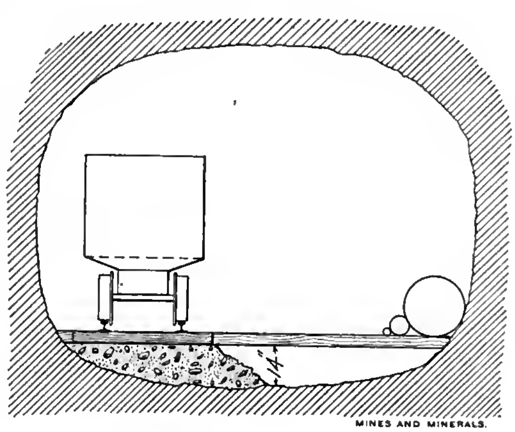

Fig. 1

The men work under the bonus system and receive an extra amount of pay for each foot driven over 250 in each calendar month and on such a record-breaking run as that of last month this bonus amounts to a very considerable sum, consequently both workmen and the contractor, Mr. James A. McIlwee, are happy.

The Laramie tunnel, Fig. 1, is driven 7 feet 6 inches high and 9 feet 6 inches wide and is nearly oval in form, thus obviating the necessity of taking out any corners and affording every possible facility for rapid driving. In fact, this was what the consulting engineer of the tunnel, Mr. D. W. Brunton, had in view in using this particular form, and in addition to this the undertaking was entirely new, no makeshift machinery had to be employed, so that in designing the big hydroelectric power plant there was nothing to be considered except actual conditions, to which every part of the plant was made to conform.

Five hundred and thirteen feet in a single heading in a calendar month is quite an achievement, but when the difficulties under which the work from the western end is carried on are considered, 332 feet is almost as good. The Laramie tunnel is driven on a grade of 1.7 per cent., sloping from the west toward the east, and consequently the material removed from the west end has to be hauled up grade, whereas on the east end the loaded cars run down grade and only empty cars have to be hauled up. In addition to this, the west end workings do not run directly out into the open air on grade, but are connected with the surface by a 200-foot incline. This was done to avoid about 1,400 feet of water-bearing rock and wash which, had it been opened up, would have drained directly down the tunnel into the heading. Even with this precaution a considerable amount of water has to be pumped, so that with the difficulties of pumping, uphill haulage, and hoisting through an incline, the 332 feet driven on the west end is a most creditable performance.

ZINC AND LEAD IN ARKANSAS

Written for Mines and Minerals, by Lucius L. Wittich

Development of New Region. Change From Tunnels to Shafts Admits Mining Deeper Deposits

The zinc and lead districts of Arkansas are attracting more outside attention than ever before and capitalists are taking a substantial interest in Arkansas properties, which should prove conclusively within the next year or two whether or not the mines of that region have been materially handicapped because of inadequate transportation facilities or whether they have failed merely because of the absence of mineral in paying quantities.

That transportation facilities have been bad cannot be denied. Many of the prospects have been miles removed from the nearest railroads; now, however, railroads are being constructed through the heart of the ore fields. Fuel in the form of pine timber has been plentiful and operators thus have been saved the trouble of shipping in coal. The roads as a rule, all through the northern part of Arkansas, are rocky and billy, and cannot be compared with the good level highways of the Joplin, Mo., district, and thus have made it difficult to haul concentrates to the railroads.

The counties of Boone, Marion, Baxter, and Searcy have seen more development possibly than any others. Newton County boasts of a number of promising prospects. Recently Washington County, farther to the west, is reported to have produced an exceptionally good zinc-blende mine. The outlook was sufficiently encouraging to warrant the operators coming to the Joplin district and purchasing a concentrating plant of 150 tons capacity, which has been removed to the new mine known as the Washington County Zinc Co. Mining at that point is conducted in an open pit, the blende occurring in brecciated chert almost identical to many of the shallow deposits of the Joplin field. And here it may be stated that the absence of breccias in Arkansas is given by many as the apparent reason for the non-existence of ore bodies of as great extent as those encountered in Missouri, Kansas, and Oklahoma. Where faults occur in Arkansas, slickensides in many instances have resulted, and such geological formation is not looked upon favorably as a place in which to find extensive ore bodies. Good mines, however, are promised with scientific development, and in the reports of the United States Geological Survey the Arkansas field is commented on favorably.

Unlike the ore deposits of the Missouri-Kansas-Oklahoma district, which are found largely in the Mississippian series of the Carboniferous system, the Arkansas ores occur chiefly in the Yellville formation of the Ordovician system, which is a much older sedimentation than the Mississippian. Above the Ordovician and below the Carboniferous is found the Devonian. Each system is divided into numerous formations, some being so thin that it is almost impossible for even an expert geologist to distinguish them.

The Yellville formation is composed of magnesian limestones, or dolomites. In the Northern Arkansas field these rocks are the oldest exposed, although the base of the system shows no outcropping and is estimated only by deep wells which indicate that it may extend down to the pre-Cambrian crystallines. Where the Yellville formation outcrops along the White River its width reaches 500 feet.

As the oolitic limestone is the guiding geological formation of the Joplin district, so is the Key sandstone a valuable guide, and is used as a datum by mining men throughout the Arkansas district. It is found in benches and often marks the cap rock overlying the dolomites in which the ore occurs. Fracturing, jointing, faulting, and slight brecciation characterize the areas where the mineral is most likely to be encountered. The ore, when a blende, is of a peculiar high grade which has distinguished the mines of that region.

In the Boone formation of the Mississippian series, some ore is found. In the Missouri-Kansas district this is the chief ore-bearing formation. The Key sandstone which forms the cap rock for the ore deposits of the Yellville formation is easily recognized through its resemblance to light brown sugar, and to its being easily pulverized.

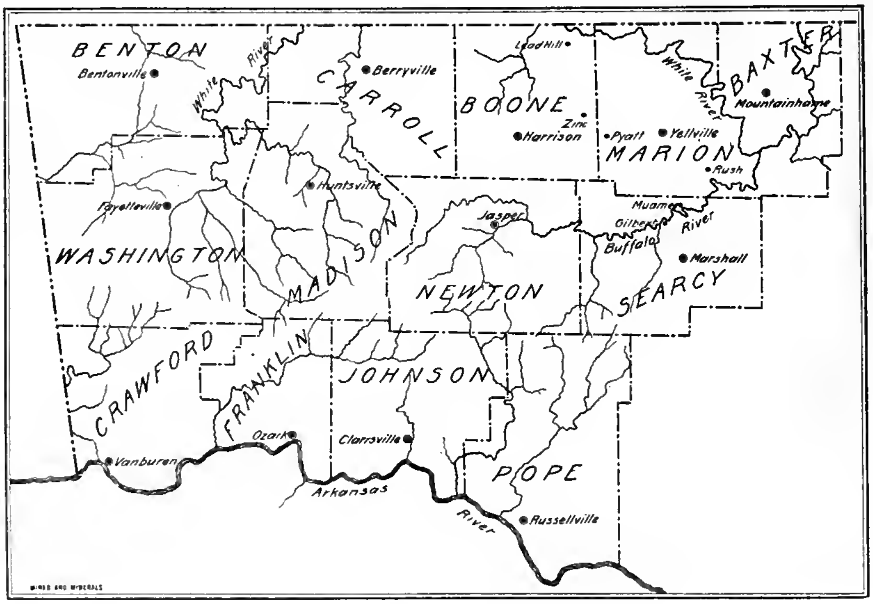

Fig. 1. Zinc Field in Arkansas

Much of the mining in the Arkansas district is done by tunneling into the mountain sides. In this way, many prospectors have sought the thinner deposits of the Boone formation in preference to the deeper ore bodies of the Yellville formation.

They would rather go up high on the mountains to mine than in the valleys, because there is less water to contend with; but, on the other hand, there is not so much ore.

One of the important steps which marks the gradual change of conditions in Arkansas was the recent purchase of the Red Cloud Mine, located in the Rush Creek district of Marion County, for $75,000. This mine has been under desultory development for 12 years, but did not produce ore until last year. Since the purchase of the mine, a modern concentrating plant of 150 tons daily capacity has been installed; a tunnel has been driven 400 feet in the mountain, and ore is being mined. Several hundred tons of concentrates have been produced within the past year. Farther down the creek this company is starting a second tunnel.

Across the Buffalo River from the Red Cloud Mine, the White Eagle Mine lies dormant, not because the ore body has been exhausted, but because the water proposition is one of the most troublesome in the entire Arkansas district. The White Eagle has a shaft 100 feet deep into a zinc ore body which has been followed for some distance, and which runs beneath the river.

The general tendency of Arkansas operators seems to be to break away from the custom of tunneling. Many companies that for years have experimented with tunnels are abandoning this system and are resorting to shaft sinking. A noteworthy example of this change is found at the Maumee Mine, 35 miles

southeast of Harrison. For years this company operated in a tunnel driven into the hillside. Now the company has sunk a shaft to a depth of 140 feet, from which levels are being driven into ore showing uniformly a height of 14 feet. This phase of the development is 300 feet deeper than the original tunneling operations. This company also has adopted prospect drilling, and out of 17 holes put down ore is reported to have been found in 15. The drifts are now out 230 feet from the shaft and considerable blende is in the crush pile. This mine is handicapped by being 8 miles removed from the nearest railroad, the Missouri & North Arkansas, which passes at Gilbert.

The concentrating mill of the Maumee Mine is shown in Fig. 2. It is so situated that pine is abundant and fuel does not have to be carted from the railroad station.

Among the new properties of the district is the Coker Hollow Mine, located near Zinc Station, on the Missouri Pacific Railroad. The discovery of ore was due to an outcropping in a clear, cold branch which bubbles through the valley. At a depth of 3 feet the mineral was found in big, free chunks, and continued to a depth of 75 feet. At the 35-foot level a drift proved the ore good for a distance of 45 feet. At the 65-foot level another drift was put out into ore. A 100-ton concentrating plant at this mine is just ready for operation. It is estimated that from 800 to 1,000 tons of blende-bearing rock is deposited in the stock pile.

That the epoch of prospecting is fast giving way to one of actual milling development is still further indicated by improvements at the Tar Kiln Mine, near Zinc Station, which is one of the pioneer 'diggings" of the district, but which was not equipped with a concentrating plant until recently. A 100-ton mill has just been completed. The mine is in Boone County. A number of drill holes show ore and a shaft is in mineral.

Fig. 2. An Arkansas "Wood Burner" Concentrator at Maumee Mine

One of the mines that actually has produced ore, both zinc and lead, is the Pilot Rock, 6 miles from Pyatt, the nearest station, which is on the Missouri Pacific Railroad. Ore was shipped from the Pilot Rock years ago, being barged down the White River. A company of Ohio capitalists has secured possession of the property and has sunk four shafts into ore, and a number of drill holes also have been put down.

Numerous other new developments are being made. At the Black Bear Mine the ore is carted to the Susquehanna Mill for treatment. The Madison Mine is a heavy producer of calamine, the ore being taken from a tunnel which has been driven 500 feet in the mountain. The Iola also has a tunnel 500 feet into the mountain, but is now working on a shaft which is to penetrate ore at a deeper level, according to drilling clippings. The North Star Mine, 3 miles from Harrison, in Boone County, is considered one of the best tunnel propositions in the district, but the owner, it is said, will not permit further development now that he knows what his property contains.

Long before the existence of zinc ore in Arkansas was realized, lead ore was mined extensively. Early records show lead ore was mined in 1818, the first settlers having used the product for rifle bullets. Until the early fifties little effort was made to produce the lead in commercial quantities. In the vicinity of what was known as Lead Hill, in the northeastern part of Boone County, the first Arkansas ore was smelted. In the seventies the smelting of lead was resumed after an idleness of many years. A few years later the works were abandoned.

The first production of zinc ore for commercial purposes occurred in 1857 when calamine was taken from a mine at Calamine, in Sharp County. Active prospecting for zinc ore began in 1886. In 1899 there was a light rush to the Arkansas fields but no extensive development was undertaken.

ORE MINING NOTES

Cobalt, Ontario.—Coniagas mine has 12 veins, only one of which is being worked at a depth of 170 feet from the surface. The Coniagas mill has been a success from the start, and produces three cars of concentrate per month which averages $1,000 per ton.

In the Cobalt Lake Mine about 15 feet from the McKinley-Darragh boundary, 13 stringers of ore were found in the face of the drift. Two of the stringers are 3 inches wide. Three assays of the smaltite in these stringers ran between 2,000 and 3,000 ounces.

Surface prospecting on the Nipissing has uncovered veins Nos. 34 and 35. They run parallel and are about 30 feet apart.

While the Cobalt Central is in liquidation and suits and cross-suits are being filed, the mill is running and mining carried on. The Bailey-Cobalt, a creditor of the Cobalt-Central, to the amount of $22,000, for ore mined, has asked that liquidation proceedings be set aside.

Those patriots who were feeling sore over the way the Canadians have been putting it over United States politicians can cheer up. The following shows how they are copying us:

"The Island Smelting and Refining Co., limited to $3,000,000, has been incorporated by Torontonians. The company controls the patents on the smelting process invented about 5 years ago by Doctor Island, formerly a dentist in Toronto. It is stated that the process will revolutionize the smelting industry, as it is available for treating low-grade and refractory ores with commercial success. It has been submitted to the leading chemists of the United States and pronounced a wonderful success. The demonstrating plant shows that metal in all classes of ore could be extracted with a loss of less than 1 per cent. and the residue made use of for commercial purposes."

This language is so familiar that all that is necessary is to read the line commencing "it is stated," then shut the eyes and declaim the rest adding, when finished, "fake."

The output of the Alaska-Treadwell mines will be $3,500,000 this year according to Superintendent R. A. Kinsie. Mr. Kinsie said that the explosion of the magazine in the 1,100-foot level some time ago has not affected the output and the company has experienced no difficulty in keeping its men. The cause of the explosion, in which seven lives were lost, has never been determined.

There has been a marked cessation of diamond drilling operations in all the Lake Superior iron-ore fields. Many drilling outfits have been transferred from the iron to the lake copper district where exploration for new lodes is actively in progress.

"Mr. Kelly who desires to be Governor of Michigan, wants the mines of iron ore and copper in his state to pay a much larger tax than now. Anything that adds to the cost of producing iron and copper must be paid out of the earnings of the mines. The farmer cries for free steel and iron manufactures. Then give us free farm produce. One family in Ishpeming pays more for farm produce in a year than the farmer pays for product of the mines in five."—*Iron Ore.*

The Oliver Iron Mining Co. has secured options on 313,000 acres of mineral and timber lands in the upper peninsula in Michigan, also 111,640 acres of mineral rights. According to the contract the Oliver company is to do exploration work on the property, and for all ore discovered and mined, is to pay a stated royalty to the Michigan Iron and Land Co.

The anticipated movement to secure a radical change in the management of the Lake Copper Co. has crystallized. The plea is a more aggressive policy. The present management has gone slowly, believing that to be the safer policy at least until the strike and course of the big lode in the company's lands becomes known.

The Quincy Copper Co. has done remarkably well when the percentage of copper to the ton of rock is considered. It cannot be expected to pay big dividends in the face of a copper market universally acknowledged to be too low to pay a fair return for the money invested and the labor required for production.

To reduce the cost of making metal at the Greene Cananea Copper Co.'s operations in Mexico, electricity is being introduced in the mines, mills, and smelters. A new reverberatory furnace is being added to the smelting plant and the old concentrator is being overhauled and made more effective. Greene Cananea is in possession of rich mineral ground and should be a money maker even under prevailing conditions with low copper prices. The Utah porphyries are not in so favorable a position as regards ore, and they are said to be making money.

The first annual report of the Lake Copper Co. shows that from 8,109 tons of rock there was a yield of 21,064 pounds of refined copper.

The Clark mines in Butte, Mont., have been taken over by the Anaconda company. From this time on the ores will be shipped to the Washoe smelter, at Anaconda, for treatment. The plan is to clean up all the ores at the mines, then to close them until such time as they can be worked in conjunction with the old Anaconda properties, the plan being to put things into condition so a saving in cost of operation may be secured. Anaconda is working at full pressure, producing about 25,000,000 pounds monthly at the two smelters of the company. The Clark mines have been yielding about 1,500,000 pounds at the Clark smelter in Butte.

The reduction in the quarterly dividend of the Calumet & Hecla Copper Co. from \$8 to \$7 is a direct result of the poor copper market, and poor outlook. This places the stock on a \$28 per annum basis. The Calumet & Hecla dividend is becoming sensitive to the price of copper. In 1900 the conglomerate below the 57th level yielded about 60 pounds of refined copper to the ton of rock; for the fiscal year the percentage has dropped to about 35 pounds per ton of rock.

There is considerable talk concerning the merging of the Superior and Pittsburg with the Calumet and Arizona companies in Arizona. When overtures were made by the Superior and Pittsburg to bring about consolidation with the Calumet and Arizona, the latter would have none of it, because Superior and Pittsburg was pumping water. Calumet and Arizona has a smelter and a good mine but a rather restricted area. Superior and Pittsburg has developed a large area of producing ground and a territory that will last a long time; it is also producing at the rate of \$110,000 per month above all expenses, even in this time of low copper prices.

It is interesting to note the record which the Calumet and Hecla, of Michigan, has made as a copper mining proposition. Figuring the past year's production at between 70,000,000 and 80,000,000 pounds the total output of the Calumet proper since organization has been approximately 2,360,000,000 pounds of refined copper, or about 45 per cent. of the total production of Lake copper. From this output the company has paid, including the latest payment, \$112,050,000, which represents slightly more than five cents for every pound of the metal which the company has produced. This compares with an average payment per pound of all lake companies of less than 3.70 cents per pound.

The directors of the Davis-Daly Copper Co., Butte, Mont. have levied an assessment of \$1 per share on the stock payabl in two equal instalments July 15 and September 20, 1910.

The Snowstorm Mining Co. has produced 500,000 tons of copper-silver ore since 1904 and has paid \$959,000 in dividends to date. The Snowstorm Mine occupies the central position in the copper belt east and north of Mullan, Idaho. Other properties in the belt are Lucky Calumet, Missoula, Independent, Pandora, Snowshoe, Snowstorm Extension, and East Snowstorm.

Years ago the old Planet Mine near Parker, Ariz., was a famous shipper of high-grade copper ore to Swansea, Wales. In the early work no attempt was made to prospect the ground below the 100-foot level. The Lewissohns, of New York, who took over the old Planet company, about one year ago, have been prospecting and have a shaft down 600 feet with large deposits of copper ore blocked out.

The Precious Metals Mining Co.'s work on the Atlanta lease in Goldfields, Nev., has developed some mineralized quartz on the St. Ives vein. Drifting from two different points on the 750-foot level is now going on.

The Atlas Leasing Co., which has taken over the Jack Pot ground for 25 years, has postponed the new work in order to give the outside stockholders of the Jack Pot Co. an opportunity to trade in their stock for shares in the Leasing company. The plans of the company include the installing of the big hoist, the sinking of the new shaft, and the building of a mill, provided the Jack Pot stockholders will come across.

The Utah Copper Co. is now established in the 100,000,000 pounds per annum class of producers. The merged Anaconda comes first, the Phelps-Dodge Co. second, and the Utah Copper Co. third.

What may prove another gold strike is reported about 8 miles south of Gold Dyke, Nev. Since the discovery, a month or two ago, there has been a rush of Manhattan people to the place and a number of San Francisco people have gone in on telegraphic communication from their Manhattan correspondents. Probably everything is "sewed up" by this time and stock companies are in order.

In cleaning out a prospect hole on the Golden Crown claim, Twin Peaks, N. Mex., a vein of ore was uncovered which panned well and showed free gold. A shaft when sunk 40 feet showed a vein 7 feet wide that had more free gold than that at the top. The ore is telluride.

Prospecting for zinc and lead ores is being extended to the remote camps of the Joplin, Mo., district. Drill rigs are working in localities never before mined, and occasionally reports are being received of encouraging finds.

In the Sarcoxie district a number of holes have been put down on the Boyd land, and according to reports the extent of the conglomerate ore mass found in a number of shafts in that district has been proven great. At the Lone Pilgrim Mine operations have been extended to the stage requiring a mill, and until a plant has been secured work is temporarily at a standstill.

The open-ground propositions as a rule do not require extensive milling equipment; in fact, the largest profits frequently are made from mines where the milling capacity is small. The soft ground mine, as a rule, will not furnish sufficient dirt to keep a large mill running continuously. In order to keep a large concentrating plant busy it is necessary to produce steadily from three or four shafts; while with a smaller plant, built at much

ess expense, an equal tonnage of cleaned ore will be turned out. This feature accounts for the erection of so many plants that appear to be inadequate for the work required of them.

Among the Tintic, Utah, mining companies to declare dividends were the Colorado and the Iron Blossom. The former paid 8 cents per share, the latter 6 cents per share. The Grand Central and Victoria, both of this district, passed their dividends.

The rich body of ore recently uncovered on the property of the Big Elk Mining Co., near Wallace, Idaho, located a half mile west of the Chicago, Milwaukee & Puget Sound tunnel, has been developed to a considerable extent, and the shaft which is being sunk on the ore is now down about 10 feet and the floor is all in ore. The ore is of a high-grade copper which will assay from 20 to 35 per cent. The property has been in the limelight recently on account of ore being uncovered by a crew of men working on the Milwaukee railroad, who were filling in trestles in that vicinity with hydraulic pressure.

Reports from the Mudhole mine of the Penn-Arizona Mining Co. state, that at a depth of 750 feet, a rich body of ore was discovered by a cross-cut. The gold runs from $50 to $80 per ton and three Huntington mills are working on the output.

Lessees on a block of ground on the Ibex mining property, Leadville, Colo., have been working with indifferent success for some time past. They took out a 13-pound nugget a few weeks ago that encouraged them, and keeping on they encountered a piece of ore that looked different from the ordinary run. It seemed to be one piece and when broken and placed on the company scales weighed 66 pounds. According to the graduated scale of royalties maintained at the Ibex the owners of the mine receive 65 per cent. of the proceeds from this kind of ore. The lessees' share of this amount—allowing them 35 per cent.—is therefore $1,435.20. The ore was found in the porphyry about 1,000 feet from the place where the nugget was found and in a stope that was thought to have been worked out 15 years ago.

A new daylight mine is being opened in the Galena camp, Mo., by H. B. Savage, of Galena; H. F. Smeltzer, of Kansas City; and John H. Estes, of Richmond, Mo., who have a lease on 12 acres of the Windsor Mining Co.'s land. The property is known as the Mess Mining Co.

The company has broken in the ground from the surface and opened one of the old drifts leading from the mill shaft of the property. The shaft is 75 feet deep, but at the 55-foot level a platform has been built over the opening. A short distance to the east the ground is opened to the surface, the ore at this point running to within 10 feet of the top.

TESTING FOR PROTECTIVE ALKALINITY

*By Bede Collingridge**

The results of experiments recently made by me show that potassium iodide influences the testing for "protective alkalinity" in cyanide solutions. As far as I can ascertain, this fact is not mentioned in standard textbooks now in use.

The experiments which I carried out show the influence exerted by potassium iodide to be important, especially with regard to cyanide solutions which contain no protective alkali, for in testing these in the presence of potassium iodide they show protective alkalinity.

Cyanide decomposes much faster in solutions which are deficient in protective alkalinity than it does when protected by an alkali; therefore, the method I give of testing without potassium iodide will mean a considerable saving of cyanide on large cyanide plants, as the method generally used is to test the cyanide and protective alkalinity in the one measured portion.

In Clennell's "Chemistry of Cyanide Solutions" (page 63), he says: "* * * so that the same measured portion of the liquid to be tested will serve for the determination of both cyanide and protective alkalinity."

The method which I have used for these tests is as follows:

Into 10 cubic centimeters of the test solution, using potassium iodide as indicator, run standardized silver nitrate until a deep brown coloration of iodide of silver shows clearly, and note number of cubic centimeters of silver nitrate taken.

Now using another 10 cubic centimeters of the test solution, without adding potassium iodide, run in twice the quantity of silver nitrate that was necessary for the above test, to make sure of getting rid of the alkalinity due to cyanide.

Add phenol phthalein and titrate with standardized acid. The result will be protective alkalinity.

A second method I have used, which I consider gives clearer results than the foregoing, and which also does away with the first part of the previous test, is as follows:

Into the measured portion of test solution, to which has been added the indicator, phenol phthalein, run in silver nitrate, until the indicator color remains constant, then titrate with standardized acid in the ordinary way. With a little practice this gives very good results.

These methods (potassium iodide being absent) will immediately show any deficiency of protective akalinity, and this deficiency may be easily remedied, and so stop rapid decomposition of cyanide by the addition of a suitable alkali.

The chemicals I used for these experiments were: Commercial sodium cyanide, 126 per cent.; pure potassium iodide, 10-per-cent. solution.

The standardized solutions, using 10 cubic centimeters of test solution, were: Silver nitrate, 1 cubic centimeter = .01 per cent. KCN; hydrochloric acid, 1 cubic centimeter = .001 per cent. alkalinity; caustic soda, 1 cubic centimeter = .001 per cent. acid.

Indicator, phenol phthalein.

For the tests a solution of the above-mentioned commercial cyanide was made up showing .117 per cent. cyanide, 10 cubic centimeters of which were used for each test.

In the following table, 10 cubic centimeters of the test solution were taken for each test, and tested for protective alkalinity by the first of the foregoing methods. The results were:

I. Without adding KI, protective alkalinity, per cent .0033, clear end reaction
II. With ½ cubic centimeter KI, protective alkalinity, per cent. .0046, indistinct reaction.
III. With 1 cubic centimeter KI, protective alkalinity, per cent. .006, indistinct reaction.
IV. With 5 cubic centimeters KI, protective alkalinity, per cent. .0095, indistinct reaction.

It will be noticed by the above table that the error in testing protective alkalinity increases with the increase of potassium iodide.

In the next table the same test solution was used as in that previous, but each 10 cubic centimeters used was made slightly acid as regards protective alkalinity by adding 3.5 cubic centimeters standard hydrochloric acid; 10 cubic centimeters of the acidulated test solution were taken for each experiment and tested for protective alkalinity by the method given, when the following results were obtained:

I. Without adding KI, protective alkalinity, per cent. nil, clear end reaction.
II. With ½ cubic centimeter KI, protective alkalinity, per cent. .002, indistinct reaction.
III. With 1 cubic centimeter KI, protective alkalinity, per cent. .0037, indistinct reaction.
IV. With 5 cubic centimeters KI, protective alkalinity, per cent. .0068, indistinct reaction.

The results of the foregoing table prove that solutions which contain no protective alkalinity give tests for protective akalinity after the addition of potassium iodide.

From these experiments it will be seen that potassium iodide must be absent when testing cyanide solutions for protective alkalinity.

I have obtained similar results from ordinary working cyanide solutions.

*A paper discussed at a meeting of the Institution of Mining and Metallurgy January 20, 1910.

THE YAMPA SMELTER AT BINGHAM

Written for Mines and Minerals, by Leroy A. Palmer

A Description of the Process by Which the Low Grade Copper Ore Is Smelted

The Yampa smelter is concentrating the lowest grade copper ore in the country and the resultant matte is the lowest in copper content of any of the smelters now in operation. An average of the ore during a recent month shows copper *Cu* 1.92 per cent., iron *Fe* 27.9 per cent., silica SiO_2 29 per cent., lime *CaO* 3.1 per cent., alumina Al_2O_3 6 per cent. Some gold and silver occur but their value is so small it is not counted on to bear any great portion of the expense of mining and concentrating. It will be seen that the per cent. of copper in the furnace charge is but little more than the Bingham Cañon copper porphyries which are only profitable when concentrated, and are out of the question as a direct smelting proposition on account of the silica they contain.

The Yampa smelter is at Bingham, Utah, about a mile and a half from the entrance to Bingham Cañon and slightly over 2 miles from the Yampa Mine which supplies the greater portion of the ore, although some custom ore is treated. The smelter is placed on the side of the cañon where it is rather steep for such a plant. This site was chosen when the plant was first built and was not expected to assume its present proportions. It has the advantage of being connected with the mine by an aerial tramway operated by gravity and of being so situated as to minimize the danger of injuring the ranches in the valley by fume. The site was all right for the small original smelter, but since the plant expanded it has presented disadvantages relative to the situation of the buildings to each other. These disadvantages, however, do not seem to be sufficient to overcome the advantage of proximity to the mine and freedom from adverse litigation.

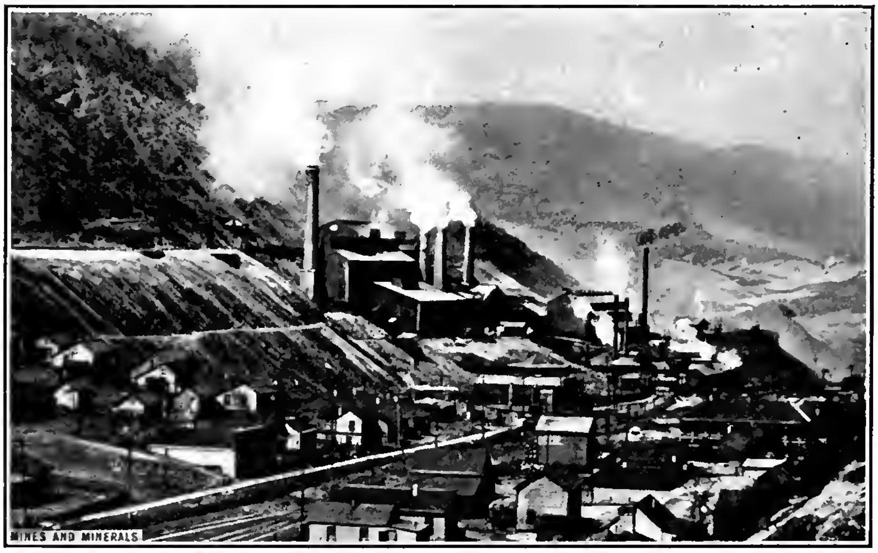

Fig. 1. Yampa Smelter

Sampling Mill.—The ore comes from the mine over a Bleichert aerial tramway in 1,500-pound buckets, which are dumped by hand to two slope-bottomed ore bins, having a capacity of 500 tons. The Yampa ore is no longer sampled as a guide to making up the furnace charge, and only a hand sample is taken from the charge cars. The custom ore is received over a standard-gage railroad spur, and dumped to a bin between the two stock bins. The bins are all lined with iron, 12-pound rails being used where the ore falls.

The custom-ore bin is provided with two hand-operated rack-and-pinion gates, and discharges direct to a 10″×20″ Blake crusher set to break to 2 inches. From the crusher the ore falls to the No. 2 elevator which is belt driven and has a lift of 75 feet and a speed of 350 feet per minute. The elevator discharges the ore to a set of 14″×28″ Cornish rolls having a speed of 95 revolutions per minute, and set to crush to ¾-inch ring. The ore from the rolls falls to the No. 3 elevator, which is also belt driven and makes a lift of 30 feet with a speed of 350 feet per minute. At the elevator dump is a Vezin sampler, which makes a one-tenth cut, the sample reject going to the boot of the No. 1 elevator. The sample is coned and quartered until about a wheelbarrowful is left when it is recrushed in a laboratory crusher and further cut down to 4 or 5 pounds.

The Yampa ore goes from bin 1 direct to trommel 1, and from bin 2 to the trommel, by a 22-inch horizontal rubber belt conveyer having a speed of 160 feet per minute. This trommel, which has a speed of 18 revolutions per minute, is 3 ft.×8 ft. with a frame of four 6-inch angle irons over which is a plate of half-inch steel in which are punched holes. Different screen plates are used so that the revolving screen has a mesh varying from one-half to 1½ inches, according to the kind of the ore received from the mine. If there is a plentiful supply of fine ore, the half-inch screen is used and as much as possible thrown into the oversize. If the ore is largely coarse and not sufficiently fine to supply two reverberatory furnaces, the coarser screen is put on and the undersize crushed to pass a three-quarter-inch mesh, and is then sent to the reverberatories.

The oversize of the first screen goes to a 30-inch rubber belt conveyer with a speed of 140 feet per minute, running at an angle of 9 degrees and dumping to the blast-furnace bins. The undersize goes to the No. 1 elevator which is gear-driven with a 14-inch belt and makes a lift of 90 feet with a speed of 285 feet per minute. This elevator discharges to trommel No. 2 which is 3 ft.×8 ft. with ¾-inch punched holes, making 22 revolutions per minute. The undersize goes to the roaster bins, and the oversize is chuted to the discharge of No. 2 elevator from which it goes through the rolls thence by No. 3 elevator to the boot of No. 1, by which it is again elevated to trommel 2.

A 40-horsepower induction motor drives the sampling mill.

Roasting Furnaces.—The fine ore is loaded from sector gates to cars of 20-cubic-feet capacity and trammed a distance of 50 feet to the top floor of the roaster building, which is on the same level as the loading floor of the sampling mill. Here it is dumped to the roasters each of which is provided with a 1-inch grizzly to keep out any coarse ore that might become mixed if the No. 2 trommel was broken or clogged.

In the roaster building are nine 18-foot McDougall roasting furnaces, in two rows. Each furnace has 6 hearths with water-cooled rabbling arms, except the two upper hearths where the heat is low and the water is not needed. The rabbling arms make a revolution every 58 seconds, and 1 hour and 15 minutes is required to work the charge through the furnace. Each roaster has a daily capacity of 47 tons and eliminates about 83 per cent. of the sulphur in the ore. In one row four of the roasters are provided with 24-inch steel elbows, two to each furnace, for the discharge of the fume. Two of the furnaces discharge through brick stacks 40 inches square, to a chamber 6 ft.×6 ft.×66 ft., connected with the main dust chamber. The other three roasters discharge direct to an **L** shaped chamber 4 ft. ×7 ft.×37 ft., connected with the main chamber 20 ft.×32 ft. 8 in.×60 ft., provided with two brick baffle walls. The main dust chamber discharges to a brick stack 120 feet high with an inside diameter of 10 feet at the top. Beneath the dust

chamber are two steel hoppers 10 ft. × 10 ft. with 12 in. × 12 in. lever-operated slide gates, for loading cars which are run beneath. The McDougall dust assays on an average: Copper 2.36 per cent., iron 30.5 per cent., silica 25.8 per cent., sulphur 21.2 per cent., lime 2.6 per cent., alumina 7.4 per cent.

The accretions which form on the sides of the roasters are barred off and trammed to a bin from which they are mixed with the charges going into the blast furnace.

A 20-horsepower direct-current motor drives the McDougall roasters.

Reverberatory Furnaces.—The roasted ore is discharged from the McDougall roasters into cars, having a capacity of 7,300 pounds each, and hauled by a motor to a building adjacent, where there are three reverberatory furnaces, two of which are in continuous operation. The furnaces (a drawing of which is shown in Fig. 2) are 17 feet wide, 47, 53, and 59 feet long, each with a rated smelting capacity of from 150 to 175 tons of raw ore per day, but they actually treat much more. The fireboxes *a* are of uniform size, 9 ft. × 12 ft., divided into two compartments by a brick wall *b*, so that each compartment is 5 ft. 6 in. × 9 ft. Each side of the firebox is connected to a 15-inch air line, while the fuel is fed from the roof through three 15-inch openings *c*. Draft for the fireboxes is supplied by a 16-inch centrifugal blower at a pressure of considerably less than 1 inch of water. A 20-horsepower induction motor drives the blower.

The furnaces are of brick, stayed with 4-inch I-beams tied across the top and spaced on 16-inch centers, except where two doors *d* 15 in. × 24 in. have been left in each side to allow the furnace men to feel the charge. A 12″ × 15″ door *e* is in the back of each furnace for skimming.

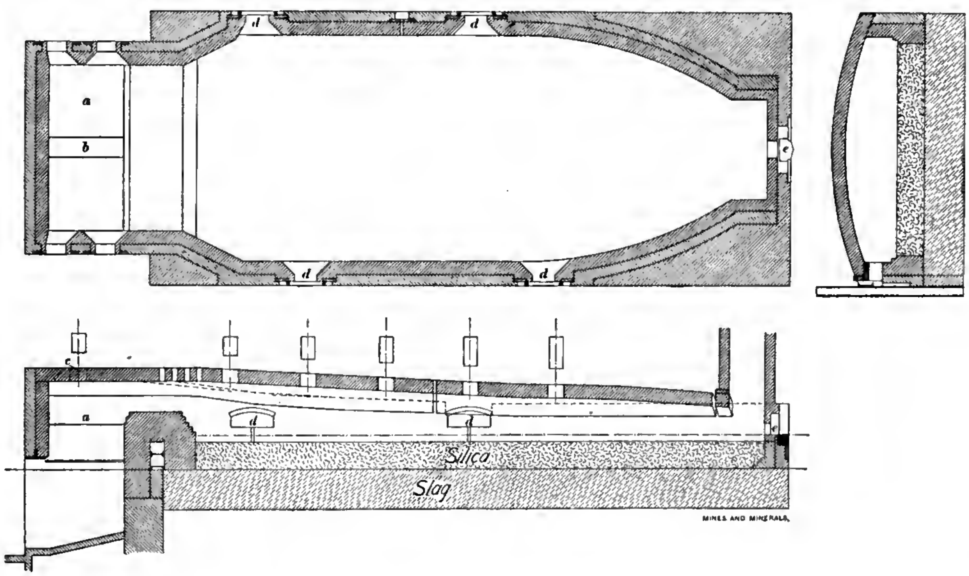

Fig. 2. Reverberatory Furnace

Between each furnace and the stack is a 300-horsepower water-tube boiler utilizing the waste heat from the furnace to generate steam at 110 pounds pressure. These boilers deliver an average of 180-horsepower, effecting thereby an economy equal to 150 tons of coal for each furnace per month. This 180 horsepower represents an efficiency of only 60 per cent., which is small. One reason for this is that in planning the installation it was deemed advisable to put in larger boilers than there would be heat to operate at full capacity, because there was room and the increased radiating surfaces presented made it possible to get a greater horsepower than would be possible with boilers with nominal ratings corresponding to the quantity of heat thrown off by the furnace. The last boiler installed is of a later model than the others and has shown a higher efficiency, due largely to the fact that the tubes are staggered while in the older models they are in regular rows. The later models of Stirling boilers seem to be most favored by smelter men for this work and in one plant this style of boiler is used in a furnace which generates heat proportional to the rating of the boiler, which in turn delivers practically the full rated boiler horsepower. The consumption of coal at this plant is somewhat higher than at the Yampa and it may be that some of this goes toward making steam. The Yampa waste-heat boilers are fed by a 7″ × 4½″ × 8″ duplex Snow piston pump, and a 5″ × 5½″ × 8″ Smith-Vaile plunger pump is held in reserve. An 8″ × 5″ × 12″ Fairbanks, Morse & Co. piston pump furnishes water at high pressure for fire protection and for operating the turbo boiler washers. Each furnace discharges through a brick stack 100 feet high with an inside diameter of 7 feet at the top.

No dust chambers are provided for the reverberatory furnaces, the fumes passing from the boilers directly to the stacks. The boilers are cleaned about every 50 days and as only a ton of dust accumulates in this time it is taken as sufficient indication that the loss from the stack is so small as to be negligible.

The question of the use of forced or open draft for reverberatory furnaces is one that has been much discussed, therefore a comparison of two plants is of interest. The plant used for comparison is of late design and in this respect has many points the advantage of the Yampa. It uses about one-half ton of good lump coal per ton of ore treated; the ashes from the furnace are extinguished and sent to the power house for reuse under the boilers, as they contain about 60 per cent. of the dry weight in good coal. The wet ash makes it necessary to use forced draft on a hand-fired boiler, and so as far as the question of draft is concerned it seems to be only whether it will be used at the furnace or in the power house. The Yampa reverberatory uses one-fourth ton of run-of-mine coal per ton of ore treated and the coal is so thoroughly consumed that an attempt to burn the ash resulted in smothering the fire. Thus the rehandling of the ash is eliminated. Once a shift, the grate bars each side of the furnace firebox are cleaned, during which time the draft is shut off from that side. This cleaning requires about half an hour for each side, and while it is going on about half of the pressure is lost from the boiler connected with the reverberatory, making it necessary to fire more heavily at the power house. When the cleaning is finished the steam rises at the power house and blows off for some time, which of course represents a certain amount of coal from which no benefit is derived. The actual amount of coal consumed at the Yampa is .83 ton per horsepower month, while at the newer plant it is only .78 ton, but the superiority of equipment of the latter should make this difference greater as it is using a late model of Babcock & Wilcox boiler in the power house, while the Yampa boilers are of the return tubular type and quite old.

The forced draft in the reverberatory furnishes almost complete combustion of the coal, so that the charge is rapidly smelted and the capacity of the furnace is increased from 150 to 175 tons of raw ore per day, to from 217 to 220 tons per day. This is accomplished with a thorough fusing of the charge so that the quality of the matte and slag is not affected.

The matte is tapped once a shift and sometimes not so often, the low grade of the ore making it slow to accumulate. The slag is skimmed two or three times a shift through the door *e*

to an iron launder which discharges to a slag car with a capacity of 60 cubic feet. In these the slag is hauled to the slag dump, by a Jeffrey locomotive. In the slag launder is a section 6 feet long made 8 inches deeper than the remainder of the launder. Should the skimmings contain matte, or an unfused piece of silica come out bringing some matte with it, the deeper portion of the launder acts as a settler to catch the escaping matte, the principle being the same as the settling or "monkey pot" used at some blast furnaces.

The matte is tapped from the reverberatory to a series of iron molds 9 in.×20 in.×48 in. in the floor. An anchor with a ring is set in the mold, as shown in Fig. 3, before casting. When cool the matte is raised by a chain block, carried to a slag car and unloaded by striking it a blow with a sledge that breaks the matte from the anchor. The cars are dumped to an iron-lined bin from which the matte is loaded into the railway cars.

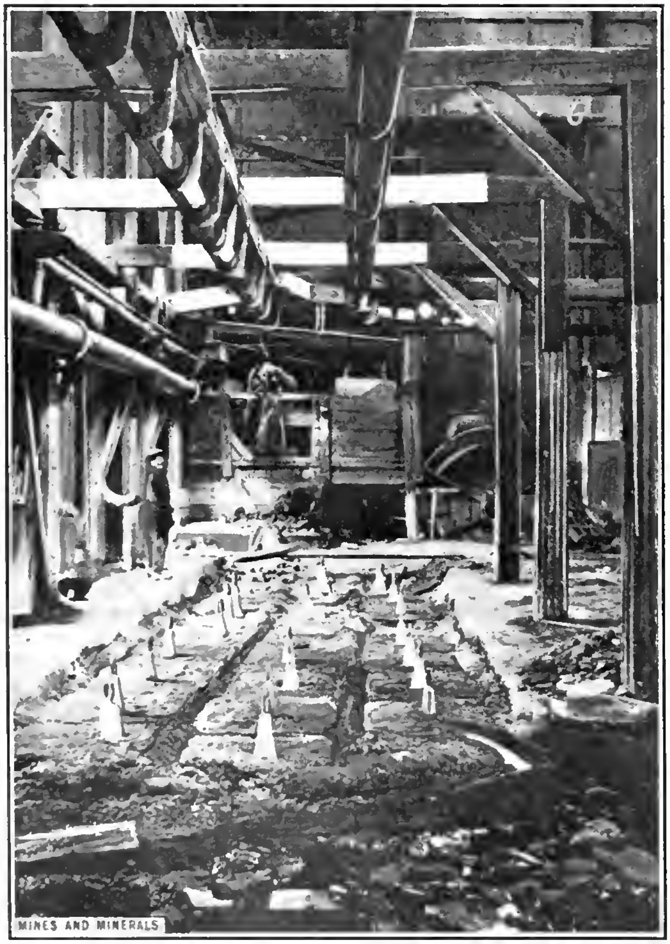

Fig. 3. Matte Molds Before Casting

A month's average of reverberatory matte assayed: *Cu* 30 per cent., *Fe* 36 per cent., *S* 26 per cent.; while the slag assayed *FeO* 39 per cent., SiO_2 40 per cent., *Ag* 1 ounce, *CaO* 3 per cent., Al_2O_3 15.5 per cent.

Blast Furnaces.—As will be seen from the analysis, the Yampa ore needs an addition of lime to make it a favorable smelting mixture. The process of making up a charge of Yampa ore for the blast furnaces is therefore a very simple one. The charge cars are drawn in front of the coarse-ore bins and loaded with 4,000 pounds of ore and 1,000 pounds of lime rock. To this charge is added an average of 525 pounds of coke so that the fuel is about 10.5 per cent. of the charge, as a rule. An electric locomotive hauls the cars to the blast-furnace building about 100 feet distant, where the charge is dumped through upward sliding doors, as shown raised in Fig. 4. The charge floor is 16 feet above the tuyeres. The slag that is barred out from the launders at the reverberatories is mixed into the charges dumped into the blast furnace. This amount which is only about 4 tons per shift serves to keep the furnace open and also affords an easy way of recovering the small quantities of matte that it contains.

The plant has three blast furnaces of the following sizes: No. 1 is 44 in.×180 in. at the tuyeres and 66 in.×180 in. at the shaft; the ratio of shaft to tuyere area is therefore $1\frac{1}{2}$ to 1. It has three water-jackets on each side and one at each end; eighteen 3-inch tuyeres 10 inches apart on each side with Siamesed tuyere pipes, individual valves and all metal connections to an 18-inch bustle pipe. The forehearth is circular, 2 ft.×11 ft. and the fumes are discharged through a brick downcomer 48 in.×102 in. in size.

No. 2 is 42 in.×168 in. at the tuyeres and 72 in.×168 in. at the shaft; thus the ratio of shaft to tuyere area is $1\frac{3}{4}$ to 1. It has three water-jackets on each side, and one at each end; also eighteen 3-inch tuyeres 9 inches apart with individual valves and all metal connections to a low 18-inch bustle pipe. The forehearth is circular, 3 ft.×12 ft., and the downcast is of brick 72 in.×92 in.

No. 3 is 44 in.×186 in. at the tuyeres and 66 in.×186 in. at the shaft, giving ratio of shaft to tuyere area of $1\frac{1}{2}$ to 1. It has six water-jackets on each side, and one at each end; and is supplied with sixteen 5-inch tuyeres 11 inches apart, controlled in groups, and with metal and canvas connections to an 18-inch bustle pipe. The forehearth is circular 3 ft.×16 ft. and the downcomer 72 in.×118 in. area.

Only one of these furnaces is operated at present, but it is handling about 300 tons of material daily. Blast is received at 32 ounces pressure through the main air line which has a diameter of 40 inches.

The blast furnace is tapped continuously, the slag being handled in 30-cubic-foot slag cars which are hauled to the dump by motors. The matte is tapped to molds in the floor casting into slabs 28 in.×44 in.×4 in., which are picked up by a chain block carried to a 6-inch grizzly and broken. Passing the grizzly they fall to an 18-cubic-foot car and are trammed to the railway bins.

The gases from the furnace discharge to a square dust chamber 20 ft.×20 ft.×400 ft. and thence to a steel stack 7 ft.×200 ft. This stack follows the slope of the hillside for 150 feet, only the last 50 feet being vertical. The dust is withdrawn from the dust chambers through iron doors 15 in.×18 in. spaced on 14-foot centers, to hooded cars having a capacity of 15 cubic feet. These cars are hauled up an incline by a small electric hoist to the top of the reverberatory building, and the contents charged into the hoppers. The dust analyzes 2.34 per cent. copper, 33.5 per cent. iron, 25.6 per cent. silica, 3.1 per cent. sulphur; 4.6 per cent. lime; 9.8 per cent. alumina. An average analysis of the blast-furnace slags for a month gave ferrous oxide *FeO* 22 per cent., silica SiO_2 44 per cent., sulphur *S* .7 per cent., lime *CaO* 4.6 per cent., alumina Al_2O_3 9.8 per cent. This slag is more silicious than would be practicable to make at many plants, but is giving good results and has the advantage of requiring less lime, with a corresponding increase in the amount of ore treated.

An analysis of the matte shows copper *Cu* 14 per cent., iron *Fe* 50 per cent., sulphur *S* 27 per cent. This is exceedingly low in copper. The company has a converter plant but it is closed down, and the matte is shipped to the Garfield smelter for converting. Before the United States plant at Midvale was forced to close its copper plant, the matte was treated there, but when this plant was put out of commission by a court order, the Yampa was forced to make other arrangements. Attempt to obtain a satisfactory arrangement with the Garfield plant failed, so the company built its own converter plant and for some time made blister copper. This was not satisfactory, as the returns

from a ton of matte were too low and the cost of converting as much as for a better grade. The Yampa matte made a desirable product for the Garfield plant where it could be mixed with the higher grade so an agreement was finally reached and the Yampa renewed shipping. No long-time contract has been made and the Yampa plant is in a position to resume converting at any time.

The question as to the advisability of following the Highland Boy practice, which will also be employed at the International smelter, at Tooele; namely, of crushing ore and treating it in the reverberatory furnaces, thus obtaining a matte of 30 per cent. copper, and then converting, was carefully considered in all phases, but rejected as the cost of crushing the matte fine enough for the reverberatories would more than offset the advantage of the company operating its own converters. There would be no saving in labor nor in treatment costs, while the slag losses from a reverberatory furnace are invariably more than from a blast furnace. A sufficient amount of ore is crushed fine to supply two reverberatories to one blast furnace, so the average matte is about 27 per cent. copper.

Power Plant.—The boiler house of the Yampa smelter contains four 85-horsepower return tubular boilers which generate steam at 120 pounds pressure. They are operated in conjunction with the waste-heat boilers and consequently are under steam only part of the time, the average for 5 months being one and one-half boilers per month. They are hand fired with slack coal, and during the 5 months mentioned 728 tons were consumed in generating 877 horsepower, an average of .83 ton per horsepower month. Considering the fact that the boilers are old and not of the most approved type this is a very creditable showing. A 7″×4½″×8″ Snow duplex piston pump is used for the boiler feed and a duplicate of this pump raises the water for the waste-heat boilers from the feedwater heater.

The steam from the waste heat boilers is carried to the engine room in a 10-inch line which is 300 feet long. The boilers are provided with dry pipes and there is a trap and separator where the main steam-pipe line enters the power house. The pipe is insulated with asbestos covering so there is very little radiation and although it is down hill no trouble is experienced from wet steam.

The engine room has the following equipment.

One 12″×30″ 110-horsepower Corliss engine direct-connected to a Connersville blower making 130 revolutions per minute, with a capacity of 130 cubic feet per revolution.

One 150-horsepower Bullock induction motor belted to a Connersville blower making 145 revolutions per minute with a capacity of 100 cubic feet per revolution.

One 10″×10″ 70-horsepower Ideal slide-valve engine belted to a Connersville blower making 165 revolutions per minute with a capacity of 55 cubic feet per revolution.

One 11″×12″ 75-horsepower Ideal slide-valve engine making 300 revolutions per minute, direct-connected to a 440-volt direct-current generator.

One 16″×16″ 175-horsepower Skinner slide-valve engine making 250 revolutions per minute direct-connected to a 440-volt direct-current generator.

One 30-horsepower 14″×14″×20″ Rand straight-line air compressor with a capacity of 75 cubic feet of free air per minute, compressing to 80 pounds for use in the shops, etc.

One 16″×34″×48″ 250-horsepower cross-compound Corliss engine, tandem connected to a 34-inch duplex air compressor with a capacity of 7,800 cubic feet of free air per minute. This was installed as a blowing engine for the converters, compressing to 15 pounds.

All except the Skinner engine are run condensing, being connected to a 16-inch Worthington barometric jet condenser with a 5″×12″×8″ dry vacuum pump which gives a vacuum of 20 inches, the mercury column at this altitude registering 22.64 inches. The exhaust from the Skinner engine is led to an open feedwater heater which raises the temperature from 54° F to 194° F. so that the feed enters the boilers at almost boiling point, which is 198° F. at this altitude. This increase in feedwater temperature is equal to 4½ pounds of steam pressure.

Three hundred additional horsepower are derived from the Telluride Power Co. This is received in the camp at 40,000 volts and stepped down at the power company's substation to 5,000 volts, at which tension it is distributed. At the Yampa it is further stepped down to 440 volts at the transformer house. Here are six 100-kilowatt transformers, three oil cooled and three water cooled, 300 horsepower being provided for an emergency. The transformer house is also equipped with three General Electric Co. 40,000-volt lightning arresters. The 300 horsepower regularly drawn from this source goes to a 300-horsepower 440-volt induction motor direct-connected to a 220-volt direct-current generator. This Telluride power is used only for such purposes as will not be affected by an interruption as the current comes into camp over very long transmission lines and is consequently liable to interruption in case of an electrical storm. The fires are kept banked under one of the boilers so that if the power from outside fails, there may be little interruption before starting one of the steam-operated generators.

Fig. 4. Furnace Charging Doors

Water Supply.—The water is derived from a shaft sunk on the premises which gives a minimum flow of 150 gallons per minute. By the use of various economies only about 50 gallons are used regularly. The shaft is provided with three pumps, only one of which is used at a time and that at only part capacity. These are two 200-gallon Cameron sinking pumps, each 14 in.×7 in.×13 in., and a 260-gallon Goulds single-acting triplex pump, 8 in.×10 in., belted to a 15-horsepower induction motor. The shaft pump discharges to a tank which also receives the water from the main cooling tower. The water is pumped from this tank to a 30,000-gallon tank on the hill back of the plant, from which it is distributed by gravity. This work is done by a 13″×12″ Aldrich single-acting triplex pump with a capacity of 900 gallons per minute, belted to a 75-horsepower induction motor. An 8″×10″ Goulds single-acting vertical triplex pump with a capacity of 260 gallons per minute, belted to a 25-horsepower motor, runs about 4 hours each day on this work. Three auxiliary pumps are provided that the flow of water to the distributing tank may not be interrupted. These are a 200-gallon 12″×7″×12″ Knowles; a 100-gallon 10″×5″×12″ Knowles, and a 200-gallon 14″×7″×13″ Cameron sinking pump.

The water runs by gravity from the roasters, water-jackets, etc. to the main cooling tower, where it is passed over a quarter-inch screen to clean it before spraying. The cooling tower reduces the temperature of the water about 30 degrees.

The condenser water flows by gravity from the hot well to a second cooling tower from which a two-stage Wheeler high-lift pump with a capacity of 1,000 gallons per minute belted to a 50-horsepower induction motor raises it 70 feet to a tank from which it flows by gravity to the condensers. This second cooling tower provides a reserve supply of 30,000 gallons which can be run to the Cameron sinker at the shaft tank and pumped to the distributing tank on the hill. The boiler blow-off is discharged to a small tank with a vent discharging to a launder to the main cooling tower. The waste water around the blast furnaces flows through a launder to a 10,000-gallon tank in which it is settled, the overflow going to the main cooling tower. This water contains some flue dust, and when the tank is cleaned, every 2 or 3 months, the sediment collected is returned to the furnace and smelted. These settlings amount to about 1½ tons per month and carry an average of 3 per cent. copper.

The furnaces use 900 gallons of water per minute; 300 gallons going to the roasters and 600 gallons to the blast furnaces. The Aldrich pump is sufficient to keep up this supply, and for boiler feed and all other purposes the 4 hours work per day by the Goulds pumps is sufficient. The total quantity of water averages 945 gallons per minute, and owing to the various devices used for conservation draws on the shaft supply only to the amount of 50 gallons per minute. It will be seen from this that the loss of water is 5 per cent.

The coke is from Sunnyside, Utah, about 175 miles distant. The Sunnyside coal cokes well and is used at all of the Salt Lake Valley smelters. The limestone is shipped from Parley's cañon across the valley, about 35 miles distant. It contains 51 per cent. lime CaO and about 5 per cent SiO_2.

The writer's acknowledgement is due the courtesy of Mr. C. A. Pringle, General Manager, Mr. Frank Murphy, Smelter Superintendent, and Mr. Thomas Maslin, Master Mechanic.

THE HISTORY OF THE ROCK DRILL

By W. L. Saunders

The rock drill is an American invention, conceived and developed in the United States. J. J. Couch, of Philadelphia, took out the first practical patents in 1849. In his experiments he was assisted by Joseph W. Fowle. The Couch drill was a crank-and-flywheel machine.

Couch and Fowle separated in 1848, the latter filing a caveat in 1849 covering a drill of his own invention and describing the successful power rock drill substantially as it is today. The most important feature of Fowle's drill is that the cutting tool was attached directly to the piston. In other words, the steel leading into the hole was an extenison of the drill piston rod.

Fowle described this invention in his testimony before the Massachusetts Legislative Committee in his contest with Burleigh in 1874, as follows:

"My first idea of ever driving a rock drill by direct action came about in this way: I was sitting in my office one day after my business had failed and happening to take up an old steam cylinder, I unconsciously put it to my mouth and blew the rod in and out, using it to drive in some tacks with which a few circulars were fastened to the walls."

Abroad, the nearest approach to rock-drill invention was the work of the German, Schumann, carried on in 1854. Fowle being without means to develop his ideas, they remained in obscurity until Charles Burleigh purchased his patents and produced the Burleigh drill, about 1866. This drill was used in driving the Hoosac Tunnel, in Massachusetts, in 1867.

Following Couch, Fowle, and Burleigh, came Haupt, Wood, Ingersoll, Sergeant, Waring, and Githens. Githens was the inventor of the Rand drill.

The Ingersoll drill was invented in 1871. Simon Ingersoll, a modest, ingenious, and honest mechanic, came to New York from Connecticut, bringing with him the models of several inventions. He was riding in a New York horse car one day and was describing one of his inventions to a fellow passenger. Another passenger in the car was John D. Miner, who overheard Ingersoll's conversation. Miner was a contractor, engaged with a gang of men on some rock excavation in New York City.

Miner broke into the conversation to ask Ingersoll why he didn't invent a rock drill, telling him that he had a gang of men at work striking a steel with a hammer to make a hole for blasting; that they could put in only about 10 feet of hole per day; and that he did not see why a machine could not be built that would do the work.

Ingersoll said he could make such a machine and would go at it at once if he had the money. Miner gave him $50, and his card, saying that, though he had never seen Ingersoll before, he had an honest face and he would trust him to spend that $50 in building a rock drill. "When you want any more," said Miner, "come to me and I'll give you another fifty."

Ingersoll's first rock drill was built in a shop at Second Avenue and Twenty-Second Street, New York City, owned by J. F. de Navarro, and was managed by Sergeant & Cullingworth.

One day Henry C. Sergeant saw the patterns for Ingersoll's drill. He noticed that the front head was attached to and was a part of the cylinder. He told the workmen that they should be in two pieces, and proceeded to saw off the pattern. At this point Ingersoll came into the shop. "What are you doing?" he asked. "I'm making this thing practical," said Sergeant, as he finished cutting off the pattern before Ingersoll could stop him. The result was the first row between Ingersoll and Sergeant, and it led later to Mr. Navarro purchasing, on Sergeant's advice, all rights and patents held by Ingersoll. The Ingersoll drill was made with the separate front head as used today.

Mr. Navarro organized the Ingersoll Rock Drill Co., investing $10,000 in the concern. Litigation arose with Burleigh, of Massachusetts, who owned the rights of Fowle and others. However, Mr. Navarro's plentiful supply of funds and his liberal nature, brought about a settlement of the suits, and all the patents became the property of the Ingersoll Rock Drill Co.

The business quickly paid back to Mr. Navarro the $10,000 he had put into it, and in later years he sold his interests to Mr. R. W. Chapin for $525,000. Sergeant sold out because of friction with the management, went West, engaged in mining, returned to New York about 1885, and organized the Sergeant Drill Co.

Early in rock-drill development the Rand brothers, Addison C. and Jasper R., had become interested through their connection with the Laflin & Rand Powder Co. Addison C. Rand formed the Rand & Waring Drill and Compressor Co., later controlled exclusively by Rand and merged with the Rand Drill Co., established in 1871, and incorporated in 1879.

J. C. Githens, superintendent of the Rand Drill Co., invented the "Little Giant" rock drill. He was the originator also of many improvements, notably the double-screw column with column arm, which made practical the application of the rock drill to mining and tunneling.

The Sergeant & Cullingworth Co., manufacturing the Ingersoll drill, the Sergeant Drill Co., and the Ingersoll Rock Drill Co., were merged into the Ingersoll-Sergeant Drill Co. Later on, the Rand Drill Co. and the Ingersoll-Sergeant Drill Co. were consolidated in the Ingersoll-Rand Co., today carrying on the business of all these pioneer concerns. The Rand drill from the beginning had been the most formidable competitor of the Ingersoll and Sergeant types. The conjunction of the Ingersoll-Sergeant and Rand companies, therefore, was a combination

of valuable patents in rock drills, compressors, and general machinery for mining, tunneling, and quarrying. Each shop received the benefit of the experience of all the others and the best features of the Ingersoll, Sergeant, and Rand types were taken to make an improved product.

POWER FOR CONCENTRATING MILL

*Compiled for Mines and Minerals, by F. C. Bowman**

No.		Horsepower Required	Horsepower of Motor
1	2 6-foot Chilian mills 1 Elevator, capacity 200 tons, 25-feet high 1 Sand pump	113.00	150.0
2	1 6-foot Chilian mill 1 Set rolls 16″ × 36″ 2 Elevators, capacity 200 tons each, 25 feet high 1 Sand pump 4 Wild shaking screens	107.20	150.0
3	1 6-foot Chilian mill 1 Elevator, capacity 200 tons, 25 feet high 1 Sand pump	53.10	150.0

METAL-MINE VENTILATION

Written for Mines and Minerals, by Evan W. Buskett

In the Joplin zinc district a large number of drill holes have been put down for prospecting purposes. The workings underground run into these holes, and at one place in the southwest portion of Joplin advantage is taken of the hole to supply fresh air to the mines.

In an open field a steam engine is seen running at full speed without any apparent connection with any industrial operation. On closer inspection it will be seen that the engine is belted to a blower and that the end of the blower is connected, as shown in Fig. 1, to a drill hole and this forces fresh air to the

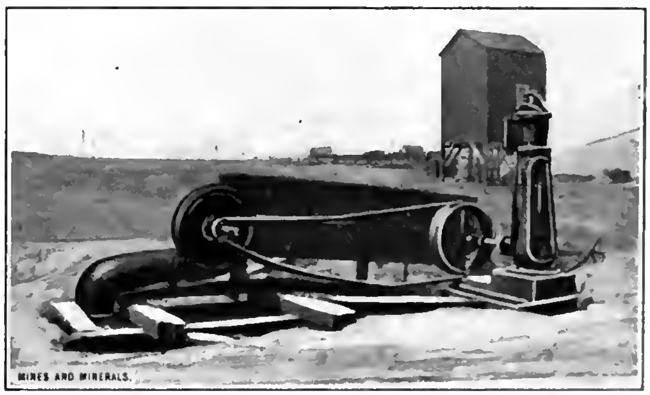

FIG. 1. BLOWING AIR DOWN A DRILL HOLE

miners several hundred feet below. The blower engine is about 8 horsepower and it obtains its steam from a boiler at the main shaft of the mine several hundred feet distant. The blower has a horizontal bottom discharge about 8 inches in diameter. This is connected with the casing of the drill hole by means of oiled-canvas air pipe.

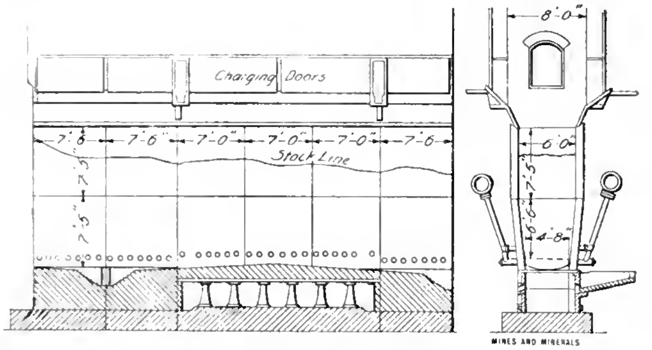
The drill hole taps one of the drifts in the mine below, and by means of this blower this drift is furnished with an ample supply of fresh air. The whole apparatus, while crude, is a step in the right direction, as better and more work will be done by men underground if furnished with pure air.

CIRCULAR COPPER BLAST FURNACES

Written for Mines and Minerals, by Thomas E. Lambert

There has been phenomenal progress made during the last few years in the treament of copper ores. In the process known as pyritic copper smelting, the constituents of sulphide ores provide almost sufficient fuel for their reduction, thereby reducing the cost of smelting and also eliminating costs of concentration, roasting, and reverberatory operations. In view of these facts, without in any manner criticising the present methods of treatment, but merely in the nature of suggestion, attention is called to the different designs of furnaces which generally are employed in copper blast furnace smelting, and to the product

Comparison of Forms of Furnaces Used for Smelting Iron and Copper Ores



(a) (b)

Fig. 1. Water-Jacketed Copper Blast Furnace, Anaconda, Mont., 1909

produced per square foot of hearth area relative to their fuel consumption, amount of air required, utilization of the air furnished, and to the by-products of their operation.

When a comparative investigation is made between the various furnaces employed in the production of copper and iron from ores, it will become evident that a similarity exists. In the early stages of the manufacture of pig iron, the operations were practically identical with those for the production of copper, but as the demand for iron increased, scientific men devised means whereby it could be more extensively and economically produced. Through their investigations and experiments the crude appliances and methods were abandoned, and today the iron and steel industry is a splendid example of what may be achieved by science.

Copper appears to have been the first metal used by man both in war and the peaceful arts, and it will eventually take the place of iron in many articles of manufacture for which it is a superior metal, and the demand will increase to enormous proportions.

Copper can be extracted from its ores at a comparatively low temperature, and in its production profits may be derived from the utilization of the by-products from the various operations.

At present the smelting of copper is in about the state of iron between the years 1850 and 1870 at which latter date improvements were made in blast furnaces, some of which were built of proportions that have not since been exceeded. Through constant study and experimentation, furnace practice has improved, until the output of a furnace has increased tenfold, and, by mechanical means the cost of operation has been reduced to a minimum.

The Washoe plant of the Anaconda Copper Mining Co., Anaconda, Mont., is the largest copper smelting plant in the world, and adopts the most modern scientific methods and appliances for the economical treatment of ores.

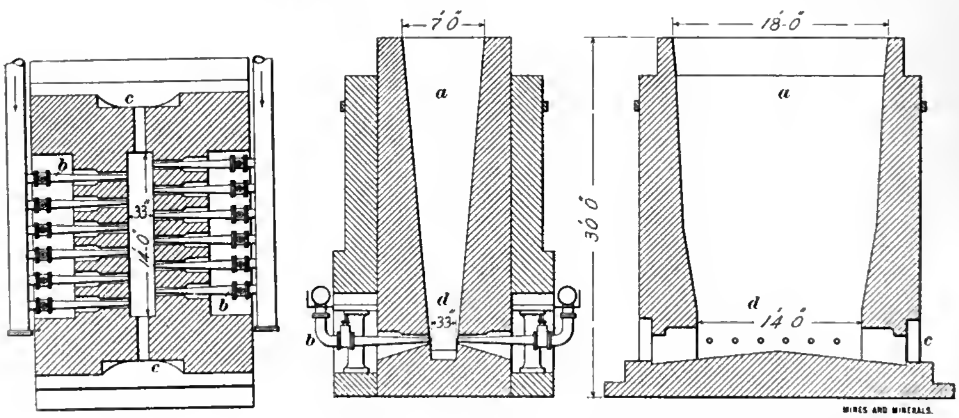
The blast-furnace building contains three furnaces, two 51 feet long by 56 inches at the tuyeres, and one 87 feet long, also 56 inches at the tuyeres. The two smaller furnaces have 88 tuyeres each, 14-inch centers by 4-inch diameter, and the larger furnace has 150 tuyeres of the same size and centers. The charges for the furnaces per 24 hours, are 1,600 tons of ore, flux, and coke for each of the smaller, and 3,000 tons for the larger.

For these furnaces, one power house contains six Connersville and four Root blowers, direct-connected to Corliss engines, each blower having a capacity of 25,000 cubic feet of free air per minute, equaling 250,000 cubic feet. Another power house contains four blowers, each with a capacity of 36,000 cubic feet per minute, equaling 144,000 cubic feet, making altogether 394,000 cubic feet of free air per minute against a pressure of 42 ounces per square inch.

Fig. 1 (*a*) shows a longitudinal, and Fig. 1 (*b*) a transverse section of a portion of the 87-foot furnace. The bottom of the crucible is formed of silica brick, laid on water-cooled plates, and has a gradual slope from the center to the discharge spouts. The 87-foot furnace has three discharge spouts and settlers, but is otherwise built similar to the smaller furnaces.

A daily report of the Anaconda furnaces gives the following information: 1,396.4 tons of material was charged in one of the 51-foot furnaces and 1,400.4 tons into the other. The hearth area being 238 square feet, the smelting capacities of the two furnaces are 5.867 and 5.88 tons per square foot of hearth area. The 87-foot furnace was charged with 2,502.9 tons of material, and as its hearth area is 406 square feet its smelting capacity is 6.165 tons per square foot. The total hearth area divided into the total charges give the capacity of these furnaces as 6 tons per square foot of hearth area. If 394,000 cubic feet of air is used per minute to reduce 5,300 tons of charged material, each ton will require 107,050 cubic feet.

The available capacity of the 87-foot furnace from the top of the bosh to the top of the jackets in the upper part of the shaft is (7 ft. 5 in. × 6 ft. × 87 ft.) = 3,871 cubic feet and below the bosh to the tuyeres (6.5 ft. × 5.33 ft. × 87 ft.) = 3,019 cubic feet or a total of 6,890 cubic feet. This is equivalent to carrying $\frac{6890}{406} = 17$ cubic feet of charge per square foot of hearth area,



Plan *Cross-Section* *Longitudinal Section*

Fig. 2. Rachette's Furnace

with a smelting column of 14 feet from the tuyeres to the top of the jackets. With a smelting column of 9 feet from the tuyeres, then the capacity will be 6 ft. 6 in. × 5 ft. 4 in. × 87 ft. = 3,019 cubic feet in the lower portion, and 2 ft. 6 in. × 6 ft. × 87 ft. = 1,305 cubic feet in the upper portion + 3,019 = 4,324 cubic feet total capacity, which divided by 406 = 10.64 cubic feet of charge to the square-foot hearth area.

A modern iron blast furnace with an available height of 81 feet from hearth to stock line, a diameter of hearth 14 feet and an area 154 square feet, has a capacity of 21,400 cubic feet, and receives over 2,000 tons of material per day; also 60,000 cubic feet of free air per minute (=43,200 cubic feet per ton), at from 15 to 30 pounds pressure. Such a furnace makes 500 tons of pig iron; carries 138 cubic feet of charge per square foot of hearth area, or nearly 13 tons per square foot of hearth area. The blast forced into the furnace having such a large amount of material to operate upon, will in traveling up the narrowing circular shaft of the furnace, thoroughly penetrate the charge, in the portions of the furnace where most required to effect the various reactions necessary to the reduction.

The Washoe furnaces are of abnormal length, and of modern design, yet it does not appear that length increases quantity of ore smelted, or is an advantage over the types in general use, and, should the three furnaces (two 51 feet and one 87 feet) be connected, making a furnace 231 feet long by 56 inches at the tuyeres, the results would be practically the same, though with an increased loss of heat and waste of blast.

To present one of the best illustrations of rectangular blast furnace, Rachette's has been selected, as with few exceptions all the modern copper blast furnaces are modifications of it, and it is the best form of furnace, next to the oval and circular types.

The Rachette furnace, Fig. 2, is employed in smelting iron ores in remote districts, and almost universally in copper-ore smelting in modified forms. It differs in shape from the modern iron blast furnace. The shaft *a* is an inverted four-sided pyramid, the throat being the widest part, 7 feet wide and 18 feet long, toward the hearth the width diminishes to 33 inches. The total height is 30 feet. At each end of the hearth is a slag hole and tapping hole *c*, *c*. The tuyeres *b*, six in number, on each side are staggered so that the nozzles will not be opposite. The advantages claimed for this shape of furnace, are, that its small height and comparatively slight construction, render it less costly to build than more massive furnaces; that the gases slacken in speed as they ascend, and must consequently be more efficacious in reducing the ore, than in furnaces, the shafts of which taper toward the top, so that the material smelted relatively to the cubic capacity is larger.

In respect to the design and claims in favor of low rectangular furnaces, it will be evident from Fig. 3 that, where the charge is distributed over so large an area, it will be impossible to maintain the charge in an even and porous condition throughout the length of the furnace. This is necessary in order to obtain an equal distribution of the blast and effect a perfect oxidation and reduction of the charge. At some place in the furnace extreme heat will be developed through concentration of the blast and there excessive reduction occurs, until finally the blast forces its way through the charge with the consequent overfire and violent agitation of the material. When this takes place the feeders put cold charge into the hollow space formed, thereby cooling and chilling that part, which then crusts over and diverts the blast to another part of the furnace where there is less resistance to its passage. With an overfire, the force of the blast and the smelting zone are being continually changed from one place in the furnace to another. This causes irregularity in the tonnage smelted and in the concentration of matte; and also is productive of large volumes of sulphur gases of a high temperature.

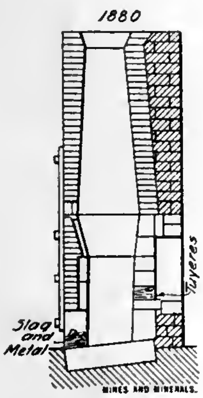


Fig. 4. Rectangular Furnace, Mansfield

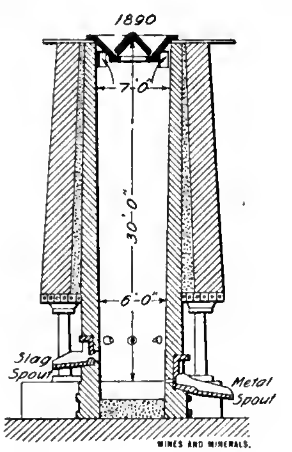

Fig. 5. Six Tuyere Furnace, Mansfield

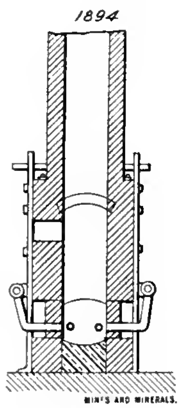

Fig. 6. Orford Brick Furnace

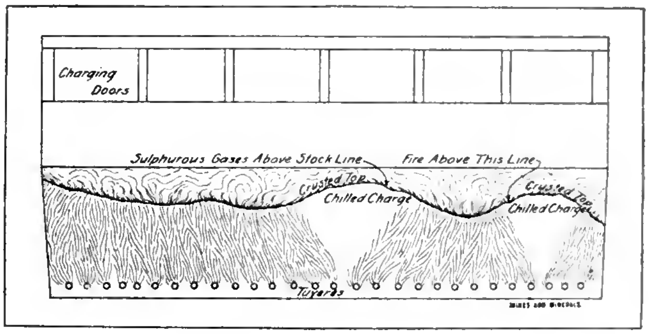
It may be inferred that, so soon as a circular or square shape of furnace is departed from, and with a low smelting column, there cannot be the same equality in the condition of the materials composing the charge, nor can there be such an even distribution and utilization of the blast to secure the necessary temperatures to effect the various reactions.



87 feet long, 56 inches at tuyeres

Fig. 3. Diagram Showing Production of Sulphurous Gases and Waste of Blast

When a long rectangular furnace is supplied with an unlimited quantity of blast, it will necessarily smelt more ore than one of half its length, still this may not prove the most economical practice, as much depends on the method of preparing the charge, charging the furnace, the amount of the blast, and the result, which is the amount of charge smelted per square foot of hearth area.

It will be evident from the following examples of different furnaces that better results are attained by the employment of shorter furnaces:

In a series of experiments made by the Tennessee Copper Co., 1903, to determine the effect produced by different volumes of blast, the following results were obtained with a blast furnace of the following dimensions: 180 in. × 72 in. at the top; 180 in. × 56 in. at the tuyeres; hearth area 70 square feet; number of 4-inch diameter tuyeres, 28; water-jackets 15 feet high; height of charge above tuyeres, 11 feet. Total amount of charge smelted in 24 hours is 581 tons, consisting of heap-roasted ore with quartz, converter slag, some custom matte and 56 tons of coke; the amount of blast used is 16,800 cubic feet per minute of free air. Tonnage 8.5 per square foot of hearth area. Free air per ton smelted 41,638 cubic feet.

The same furnace running on 507 tons of raw sulphides with quartz and 11.7 tons of coke, carried a charge 6.5 feet above the tuyeres, smelted 7.4 tons of material with a blast of 22,080 cubic feet of air per minute, or 61,262 cubic feet of air per ton.

The blast furnaces of the American Smelting and Refining Co., Garfield, Utah, 20 feet long by 4 feet at the tuyeres, smelt from 550 to 600 tons a day equaling 7.5 tons per square foot of hearth area.

At the Mt. Lyell copper works in Tasmania, a blast furnace

210 in. × 42 in. at the tuyeres with a column of ore 9.5 feet, made a phenomenal run by smelting 724 tons of mixed matte, silica, limestone, and slag, in 24 hours. There were forty 3-inch diameter tuyeres to this furnace, which with 40 ounces of blast

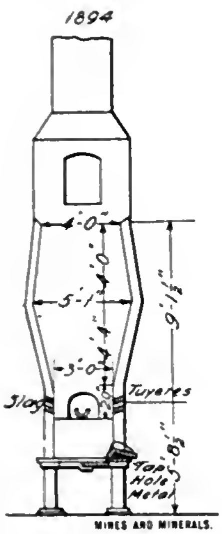


Fig. 7. Rectangular Copper Furnace

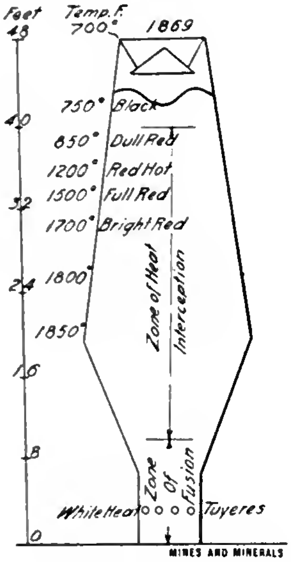

Fig. 8. Iron Blast Furnace

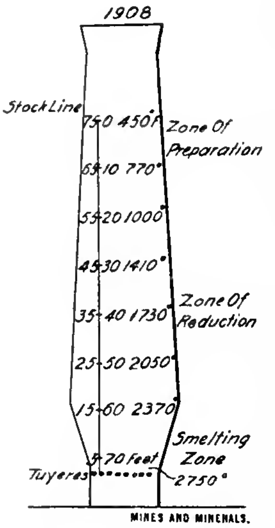

Fig. 9. Iron Blast Furnace

pressure smelted 11.83 tons of material to the square foot of hearth area.

The operations at the Mansfield copper works, Germany, are, according to some writers an excellent example of modern economical smelting practice. Fig. 4 shows a vertical section of the rectangular blast furnace formerly used at the Mansfield works, which was replaced by a circular furnace of much larger dimensions between the years 1885 and 1890. The old furnaces were from 15 to 20 feet in height.

Fig. 5 is a vertical section through the center of the circular furnaces, which as shown is 5 feet 4 inches in diameter at the tuyeres, 7 feet diameter at the top, with a height of 30 feet from the crucible to top of the furnace, and widening evenly from the crucible to the top. The blast is heated to 576° F. and enters the furnace by six water-cooled tuyeres at a pressure of 2 pounds per square inch. The top which is closed by a bell permits the collection of the escaping gases.

A furnace of this description, with the blast heated to 576° F. will smelt from 120 to 135 tons of burnt schist in 24 hours, with from 26 to 29 tons of coke. Total tonnage 164, hearth area 23 square feet, equal to 7 tons per square foot.

The escaping gases are collected, purified, and used in gas engines from which is developed a mean of 2,700 horsepower and at times as high as 4,500 horsepower.

Fig. 6 shows an altered form of Rachette's furnace, as employed by the Orford Copper Co. The interior dimensions are 11 ft 8 in. long × 3 ft. 5 in. wide, with 14 tuyeres—6 behind, 4 in front, and 2 at each end, with a diameter of from 5 to 6 inches. The height from the tuyeres to the charging doors is 8 feet.

Fig. 7 illustrates a rectangular, copper-lined, water-jacketed furnace of the United Verde Copper Co., Arizona. The cross-section is similar to iron blast furnaces except in height from the bosh to the throat, which is only 4 feet, and 9 feet 1½ inches from the tuyeres to top of jackets.

Figs. 8, 9, and 10 show different sections of iron blast furnaces, and are given because a consideration of the shape, dimensions, capacities, temperatures at different heights, color of the materials at different temperatures and heights, and the various temperatures in the zones of preparation, reduction, and fusion, will make the adaptation of similar furnaces for smelting copper ores appear more feasible.

To discuss all the matter presented by these illustrations, which practically cover the process of smelting iron ores, is beyond the scope of this article, nor is it necessary, because various solutions of these problems are given in several text-books on the metallurgy of iron; however, as the blast is one of the most important agents in successful smelting, in conjunction with the shape of the furnace a few remarks will be made as to the use of hot blast in preference to cold.

Whether hot or cold blast is used, it is produced from the same air at the same atmospheric temperature and in order that it may effect a perfect oxidation and reduction of the charge it must be of sufficient volume to contain the requisite amount of oxygen.

A modern iron blast furnace requires approximately 60,000 cubic feet of free air per minute at a pressure of from 15 to 30 pounds per square inch, with an available charge column of 80 feet height to smelt 2,000 tons of material per 24 hours. When the air is blown into the furnace direct at a temperature of 70° F., it absorbs heat from the furnace until it reaches the temperature required for fusion, 2,750° F. The air also expands in volume and raises the zone of fusion to a height governed by the time required to raise its temperature from 70° F., say, to the temperature of fusion. As the smelting zone is raised in the furnace, so also are the zones of reduction and preparation with increase in temperature toward the top and a consequent loss of heat in the hot escaping gases.

The same furnace supplied with the same volume and pressure of free air per minute at 70° F., but heated after leaving the blowing engines to a temperature of 1,000° F., will expand by the increase in temperature to a volume of approximately 230,000 cubic feet per minute, yet only contain the same

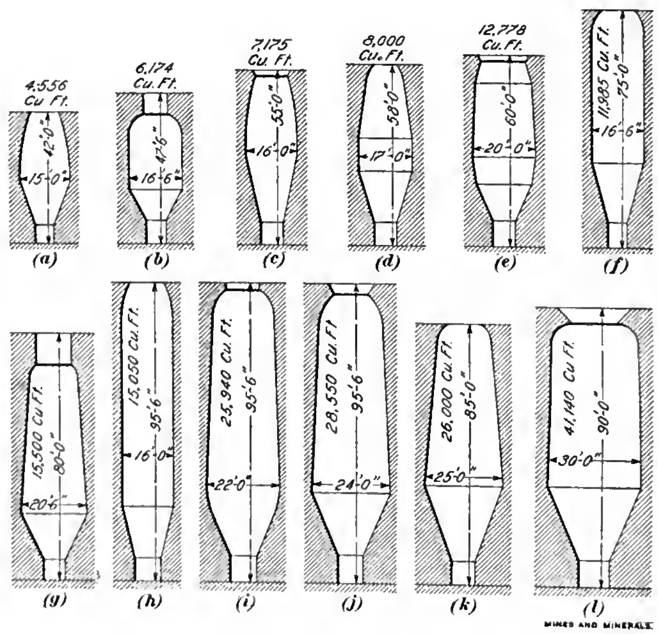

Fig. 10. Different Forms of Blast Furnaces

weight of oxygen. This hot air forced into the furnace absorbs the heat to bring it to the temperature of fusion at 2,750° F. (see Fig. 9) in the vicinity of the tuyeres, and in passing upwards the temperature is gradually reduced until it descends to 450° F. at the stock line, with a reduction in volume to about

90,000 cubic feet of escaping gases, and with a practically cold top.

It will appear from the shape of the furnace that, being so much wider at the bosh, this will provide a larger area for the expanded air to exert its force in sustaining the weight of the high smelting column, and, as it becomes diffused with the charge in passing up the narrowing shaft of the furnace its heat and other values are absorbed where required, to produce the reactions necessary to the perfect oxidation and reduction of the charge.

The use of hot blast has proved so economical in smelting iron ores in furnaces, with high smelting columns and a high pressure blast, it seems as if equally good results should be attained with smaller furnaces of the same shape with a proportionate reduction in volume and blast pressure.

The dimensions and shape of blast furnaces cannot be definitely stated as will be understood by examining the different shapes shown in Fig. 10; therefore, in order to obtain the best design, those that have given the best results should be taken as they represent the latest achievements of scientific and practical men after years of study and experiments.

Blast furnaces similar to those employed in smelting iron ores can be employed in copper smelting to advantage especially with sulphide ores containing gold, silver, lead, zinc, etc.

In regard to the use of hot blast in the modern copper furnace, there are differences of opinion. It has been experimented with and abandoned; however, this should not condemn its use with different furnaces. The trouble heretofore consisted in the use of rectangular furnaces with low smelting columns, and as shown, such furnaces are not suitable for effective smelting, nor as used do they furnish the best results from either hot or cold blast. With either kind of furnace the amount of free air required, when expanded by the temperature of 2,000° F. in the smelting zone, not having sufficient height of material to act upon, passes through the charge in its impoverished state, that is, with a smaller percentage of oxygen, with the resultant hot top, volatilization of material, loss of heat and waste of blast, whereas, should the furnaces be of the same shape and dimensions as those employed in smelting iron ores, it is manifest that similar heat reactions would take place as when smelting iron ores.

A DURABLE TRIANGULATION STATION

Written for Mines and Minerals

Mining engineers and deputy surveyors will doubtless appreciate the following details concerning a durable station which has come into extended use in the Globe, Ariz., district. Fig. 1 will serve to illustrate its construction. At the point selected for the station a block of concrete 15 inches square is set with three ¾″ × 12″ bolts, protruding from it as shown. The concrete is allowed to set for several days before attempting to attach to it the rest of the station, whose parts are of steel. These consist of a triangular base plate, 15 inches on each side, of ⅜-inch sheet metal bored in the center to receive the threaded end of a 1¼-inch pipe. It is likewise bored at the corners with

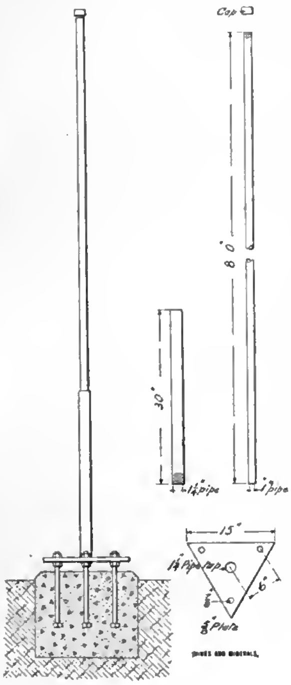

Fig. 1

⅞-inch holes to receive the holding bolts set in concrete. This base plate is first set on its bolts approximately level by eye but the locknuts not tightened. The 30-inch length of 1¼-inch pipe is then screwed in and the tight-fitting 8-foot length of 1-inch diameter pipe, capped, is set inside it. It then remains to accurately level up the base plate. To do this the transit is set up about 25 feet off at *A*, Fig. 2.

Sighting on the station rod, the base plate is leveled by adjusting the locknuts till O. K. in the direction *B C*, when the bolt nuts *1* and *2* are jammed down tight. The transit is

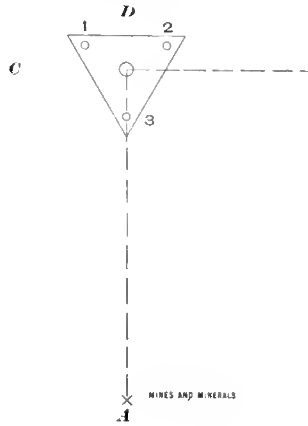

Fig. 2

then set up again at *B* and the locknut at *3* adjusted till the plate is level in direction *A D*, when the bolt nut *3* is jammed tight and the leveling is complete. The station is best painted with a black base, but with broad alternating black and white stripes on the flag, thus making it easily discernible for miles.

In case the station is located near enough to town to make it a probability that some one will fancy the striped flag for a walking stick or fish pole, it is easily kept in place by putting a steel pin through both pipes and locking with a padlock.

There are several varieties of this station in use in the Globe district, the form shown being that used by the Superior and Boston Co., and devised by Superintendent John D. Wanviz.

TARRIFF ON ALLOY OF IRON AND CERIUM

The protest of American Express Co. was overruled. The merchandise consisted of a metal alloy of iron and cerium, imported in slabs as a raw material. The merchandise in this case was a piece of steel 15 feet long, 4 feet 2 inches wide, 6½ inches thick, and weighing over 6 tons, with a geometrical design engraved on one side. It was a completed article ready for use in the manufacture of glass. The circuit court affirmed the decision of the Board of General Appraisers assessing it under paragraph 193 of the tariff act of 1897, which reads:

"Articles or wares not specially provided for in this act, composed wholly or in part of iron, steel, lead, copper, nickel, pewter, zinc, gold, silver, plantinum, aluminum, or other metal, and whether partly or wholly manufactured, 45 per centum ad valorem."

The importers, on the other hand, claimed that it should have been assessed under paragraph 135, the relevant parts of which read as follows:

"Steel ingots, cogged ingots, blooms, and slabs, by whatever process made; die blocks or blanks; billets and bars and tapered or beveled bars; mill shafting; pressed, sheared, or stamped shapes; saw plates, wholly or partially manufactured; hammer molds or swaged steel; gun-barrel molds not in bars; alloys used as substitutes for steel in the manufacture of tools; all descriptions and shapes of dry sand, loam, or iron-molded steel castings; sheets and plates and steel in all forms and shapes not specially provided for in this act * * *."

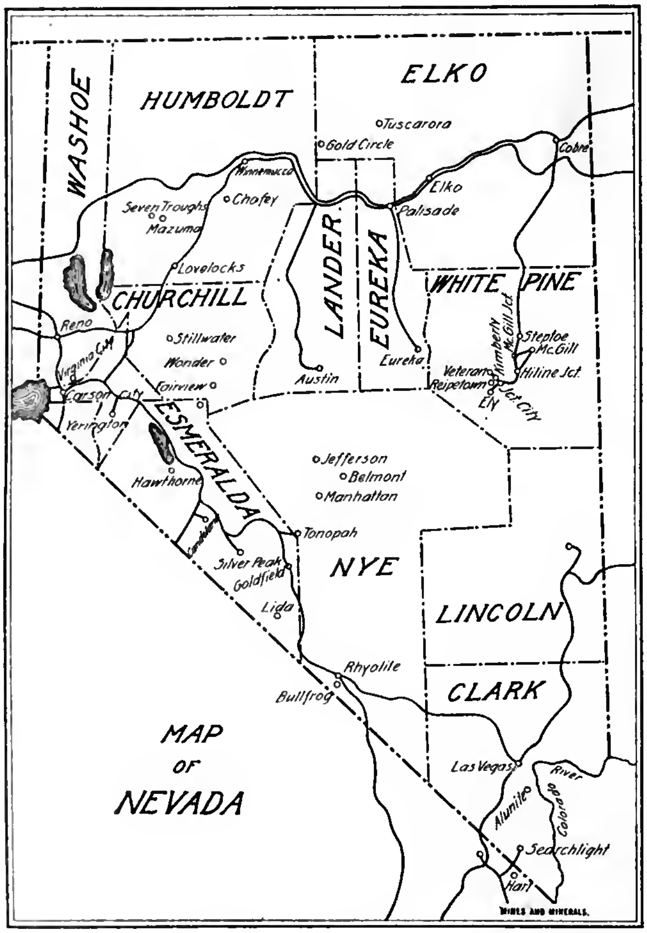
THE YERINGTON DISTRICT

*Written for Mines and Minerals, by C. S. Durand**

Reopening of Old Mines Made Possible by Improved Transportation and Cheaper Power

The Yerington mining district is in Lyon County, Nev., 20 miles southeast of the Comstock lode. As a gold camp it was abandoned when the Pine Grove Mine, credited with shipping \$6,000,000, shut down owing to an inrush of water which took place about the time that the Comstock was drowned out in 1882. That the mine was not closed from lack of ore, may be understood from the fact that it is now being opened by a tunnel. The conditions which caused the Pine Grove owners to stop operations were quite different from those of today. At that time labor, supplies, and freightage were costly, and when to this is added the cost of wood at \$55 per cord, it is not improbable that \$100 gold ore would be too low grade to pay. Comparing the past with the present, labor, supplies, and power are about one-tenth of the early days, a condition which makes \$20 ore a good mining venture. Yerington is in Mason Valley Mountains, a small range about 25 miles long, 5 miles wide, and of an extreme height of 6,500 feet. The district about 3 years ago received a new impetus through Boston capitalists acquiring copper prospects and developing them into mines, although copper has been removed in a desultory way for 30 years. The Nevada-Douglas Copper Co. is 20 miles from the nearest railroad station and hopes to have railroad connections this year. According to E. P. Jennings, the property carries 10,000,000 tons of ore averaging 3.5 per cent. copper and by expending \$1,500,000 for railroad, concentrating mill, and smelter, it should produce 24,000,000 pounds of copper yearly for 8.5 cents per pound at Atlantic seaports. The Mason Valley Copper Co., organized in December, 1906, has so promising a property and so large a tonnage of ore blocked out that it is building a smelter. This company uses electric power which it obtains from the Truckee River Power Co. It owns approximately 150 acres of copper properties. The Spragg Mine of this company, lying south of the Bluestone, was apparently opened on a contact between porphyry and limestone. This deposit was said to be 70 feet wide, with gossan top, and carbonate ore from the gossan to a depth of 100 feet, where it changed to copper sulphide.

About one year ago another gold property was discovered, which bids fair to help rehabilitate the district. This was the Effie May, now owned by the Yerington Mines and Exploration Co. In the search for copper this well-defined vein, 4 feet wide and now traced 2,000 feet on the surface, was overlooked. The ore from this vein averages about \$30 per ton, although one assay went as high as \$588. There has been no excitement over the find, as the Yerington company increased its holdings to 450 acres to include what is known as the "Mohawk group," located at the north end of the copper dike on which the other copper companies are located. Where the other companies have a carbonate outcrop, the Mohawk claims have a sulphide outcrop that contains gold. The basement complex rock of the Yerington district is given in "The Copper Handbook"† as intrusive granite, exposed by erosion in the higher peaks and deeper cañons, and covered by metamorphosed sedimentary strata on both slopes, with rhyolite flows along the eastern base. Copper ores occur in fractures and shear zones, and as bedded veins in dolomitic limestone, also as impregnations in limestone of the Carboniferous period. The ores found in the dolomitic limestone are mainly oxidized, with quartz and calcite gangue, while the Carboniferous limestone shows mainly chalcopyrite, with a little chrysocolla and covellite in the oxidized zone, but the secondary sulphides, chalcocite, and bornite are found rarely. Ore charges of two-thirds sulphides and one-third oxides and carbonates are self-fluxing, making concentration by smelting a rather easy proposition so soon as the railroad is completed this year.



The Mason Valley property which has gossan cap, with copper carbonates underneath and chalcopyrite below that carries 4 per cent. copper, merely follows the law of copper ore deposits formed by secondary concentration. The Nevada-Douglas Co. shows granite porphyry and wollastonite, carrying veins and contact deposits. The principal ore deposits are in contacts between porphyry and limestone with quartz veins carrying oxidized ores and copper pyrite mainly in wollastonite‡ rock which is also a contact deposit. At the surface, and to a depth of 10 feet, there are oxidized ores and chrysocolla, succeeded by a secondary zone carrying oxidized ores and secondary sulphides. The zone of oxidation and secondary enrichment apparently extends to a depth of 500 feet, giving an ore zone of 100 feet to 400 feet thickness in wollastonite with claimed superficial area of approximately 42 acres. The principal ore body is chalcopyrite associated with pyrite in granules, in wollastonite. The three principal veins of about 20 feet average width are estimated by the company officials to carry an average of 6.5 per cent. copper. The Mohawk group of the Yerington company covers a particularly interesting piece of ground geologically and mineralogically. Located at the north end of the copper dike it has a sulphide outcrop 100 feet wide, with eight veins carrying gold, some paralleling the copper deposit and some intersecting it at various angles. These veins carry little or no copper and are evidently from a different source and were formed at a different time. In addition to the copper dike and gold veins there are several vein-like deposits of fine turquoise which is suitable for jewelry.

Probably no other mining district in Nevada is so favorably situated for food and water as the Yerington, and this will

*[illegible], Peoria, Ill.

†Vol. IX, page 195.

‡Calcium silicate $CaSiO_3$.

materially add to its importance. Water is available from the Walker River and from artesian wells. The Singatse Mountain range, on which most of these mines are situated, overlooks the Walker River Valley, which is probably the best agricultural part of the state. Power for the mines is brought by wire from the Truckee River power plant, near Reno, Nev. With the advent of the railroad, the construction of concentrating mills and smelting furnaces, Yerington will become a noted copper camp, and with the development of its gold mines it will be no mean factor in restoring the pristine vigor of this part of Nevada made famous by the Comstock lode

PORTLAND CEMENT CALCULATIONS

Written for Mines and Minerals

Portland cement is a finely ground slag containing definite proportions of silica SiO_2, alumina Al_2O_3, iron oxide Fe_2O_3, lime CaO, magnesia MgO, potash K_2O, soda Na_2O, and small quantities of other ingredients as impurities.

Various proportions of limestone and clay are finely ground and fused to a clinker, but the mixture must be such that the lime formed shall have a definite ratio to the silica, alumina, and ferric oxide in the slag, or if magnesia be present in small proportions the same conditions must apply as for lime. The slag should have the following ratios for lime:

$$\frac{3CaO}{SiO_2}=\frac{3\times 40+3\times 16}{28+32}=2.8$$

$$\frac{2CaO}{Al_2O_3}=\frac{2\times 40+2\times 16}{2\times 27+3\times 16}=1.1$$

$$\frac{2CaO}{Fe_2O_3}=\frac{2\times 40+16}{2\times 56+3\times 16}=.7$$

The results show that 2.8 times as much lime as silica, 1.1 times as much lime as alumina, and .7 as much lime as ferric oxide must be used to form a proper cement slag. The figures used are the atomic weights of the various elements.

Magnesia should not be present in the mixture beyond 5 per cent., and what is present should be proportioned to form the following combinations:

$$\frac{3MgO}{SiO_2}=\frac{3\times 24+3\times 16}{28+32}=2$$

$$\frac{2MgO}{Al_2O_3}=\frac{2\times 24+2\times 16}{2\times 27+3\times 16}=.784$$

$$\frac{2MgO}{Fe_2O_3}=\frac{2\times 24+2\times 16}{2\times 56+3\times 16}=.5$$

The results show that there must be 2 parts of magnesia to 1 of silica; .784 part to 1 of alumina; and .5 part to 1 of ferric oxide. It is usual, however, to reckon magnesia in terms of lime, thus, $\frac{CaO}{MgO}=\frac{56}{40}=1.4$ parts of lime are equivalent to 1 part of magnesia.

The lime is obtained from the limestone used and contains some impurities, but these are ascertained by analysis. The clay is also analyzed so that the product to be derived from the fused mixture can be accurately foretold. Special rotary furnaces are used at present in preference to the old stack furnaces, and these are fired by gas or pulverized coal. The clayey material which is practically aluminum silicate, with small percentages of impurities is said to commence to fuse at 2,912° F. Pure limestone does not fuse but is converted into lime and then uniting with the materials in the clay forms the cement clinker. The lumps of clinker are separated from the unfused material and pulverized to form Portland cement. It has been ascertained that the finer the clinker is pulverized the better will be the cement, since, in extremely fine condition the cement forms a silicate with the sand used in practical construction work. The majority of limestones contain some clay and clays often contain limestone, and in making a mixture of raw materials previous to slagging these must be balanced. Magnesia may replace the lime up to 5 per cent. without bad results, and ferric oxide may replace alumina. A certain amount of iron acts as a flux, lowers the fusion point of the mixture, and promotes the combination of lime and silica. The replacement of practically all the alumina by iron has been advocated for cement that is to be used in sea water. Limestone containing approximately 75 per cent. calcium carbonate $CaCO_3$ and 20 per cent. of silica, alumina, and iron oxide is termed natural cement rock because it contains as impurities the quantity of clayey material that must be added to pure limestone in making cement. It is seldom that the right proportions are found as impurities in limestone to make a good natural cement, and to produce the right proportions clay or limestone must be added.

Other things being equal, raw material approaching natural cement rock can be a little more cheaply prepared than a mixture of pure limestone and shale.

Assuming a clay and a limestone to contain the following ingredients, it is desired to calculate a cement mixture:

	Clay	Limestone
Silica SiO_2	60.17	.38
Alumina Al_2O_3	22.65	.18
Ferric oxide Fe_2O_3	4.66	
Calcium oxide CaO	.31	55.62
Magnesia MgO	1.85	
Alkalies K_2O and Na_2O		
Loss on ignition	6.35	43.50
Water H_2O below 220° F.		.17

Clay.—

60.17×2.8 = 168.47 parts CaO for 100 parts SiO_2
22.65×1.1 = 24.92 parts CaO for 100 parts Al_2O_3
4.66×0.7 = 3.26 parts CaO for 100 parts Fe_2O_3
196.65 parts CaO for 100 parts clay
.31 + (1.85×1.4) = 2.90 parts CaO in 100 parts clay
193.75 parts CaO to every 100 parts clay

Limestone.—

$\left.\begin{array}{l}.38\times 2.8=1.064\\ .18\times 1.1=\ .198\end{array}\right\}$ 1.262 parts CaO in 100 parts limestone which is not available, hence 55.62 − 1.26 = 54.36 parts calcium oxide available in 100 parts of limestone.

Cement Mixture.—

$\frac{193.75}{54.36}=3.54$ parts limestone required for 1 part clay, or 354 pounds of limestone for every 100 pounds clay. The quantity of volatile matter in the limestone is 354×(43.5+.17) = 154.59; the volatile matter in the clay 6.35; hence the cement when burned will weigh

$$454-154.59=299.41\text{ lb.}$$

PARTS OF MATERIALS BY WEIGHT

	Clay	Limestone	Burned
Total	100.00	354.00	299.41
Silica	60.17	1.27	20.50
Alumina	22.65	.60	7.76
Ferric oxide	4.66		1.55
Lime	.31	196.89	65.90
Magnesia	1.85		.61
Volatile	6.35	153.99	

The percentage of lime should be from 60 to 63.5 per cent. in good Portland cement, while in the above mixture it is 65.9. The ratio for the silica-alumina must be within 3 : 1 to 4 : 1 or 2.5 : 1 to 3.5 : 1. A richer clay will have a lower burning temperature and carry less lime, which makes a poorer cement

GEOCHEMISTRY

*By George T. Holloway**

(Continued from July)

Probably the most promising field for ore bodies exists in the oldest plutonic rocks and particularly in such pegmatites and other extremely old granitic and other rocks as have been subjected at great depth and pressure and at high temperatures, to the action of intruded flows of fused mineral matter from still deeper-seated sources, or of vaporized mineral matter of similar origin. Such rocks exist in many parts of the world, but the pegmatites of Norway, the old granites of Greenland, and many of the old but less highly crystalline tin-bearing deposits of Cornwall may be instanced as likely to throw light on the origin of many metals, and especially of those at the "heavy" and "light" ends of the periodic table.

The Relation Between the Mineral and the Chemical Industries

It is extremely probable that some of the many missing heavy elements near the uranium end of the table will be found in such rocks and that certain light elements for which room may have to be made in the table, may also be unearthed.

My experience of the rare minerals found in the older rocks induces me to particularly refer to the vast field which they furnish for research for those who regard the rare metals from the commercial point of view, for those who wish to improve our present defective methods of both qualitative and quantitative analysis, and for those who are searching for new elements. I would specially draw attention to the "black tin" concentrates obtained from the tailings and slimes run to waste from the "dressing floors" of the Cornish tin mines. This waste passes down what is known as the "Red River" from Camborne to the sea at Gwithian, and is collected and retreated over a length of about 8 miles, by 16 independent firms or individuals known as "streamers," each of whom extracts as much as possible from what passes by his holding. Finally, on Gwithian beach, where the waste passes into the sea, the waves perform the last dressing operation, and, at low tide, little patches of the heavy tin ore which have thus been collected, are scraped up by the last of the tin dressers, to complete the tally. It is an interesting proof of the necessity for efficient dressing appliances for minerals, to note that the Red River produce amounts to over 800 tons annually of "black tin"—which by the way is red—containing an average of about 50 per cent. of metal, notwithstanding that the ore, before its waste is rejected by the mines, has passed through more "dressing" processes than any other mineral with which I am acquainted.

My excuse for this digression, is that the black tin from the Red River contains not only the tin, the only substance which is extracted from it, but there have become concentrated in it minerals of tungsten (representing according to my analyses, an annual loss of over 100 tons of wolfram), uranium, vanadium, tantalum, niobium, molybdenum, and other known heavy rare metals as well as strong indications of rare elements, which have somewhat similar properties, but which have not yet been isolated.

The occurrence together of practically all the heavy rare elements and the almost invariable occurrence with them or at any rate in the same or similar rocks, of many of the rare alkali, alkaline earth and allied elements such as lithium, caesium, rubidium, cerium, thorium, didymium, beryllium, zirconium, etc., is of extreme interest. All occur in pegmatites or others of the oldest and particularly the acid rocks, and practically none are found elsewhere except under conditions directly traceable to such an origin. Where uranium abounds, the other heavy metals are usually present in comparatively small quantities and the other groups of rare elements are practically non-existent while, under conditions where uranium is absent or only found in comparatively small quantity, the others may be found associated together either as components of minerals of complicated constitution or each in its own characteristic mineral form.

The occurrence of fluorides with these rare metals or in the rocks where the same occur, is also of importance. Both fluorspar and cryolite are commonly, although by no means always, associates of them, and it is considered by many that these fluorides, which often occur in fissure veins in granites, diorites, gneisses, etc., of great age, have been produced, in many cases, by the action of metallic fluorides whose decomposition has resulted in the production of metalliferous deposits and of such fluorides as fluorspar, cryolite, etc., and minerals containing fluorine such as topaz, tourmaline, etc.

The peculiar action which the heavy rare metals have when added to steel shows how curiously they stand as a class distinct from others. Uranium, tungsten, molybdenum, tantalum, niobium, vanadium, and even titanium, have extraordinary powers in producing special effects when added to steel, even in small quantity. These powers might be considered only as of passing interest from the point of view of the chemist, were they not practically confined to one group of metals and possessed more or less by each member of that group. It is true that valuable properties are imparted by other metals such as aluminum, manganese, nickel, and chromium, but their effects are less marked and are produced by the addition of a comparatively large quantity of the metal, excepting in the case of aluminum, whose action is, however, of an entirely different nature.

The recent demand for these rare metals has resulted in a large increase in the production of the minerals containing them. They were commonly passed over by the prospector or ignored by the analyst, and the present increased supply is mainly due to increased education, and is much on a par with the production of monazite and other thorium-containing minerals used for incandescent lamp mantles, and now obtainable from alluvial and other deposits in many parts of the world, in addition to its early and only source in Brazil. Over 200,000,000 of such gas mantles are now produced annually. The best concentrated monazite sand averages only about 5 per cent. of thoria and other earths actually required by the mantle industry, so that a large field is open for research to utilize the ceria, zirconia, didymia, etc., which are obtained as by-products.

Tantalite, at one time almost unobtainable, is now found in larger quantities than are required, and is even produced as a by-product in washing cryolite, with which it occurs, as might have been expected from a study of the natural associations of the rare elements mentioned above.

Reliable statistics as to the output of minerals of the rare metals are not obtainable, but it may be mentioned that the world's output of tungsten ores was over 5,500 tons in 1908, as against about half as much in 1905, although the price obtainable per ton had nearly doubled by 1907-8.

Indications of a simultaneous primary origin exist in the case of a large number of minerals and mineral aggregates. No lead mineral has, I believe, ever been found free from silver or from gold nor has any metallic lead or salt of lead free from silver or gold been prepared except by the most costly processes and in extremely small quantity. Practically all commercially treated copper minerals also contain gold and silver and modern methods of treatment now permit the buyer to pay for both, even when present in little more than traces which, 20 years ago, would have been totally lost. The attempts at obtaining the gold and silver from antimony ores in which both metals also invariably occur, have been largely responsible for the highly successful volatilization methods of extracting antimony which have resulted in so great a fall in the price of that metal.

The invariable association of selenium and tellurium with sulphur, of cadmium with zinc, and of nickel with cobalt, and

* An abstract of part of paper printed in the Journal of the Society of Chemical Industry, January 31, 1910, Vol. XXIX, pages 53-65.

the common association of potassium and sodium, of calcium, barium, and strontium and of the halogens, excluding fluorine, is too well known to need comment. It may be explained by the similarity of their properties, but there are many other mineral associations of elements which, like that of the precious metals as compared with lead, are not in any way similar, and a knowledge of them is of great assistance to the mining man and mineralogist in searching for minerals and in his anticipation of what may be expected to follow such indications as are found in prospecting, as well as to the metallurgist and chemist as a guide in searching for valuable or objectionable constituents in such minerals as he has to treat.

One of the most common associations is that of zinc blende with galena, copper and iron pyrites being also usually present. Such an association is objectionable in every way commercially, and although these minerals may be separated mechanically, hydraulically, or magnetically, when the minerals are not so fine grained or so intimately interlocked that a preliminary crushing will not break them apart, millions of tons of ore of high "assay value" exist which have not yet been treated at a profit and which are known as "refractory zinc-lead ores." When it is remembered that ores containing metal values of zinc, lead, silver, and gold to the amount of perhaps 10 pounds or more can be obtained for little more than the cost of mining, of almost uniform composition and in unlimited quantity, one cannot wonder at the numberless attempts which have been made to solve the problem and which have raised more hopes and emptied more pockets than any other metallurgical problem during the last century.

A knowledge of the common associations of minerals and especially of the metalliferous minerals, may often save the miner and the metallurgist from serious error and loss, and experience as to the condition in which they are required for the market is of equal importance. In the earlier days of mining, zinc blende, the most important ore of zinc, was regarded as a worthless mineral and was picked out from the galena with which it occurred and thrown away. Nickel ores are still commonly mistaken for copper ores and the writer, in one of the outports of Newfoundland, has seen molybdenite picked out from granitic rocks where it occurs under conditions which, to the mineralogist, would at once identify it, and used as black lead for blacking grates.

Even within the last few years, amblygonite, the hydrated phosphate of lithium and aluminum—now the most important source of lithia—was sold from a tin mine abroad as inferior phosphate for making fertilizers. The purchaser sold it to the lithia manufacturers at a large profit until the mine owners had their eyes opened by a friendly chemist.

Concerning metalliferous minerals generally, the Cornishman's adage, "Where they are, there they are," is a safe one for a non-geological paper.

As the most important group, and as typical of others, the sulphides are deserving of especial consideration by the chemist. In conjunction with the selenides, tellurides, arsenides, etc., with small quantities of which they are so commonly associated and which they so strongly resemble mineralogically, the sulphides directly or indirectly furnish a large proportion of the ores from which the world's metal supplies are derived.

It is true that pyrites as such, does not constitute a commercial ore of iron, but the oxide left by the roasting of pyrites is regularly smelted for the production of pig iron and it must not be forgotten that a considerable proportion of our iron ore deposits are themselves the result of the decomposition of sulphide of iron in one or other of its various mineralogical forms.

Where exposed to atmospheric action, or roughly speaking, above "water level" (that is, above the line below which pumping is necessary in the working of a mine) most of these sulphides oxidize more or less, often completely, so that metallic sulphates, carbonates, and oxides, commonly occur at and near the surface, the proportion decreasing as depth increases and finally giving place entirely to the sulphides from which they were derived.

The "gossans," or oxidized outcrops, which, in so many instances, have been the surface indications leading to the discovery of important mining fields, are of this class and have furnished more of the rare mineral specimens which grace our museums than all other sources combined.

Since iron pyrites is of such commercial importance, being the chief source of the world's supply of sulphuric acid upon which so many of the chemical industries depend, it may be well to discuss the changes which occur during the weathering of this mineral, and their important and far reaching results.

Briefly stated, the result of the weathering of iron pyrites is the production of ferrous sulphate and free sulphuric acid, followed by the oxidation of the ferrous—to normal, and ultimately, to basic, ferric sulphate. With certain kinds of iron pyrites—notably marcasite—the decomposition proceeds with great rapidity, a clean specimen soon becoming coated with minute crystals of ferrous sulphate even when enclosed in a mineral cabinet.

The sulphates so produced are mainly carried away in solution or suspension, but a small quantity usually remains and, by final conversion into oxide, reddens the mineral mass from which the pyrites has been leached out.

Should gold be present in the solutions acting upon the pyrites, the reducing action of the ferrous sulphate precipitates it as metal, producing oxidized ferruginous gold ore. The presence of extremely minute traces of gold in many saline and other natural waters is well known and, although this store of precious metal will most certainly never be profitably tapped by mankind, nature is continually drawing from it and depositing the gold in concentrated and therefore available forms. Such gold ores are often of great beauty and richness, and probably most of those in which the metal occurs in the crystalline state have been produced by the above or some similar reducing action.

Enormous quantities of pyritic ores containing the precious metal exist under conditions which altogether preclude such an explanation of the deposition, but the fact that the rich surface indications of a gold mine are by no means a sign of continuance in depth (as would be the case were the gold merely left behind by the weathering of the pyrites already containing it) is a significant proof of the frequent deposition of gold from surface and other waters.

In addition to their far reaching effects upon the igneous and other rocks already referred to, the soluble products from the weathering of pyrites also react upon such carbonates and other compounds of lime, magnesia, alumina, etc., as they come into contact with, producing the corresponding sulphates.

The carbonate of iron produced from such interaction may be directly deposited as chalybite or spathic iron ore, but is more commonly converted, by loss of carbonic acid and subsequent oxidation, into various forms of ferric hydrate or oxide, such as limonite, hematite, etc.

The familiar rusty iron stain which settles from chalybeate waters, affords an indication of the manner in which such ores have been produced, and the thick brown mud so frequently found in disused mines and on the beds of streams, are further examples.

The natural or induced weathering of iron pyrites is taken advantage of in the case of low-grade cupriferous iron pyrites at the Rio Tinto Mine, both metals being dissolved out as sulphate and the copper finally precipitated as metal by treatment with pig or scrap iron.

It is interesting to note that the Rio Tinto ore is one of the very few which lend themselves to such weathering. Many large deposits exist, which, although very similar in appearance, are almost incapable of such weathering and, being too poor for smelting, have had to be abandoned.

Although not a tenth of the total sulphur mined yearly in the form of pyrites, and practically none of that existing in other minerals, is utilized, the remainder passing into the atmosphere or being otherwise directly lost, nearly 2,000,000 tons of iron pyrites averaging about 45 per cent. of sulphur, is annually mined, as a source of sulphur, mainly for utilization in the manufacture of sulphuric acid. This huge supply is supplemented by a comparatively small return of sulphur recovered from alkali waste by the Claus-Chance process, and particularly by the large amounts of native sulphur mined in Italy and probably attributable to natural processes acting on sulphurous gases somewhat as in the Claus-Chance process, and by the rapidly increasing output of Louisiana. The two latter sources account between them for about three quarters of a million tons of crude native sulphur annually.

The consideration of the pyrites and sulphur industry must be left for the writers of special papers, but a few words may be devoted to the many by-products which are obtained during roasting, smelting, or other treatment of pyritic ores.

Selenium occurs, although only in minute quantities, in native sulphur and in all pyritic ores, and becomes concentrated throughout various stages of their treatment. Its production as a by-product of sulphuric acid manufacture is well known, but its latest and principal source is the anode mud or slime from the electrolytic purification of crude copper. Although its percentage in the cupriferous pyritic ores from which the bulk of the world's copper is obtained is so small that it cannot usually be determined, it becomes to a large extent concentrated with the copper through the various stages of treatment, and when one remembers that the bulk of the world's copper is purified by that process and that most of the selenium becomes accumulated in the mud left by solution of the anodes, the possibilities as to supply of selenium, should the demand increase, will be readily realized. Not only do these anode residues contain selenium; they contain often as much as 50 per cent. of their weight of gold and silver, together with much bismuth, all similarly concentrated by the selective power of metallic copper from the otherwise non-recoverable traces which occur in the original ore and all obtained as true by-products by a treatment which would be necessary in most cases even were they not present. As regards bismuth, it may be noted that, in addition to the amount recoverable from the copper, over 800 pounds is stated to escape daily from the smoke stack of a single copper smelter, the Washoe smelter, of Montana, and that bismuth is now obtained from the anode mud from the electrolytic refining of lead bullion.

In the roasting of tin ores and of many others where pyrites is present, large quantities of arsenious oxide are produced from the arsenical pyrites which almost invariably accompanies even ordinary iron pyrites and which is still more common with mixed ores. Although in mining districts unlimited amounts of sulphurous acid are often permitted to pass into the air, the escape of arsenic fumes is usually rigidly forbidden. A large proportion of the white arsenic of commerce and, through it, of practically all other arsenical compounds, is thus obtained as a by-product. The residues from the roasting of pyrites for sulphuric-acid manufacture are by no means exhausted of their values. The extraction of their copper contents and the recovery of their silver and gold by the Claudet process are well known, and the use of the burnt pyrites as pigments and polishing material and for smelting down for production of pig iron may be mentioned as the principal among its other applications.

In conclusion, the writer expresses his indebtedness to Mr. W. E. F. Powney and Mr. F. Rowley, whose help has been invaluable both in the preparation of the notes and as critics and correctors of the manuscript.

THE HECLA MINE HOIST

Written for Mines and Minerals, by J. C. McQuiston

An Electric Mine Hoist, Capacity 16,000 lb. From a Depth of 2,500 Feet at Speed of 2,400 Feet per Minute

The operation of large electric hoists, with mutual satisfaction to the mining company and the power company, has, during the past few years, received very careful consideration and today there is no question but that this problem has been satisfactorily solved.

With the introduction of the polyphase alternating-current generators and high-tension transmission lines, electric power has become available in most of the great mining districts. The simplest method of utilizing this power for hoist work is through the direct application of an alternating-current induction motor. If the capacity of the hoist is comparatively small, this is quite satisfactory, but where heavy loads must be handled at high speed, the peak due to acceleration of the moving parts is often far in excess of the average requirements of the hoist, in which case, if the current is purchased from a power company which also carries a lighting load, the voltage fluctuation each recurrence of the hoist cycle peak will prove most objectionable. If the hoist is located at the end of a long transmission line, an excessive amount of copper must be installed to prevent an undue drop in the voltage during the maximum demand. In any case, the power company must install all its equipment with reference to peak instead of the average load, and must charge accordingly. To meet these conditions the flywheel motor-generator type of hoist has been developed. The essential parts of such a hoist system are:

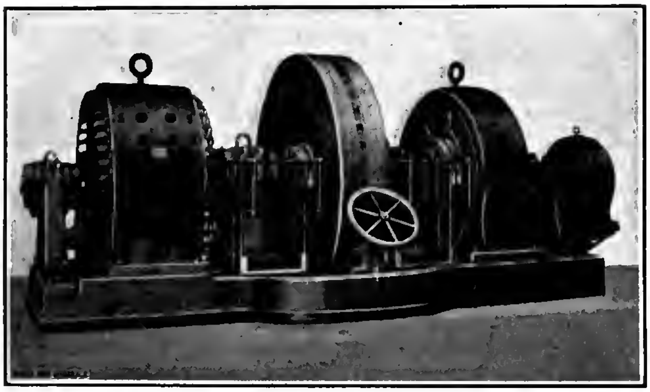


Fig. 1. Motor Generator

(*A*) A shunt-wound direct-current motor geared or coupled to the hoisting drums.

(*B*) A flywheel motor-generator set consisting of: (*a*) An alternating-current induction motor with variable external secondary resistance; (*b*) a direct-current shunt-wound generator with auxiliary commutating poles; (*c*) a heavy flywheel mounted on the motor-generator shaft; (*d*) a direct-current exciter for separately exciting both generator and hoist motor.

(*C*) A slip regulator which, by varying the secondary resistance of the alternating-current motor causes it to slow down under heavy loads.

(*D*) A suitable controller for varying and reversing the direct-current generator field current.

The armatures of the direct-current generator and hoist motor are connected in series, and the field of each machine is separately excited, constant full field being maintained on the motor. The hoist is started by applying a gradually increasing field to the generator, thus causing a proportionate voltage to be impressed upon the armature of the hoist motor. When the load on the alternating-current motor reaches a predetermined limit, resistance is automatically cut into its secondary circuit by means of the slip regulator. The speed of the motor

generator is thus reduced and a portion of the stored energy in the flywheel utilized in overcoming the peak of the hoisting cycle, with a minimum demand on the power system. In stopping the hoist at the end of a cycle the generator field is gradually weakened so that any excess energy stored in the descending cage, rotating hoist motor, and drums, is returned to the flywheel through the direct-current generator which momentarily acts as a motor, receiving electrical energy from the hoist motor, the functions of which are also momentarily reversed. To reverse the hoist, the field of the generator is reversed, causing the motor to rotate in the opposite direction. The heavy peak loads are thus eliminated from the line and the wear on the mechanical brakes is very much reduced. Since the current handled by the controller is very small, a great many steps can be provided, giving the operator a very elastic and sensitive control under all conditions.

Perhaps no electric-hoisting plant has attracted more attention from the mining men of the entire country than that of the Hecla Mining Co., at Burke, Idaho; the American Institute of Mining Engineers during their 1909 tour, made the trip to this mine for the express purpose of inspecting the installation.

The power available for this plant is three-phase, 60-cycle current, ranging from 2,080 to 2,300 volts. The motor generator, Fig. 1, is self-contained, having a cast-iron base, four bearings, and shaft. A 450-horsepower, three-phase, 60-cycle motor drives the direct-current generator, which is equipped with commutating poles to enable it to handle full-load current at any voltage between 0 and 600 volts. The flywheel, weighing 30,000 pounds, is mounted on the shaft between the motor and generator, while the direct-connected exciter is carried upon the shaft extension at the end of the set. The direct-current 550-horsepower, 600-volt hoist motor, operating at 60 revolutions per minute, Fig. 2, is direct-connected to the main reel shaft by a flange coupling.

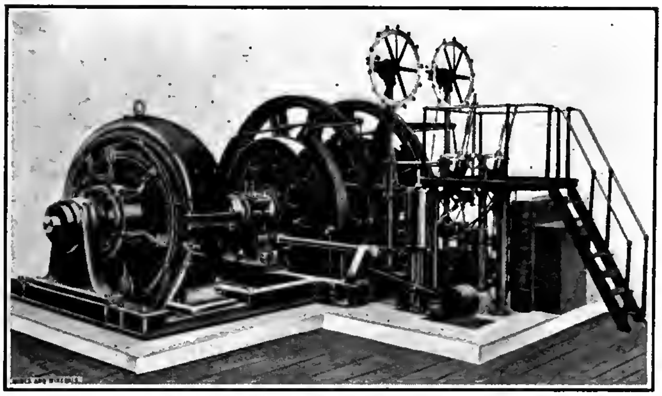

Fig. 2. Electric Hoist, at Hecla Mine

The control of the direct-current circuit for operating the hoist is obtained by means of a lever, the forward movement of which starts the hoist in one direction, and the backward movement in the opposite direction. This lever is direct-connected to a reversing field rheostat with a large number of points; since it is used to vary the generator voltage instead of cutting resistance into and out of the hoist-motor armature circuit, economical operation is secured at all points even when conditions necessitate running at lower than normal speed. All the operating levers have the same direction of throw with a movement of less than 30 inches. They are conveniently grouped upon a raised platform consisting of an iron frame and hardwood floor, with a suitable stairway leading from the engine-room floor to the platform, and a brass hand rail enclosing the stairway and platform. The entire electrical equipment described above was supplied by the Westinghouse Electric and Mfg. Co.

The hoist, Fig. 2, which was built by the Wellman-Seaver-Morgan Co., consists of two reels, each capable of holding 2,500 feet of $\frac{3}{8}'' \times 4''$ flat rope. Under normal conditions the hoist operates in balance, that is, the empty cage descends as the loaded cage is raised. If desired, however, either reel may be operated independently of the other. The winding diameter of the reel varies from a minimum of 5 feet when empty, to a maximum of 13 feet when the entire 2,500 feet of rope is wound up. Each of these reels is fitted with a Webster, Camp & Lane band friction clutch, post brake, and indicator.

The brakes, which are operated by means of combined air and oil cylinders and heavy counterweights, are so designed that they are set by the weights and released by means of air cylinders.

This hoist has a maximum hoisting speed of 2,400 feet per minute, and will handle an unbalanced load of 16,000 pounds, including rope, from a depth of 2,500 feet; yet its operation is the acme of simplicity.

The complete equipment, including the motor-generator set, hoist motor, slip regulator, switchboard, and hoist, weighs over 300,000 pounds.

STOPE TIMBERING

Written for Mines and Minerals

In many cases where a stope is not more than 8 feet wide stulls are set across with plank lagging for floor, and this is all the timbering required when the stulls are formed. In the case of crumbling walls, which require support, square sets and lagging are necessary. In stopes of a width only requiring one length of timber to reach across, but also requiring posts, the sill stulls are set first in an overhead stope, and the cap stull set first in an underhand. In all cases the stulls are cut of such length as to fit tightly against both walls, and a wedge is driven between the wall and the end of the stull to make it very tight. Each stull is set so that the end against the hanging wall makes an angle which is slightly greater than a right angle, in order that the least settling of the hanging wall may tighten the stull. The side posts are set after the stulls are in place in cases where the lower stull is set after the upper in underhand stopes.

In overhead stopes the posts can be set on the ends of the lower stulls and the upper stull driven down upon the top of the posts. When the side posts have to be set, after both top and bottom stulls, it is well to have the top of the posts framed for a gain in the end of the stull, then drive the bottom of the posts to place and secure it by drive bolts. The lower end of the posts and the upper side of the stull are not cut at all in this case, provided the timber is sawed.

Another way to put in square sets is to have them properly framed at the ends and of such a width as to approximately fit the width of the stope, and drive lagging between the square set and the wall to tighten the frame and support the walls. If the timber is to be removed and used again, this is much the better way, but in cases where there is no intention of removing the timber the framed method is to be preferred, as being both quicker and giving stronger support to the walls, although not making so neat a job. These methods have both been described, presupposing that each square set stands by itself, the sets being only connected loosely with one another by the lagging.

It is sometimes necessary in working in wide stopes to frame two or more wide sides so that they fit together to span the distance between the walls. In this case ties are necessary besides the caps, sills, and posts, the ties being similar timbers to the others, and framed so as to join the square sets together lengthwise of the stope and form a good joint. In case there is a squeeze on the square set timbers it is customary to use reinforcing sets which fit snugly with the square sets. If the pressure comes from the top, posts are employed to take it up, if from the sides, braces.

GASOLINE MINE LOCOMOTIVES

Written for Mines and Minerals

For a considerable time German and Austrian mining companies have been using gasoline locomotives for mine haulage, and there are now about 300 of these engines in various parts of the globe.

Application of Gasoline Locomotives for Mine Haulage. Successful Use in Germany

This shows that this system of haulage has long passed the experimental stage, and judging from the advantages such motors have over other kinds of locomotives, it seems reasonable to suppose that there will be a demand for them in this country. There is a large field for internal combustion locomotives in the West, where coal for fuel is scarce, or electric power is lacking; where water is lacking, or too bad for use in boilers; where great expense for fuel or the installation of electric power makes air, electric, or steam power prohibitive.

Compared with steam locomotives for mine haulage in general, these machines have the following advantages which may appeal to some, even though equipped with steam locomotives: They consume no fuel during stoppages; they require no water to replace that evaporated in the boiler; they possess no boiler to require repairs or inspection; they are of less weight; and when at work or idle do not fill an excavation with foul gases. They may be used also in mines where naked lights are prohibited and the purity of the ventilation is essential.

FIG. 1. GASOLINE MINE LOCOMOTIVE

The various advantages offered by gasoline locomotives of the explosive type suggest that they might be employed to distribute and gather cars, from mine rooms, where small wheel-base is required to round curves of small radius, and where mine tracks are not made sufficiently strong and solid for weightier motors. The makers of this locomotive claim that their "Century" model shown in Fig. 1 can, by special design, be constructed to replace mules for gathering purposes. This machine is made absolutely explosive-proof by the total elimination of any form of carbureter (or vessel for vaporizing fuel) outside the cylinder and by the ignition of the charge in the cylinder, which is effected by means of a low-tension magneto. For underground haulage in fiery mines, both terminals are insulated to comply with the Austrian Coal Mining Regulations, and the electric current conveyed to and from the sparking points in special metallic-woven cables so that all chance of fraying is obviated.

Compared with electric locomotives, internal combustion locomotives have the following advantages in general: The danger from accidents due to over head trolley wires of high voltage is eliminated. The danger of fire arising from defective insulation is also removed. The danger arising from explosion due to sparks setting fire to mine gases is obviated. They require no central or other power plant and are independent machines, which if out of order can be speedily repaired or be replaced. They represent considerable economy in first cost over an electric installation, in the comparative cost of the two different kinds of motors, and in track construction. Another advantage is found in the haulage system being capable of large expansion by the employment of more locomotives as the ouput demands, where a new electric installation and its accompanying expense is avoided.

Compared with compressed-air locomotives, they have several advantages, the chief of which when enumerated are: The first cost of installation; the decreased cost of operation; the increased flexibility of the system; and the smaller size of the motors.

Compared with rope-haulage systems they have all advantages which other kinds of motors have over the systems, and those mentioned, which others do not possess. To be sure they can not haul up as steep grades, nevertheless they are able to negotiate reasonable grades and uneven roads; however, they are not dependent on a central power station and admit of more ready extension as the mine expands. The cost of maintenance and of operation is less, the latter varying for underground haulage with inferior tracks and sharp curves from 2.4 cents to 2.6 cents per ton-mile. Actual working costs taken by owners over a sufficiently long time show figures for surface haulage as low as 1.2 cents per ton-mile, after deducting 20 per cent. for amortization.

This type of locomotive is regarded as perfectly safe by the Austrian, French, and German Government Mine Inspectors, for they permit the use of this engine in gassy mines in which firedamp is continually present. The locomotive machinery is housed over to prevent its being injured by falls of slate or rock from the roof; and is housed in on the sides to protect it from dust. The sides are readily removed as shown in Fig. 2, so that examination and repairs can be quickly made. The machinery in the rear end of the locomotive is easily reached by swinging doors, as shown in Fig. 3.

The gasoline engine employed in this locomotive is the most important part of the machine and upon this the manufacturers lay particular stress. The engine has a single cylinder, that makes a comparatively small number of strokes per minute, and operates in cycles common to all internal combustion engines, by taking in a quantity of air, next gas, then compressing the mixture and finally, by the explosion of the mixture, generating the power.

To control the speed of the engine, there is a regulator which is operated from the cab, by the engineer who runs the locomotive. The motor which is horizontal has the advantage over vertical motors of a low center of gravity, a point of considerable importance when one considers the narrow track gauges, sharp curves, and the limited head room in most mines. The fuel may be alcohol, gasoline, naphtha, or petroleum, although for underground work the volatile liquids, naphtha and gasoline, are recommended on account of their combustion being better than petroleum and less costly than alcohol. By means of a specially constructed inlet valve it is impossible for any explosive mixture to be formed anywhere except in the cylinder, although as an additional precaution the air intake pipe is provided with

gauze baffles as an additional precaution. The exhaust gases are sprayed with a small quantity of water as they enter the exhaust box from the cylinder, with the result that they are cooled, condensed, rendered harmless, and cause no inconvenience to the mine workers. It is said that mine air is vitiated by gasoline locomotives to a considerable less degree than by animals and miner's lamps, on account of the treatment given

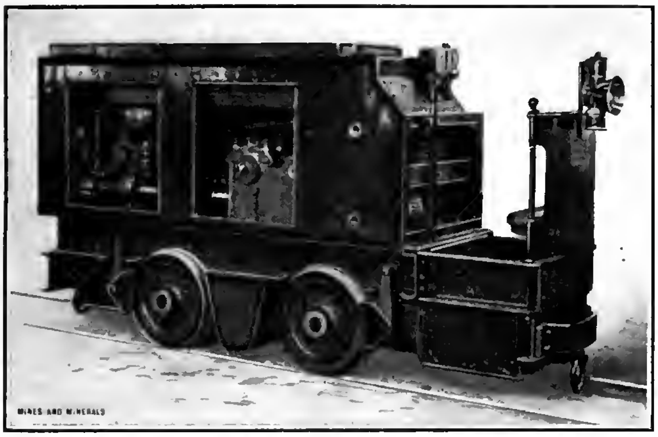

Fig. 2. Locomotive With Sides Removed

the exhaust, and further the spray is an absolute safeguard against any flame entering the exhaust box. The motor cylinder is cooled by a thermosyphon of such generous proportions that no circulating pumps or other mechanical devices are required. The water tank is of large capacity, but it should be refilled after each shift in order to replace the water lost by cooling the gases in the exhaust box.

The fuel tank has a capacity of 10 gallons, although the consumption is rather less than $\frac{1}{10}$ gallon per horsepower hour at full load. As, however, the locomotive is never run at full load except when starting and traveling up grade, it is found that $\frac{1}{20}$ gallon of liquid is rarely exceeded, so that a 12-horsepower gasoline locomotive consumes 6 gallons per shift of 10 hours. The fuel tank, which is perfectly air-tight, is arranged beside the water tank and is refilled at the end of each shift. The motor is mounted on a strong iron or steel frame, which rests on the boxes of four driving wheels having steel tires. Power is transmitted from the motor to all four wheels by means of a system of gearing, and in order to balance the power a heavy flywheel is fitted to the crank-shaft.

The gears which are always in mesh are engaged by means of clutches so arranged that their operation is quite "fool-proof." Powerful brakes are applied by means of a screw and lever fixed in the cab where the engineer can reach it readily. All the necessary appurtenances common to mine locomotives are attached to this, such for instance as headlights, warning bell, sandbox, etc., etc.

Small mining companies having an expensive haulage account can lessen it by the introduction of these locomotives, as they can be had in sizes that vary from 6 to 50 horsepower, and that will haul from 15 to 150 tons at speeds from 4 to 14 miles an hour. The engine for propelling the locomotive illustrated develops 16 horsepower, and a speed of 8 miles per hour.

The drawbar pull of such locomotives depends on their weight, condition of the tracks and road bed, and the grade; based on a drawbar pull of 1,500 pounds on the level the locomotive should have a hauling capacity of 50 tons on a good track, any grade of course will proportionally reduce the amount that can be hauled.

The drive is as stated on all four wheels and the locomotive moves forward or backward according to the motion given to a wheel in the driver's cab.

JOPLIN DISTRICT ZINC AND LEAD ORES

Written for Mines and Minerals, by L. L. Wittich

No proposed mining development of recent years has meant so much to the Joplin district as the announcement of the Granby Mining and Smelting Co. that it will mine its own properties. Heretofore the Granby company has done only a leasing business. Being the largest land owning company in the district, the decision to conduct mining operations means an era of development more extensive than any undertaken heretofore on the Granby land. As a starter the Granby company has drill rigs at work testing its holdings in the West Joplin camp and in the Oronogo camp, north of Webb City. At the former place open ground is found to contain good ore at shallow depths, while a deeper sheet formation exists. In the Oronogo camp efforts are being made to determine the extent of the deeper ore bodies which are just being discovered below the 400-foot level.

The Oronogo Circle Mining Co., operating on the Granby land, at Oronogo, has inaugurated a new system of keeping accurate accounts of all prospecting done in the mine. The machine drill men have received instructions to drill holes into the roofs, a distance of 8 to 10 feet apart, and also into the floor when stoping. The cuttings of all holes are saved and assays made. These cuttings are carefully bottled and labeled and placed away for future reference. A complete system of mapping enables the manager to tell at a glance how much ore has been left in reserve in roofs, floors, and stopes. The new system avoids the necessity of prospecting with winzes and rises.

At the 175-foot level of the Jack Harvard Mine on the Joplin tract of the Continental Zinc Co's. ground, a hoister has been

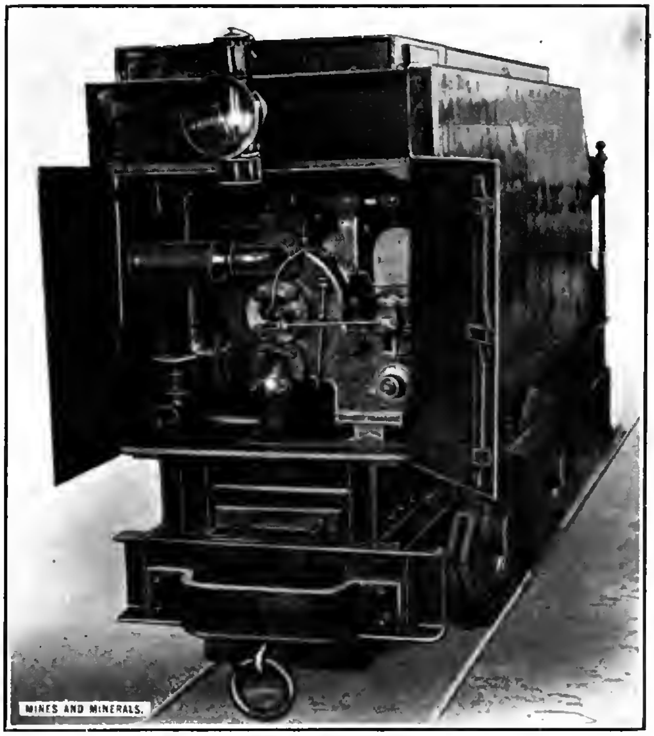

Fig. 3. End View of Gasoline Locomotive

installed and an inclined tramway leading into a winze has been put in operation. The winze extends at a gentle angle to the 190-foot level. A 15-foot stope in open ground is being taken up. Cars containing 1,000 pounds of ore are operated on the incline and are trammed to the shaft and hoisted. The company has drilled to 230 feet, encountering sheet ground at 210 feet.

On the Gregg land and on the Mattes Brothers' land, southwest of Joplin, in a region little mined since the early boom days

of the district, several drill rigs are at work and a number of new shafts are being sunk. Zinc blende has been found in a number of places near the surface while open ground at greater depths has been encountered. A number of concentrating plants have been erected recently and more are contemplated.

Allen Hardy and associates have taken a lease on the Weissbrod land, northwest of Joplin, and the 75-acre tract is to be thoroughly developed. A big daylight mine on this land is to be reopened.

The first turn in of ore from the Holy Moses Mine on a 40-acre lease of the Leckie land, northwest of Joplin, has been made. Hand jigs are used temporarily at the property which is operated by H. C. Moses.

The Tiwah Mining Co., operating on the McElroy land at Galena, Kans., has purchased a 250-ton concentrating plant from the Nowata Mining Co. The mill recently was purchased by the Nowata company and was to have been stationed on a tract west of Joplin. The plant was operated by the Kenwood Mining Co., at the Miami, Okla., camp. The Tiwah company has open ground ore in limestone and dolomite at a depth of from 250 to 300 feet.

The Nowata Mining Co. has purchased from J. C. Barr the Ave Maria concentrating plant, stationed south of Webb City. The company had planned to remove the mill to one of its Joplin leases, but an experimental try-out of the Ave Maria ground is being made. Former operations on this tract were unsuccessful but the present company is getting into exceptionally good zinc blende in ground heretofore overlooked.

The Peacock Valley Mining Co. has purchased an 18-acre tract from George Boughton, at Galena, Kans. Operations both with drill and with prospect shafts have shown exceptionally good zinc and lead ores, both near the surface and at depths below the 100-foot level.

The Victoria Mining Co., operated by George Lurwick in Cottonwood Hollow, northwest of Joplin, is getting into a rich pocket of zinc and lead ore at a depth of 60 feet.

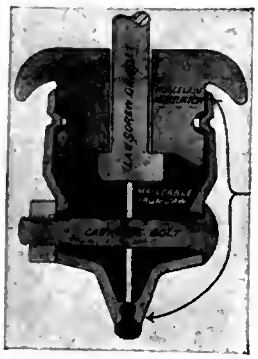
TROLLEY-WIRE SUPPORT FOR MINES

The conditions existing in mines demand trolley-wire supports of different design than those commonly used on the surface, and several hangers of excellent design have been in use. Recently, however, a new hanger has been devised which embodies some radical departures from other types, and contains features of a very desirable nature This hanger, known as the "Vise Grip" has been but recently placed on the market, and has met with success

The following description of the device, which is being manufactured by the Trolley Wire Support Co., of Syracuse, N. Y., is furnished through the courtesy of Mr. John L. Wagner, of the Pneumelectric Machine Co., of Syracuse, N. Y.

One of the features of this hanger, which departs most radically from prior practice, is the material used for insulation. Heretofore the insulation has been a composition, molded, under pressure and heat, into an outer casing of iron or other metal. In this composition was embodied a stud bolt to which the hanger was to be attached. This manner of constructing insulators has been exclusively used, and while it is efficient, if the composition is of uniform and proper quality, there has always been much difficulty in maintaining uniformity of composition and absence of imperfection in molding; so that absolute protection from electrical leakage and assurance of proper mechanical strength could not be obtained.

The insulator used with the Vise-Grip hanger is porcelain, a material noted for its high insulating qualities and great mechanical strength under tension or compression. In all the high-tension transmission work of 30,000 to 40,000, and even in some cases 100,000 volts, porcelain is used and is giving more satisfactory results than any known insulator commercially available. In addition to the use of porcelain in the "Vise Grip," there is no imbedding in an outer metallic cap, but a plain, specially formed, highly glazed insulator is provided, to which the jaws for supporting the trolley wire are attached without the use of an intermediate stud bolt or other device imbedded in the insulation.



Malleable iron jaw grips at these two points only. A "Vise-Like" grip to insulator and trolley wire.

Vise-Grip Trolley-Wire Hanger

The insulator being cylindrical in form, provided with a drip hood made integral with the body, permits the attaching of the jaws for supporting the wire in a very simple and effective way. The jaws are made semi-cylindrical in section at one end and straight at the other. The cylindrical part of the jaw is made to conform to the insulator and a bead is provided which fits in a corresponding groove in the insulator. The straight end of the jaw is formed to correspond to the shape of trolley wire to be suspended, and in the middle of the casting a hole is provided suitable for an ordinary carriage bolt. Two of these jaws, both alike, with a porcelain insulator and a carriage bolt, constitute the complete hanger. Its simplicity can accordingly be appreciated.

A hole through the insulator provides for suspending it by means of lagscrew, bolt, or other device. When this is in place the jaws are put in position, the carriage bolt passed through the holes provided for that purpose, and the nut screwed on with the fingers; the jaws will then be suspended from the insulator by means of the beads on the jaws resting in the groove of the insulator. The jaws are loose on the insulator, until finally clamped tight, and can be revolved at will to line up with the trolley wire when it is ready to be strung. In attaching the jaws to the wire it is only necessary to place it in the jaws and further tighten the carriage-bolt nut with the fingers. This will bring the jaws sufficiently together to permit the wire to hang in them loosely. After the wire has been thus suspended throughout the distance to be covered, the slack can be taken up in the usual way with assurance that the hanger will not be damaged, and the wire will remain suspended thereby until the carriage-bolt nuts are permanently tightened. To do this an ordinary monkeywrench, open end, or socket, wrench, is required. The nuts can be tightened to any degree desired and the jaws powerfully and simultaneously clamped to the insulator and wire. This manner of simultaneously clamping the insulator and wire discloses the underlying principle of the Vise-Grip hanger, for it is nothing more or less than a vise-like action, or the applying of great pressure by means of a screw.

POWER PRODUCTION AT COLLIERIES

At a meeting of the Mining Institute of Scotland, a paper on "Power Production at Collieries, with Special Reference to Gas Power and Electrical Centralization" was read by Mr. Robert Crawford and Mr. Harold Moores.

The authors said that the growing need for economy made the subject of power cost one to which the colliery manager must devote considerable attention, with a view to generating and transmitting his power in such a manner as would insure the highest possible efficiency. The report of the Royal Commission on Coal Supplies pointed out that collieries were extremely wasteful in the amount of fuel consumed in driving their own plants, the annual consumption in British mines reaching the enormous total of 18,000,000 tons. This was equivalent to about 7 per cent. of the total output, whilst it was an ascertained fact that in some individual cases the consumption in the colliery boilers reached the high proportion of 11 per cent. This proved the urgent need for economy, and an effort would be made to demonstrate that very high economies could be obtained by various methods and in varying degrees according to individual circumstances. Of late years the adoption of electricity as a secondary power for pumping, ventilation, haulage, coal cutting, etc., had greatly increased the efficiency of mining power plant by displacing small steam units. Much good work had also been done by the introduction of low- and mixed-pressure turbines so arranged as to utilize the large amount of exhaust steam from the winding engines, and to a less extent from haulage and other engines about the colliery. But while a good deal of attention had been devoted to electrical centralization of power at large collieries by means of exhaust-steam turbines, the authors said it was found that much higher economies could be obtained by converting the fuel into gas for the purpose of driving gas-engine electrical-generating sets, from which energy would be transmitted at high tension to the machinery at outlying pits; and accordingly they described the main types of producer gas plant available, showing the special functions and advantages of each in relation to colliery practice.

In conclusion, they observed that the heat possibilities of gas-engine exhaust did not yet appear to have been fully appreciated. Special exhaust-heat boilers were available, and many of them were in use in connection with gas-engine installations in Great Britain, with such an efficiency that 2 pounds to 2½ pounds of steam per boiler horsepower-hour might be obtained at 130 pounds pressure, without placing any appreciable back pressure upon the engine. Thus, an installation working at an average load of 3,000 kilowatts would evaporate about 9,000 pounds to 11,000 pounds of water an hour, which would easily drive a steam engine continuously at a load of 625 horsepower, allowing 16 pounds of steam per indicated horsepower-hour. This was waste heat converted into useful work, as in the case of the exhaust-steam turbine. It might be wondered why British colliery owners and power users in general had been so slow to take up the large gas engine, but no satisfactory answer was yet forthcoming. Great strides had been made in this matter in Germany, Belgium, and the United States, and large numbers of instances might be quoted in which units of 1,000 horsepower and upwards had been installed, with most satisfactory results. In one case, that of the Indiana Steel Co. of Gary (Indiana), there was an installation of 63,750 horsepower, consisting of 17 engines of 3,751 boiler horsepower each, whilst installations of 30,000 horsepower and 40,000 horsepower might also be mentioned. If did now appear, however, that the day of the large gas engine in Great Britain had at length arrived. Several large sets were at work in the Clyde, Cleveland, and South Wales districts, together with an installation of 20,000 horsepower at Messrs. Brunner, Mond & Co.'s works, Northwich, and one of 10,000 horsepower at the works of the Castner-Kellner Alkali Co., Ltd., Runcorn. It was also worthy of note that one prominent firm of gas-engine makers was building and equipping a special works solely for the manufacture of large vertical gas engines in units up to 3,000 horsepower. Actual experience had undoubtedly proved this system of gas-power production to be convenient and economical, and there were substantial reasons for believing that, as the possibilities of the system became more fully understood, its applications would be increasingly extended. A gas-driven central electrical power station for a group of collieries was the ideal arrangement, where circumstances admitted of the outlay which such a scheme involved; and there appeared to be no doubt that many such would spring into existence during the next few years, with a view to using to the best advantage the heat possibilities of the coal consumed.

A TENT AND SHACK LIGHTING OUTFIT

The John Simmons Co., of New York, have recently adapted their acetylene mine lamp to use as a lamp for tents or shacks in mining camps. A larger generating outfit has been made for this purpose that gives a twenty-five candlepower light lasting eight or nine hours without recharging.

The Baldwin Camp Lighting Outfit

The generating outfit hangs to the tent pole or wall of the shack in a convenient place, and a rubber tube leads to a fixture similar to an ordinary gas fixture.

This light is sold at the price of $5 and, when desired, a portable table lamp is furnished for $1 extra. The outfit is something which, if once used by prospectors or miners in their tents or shacks, will be recognized as one of the greatest comforts and luxuries possible in such a temporary home.

TESTS FOR CARBON MONOXIDE

At the fifty-second general meeting of the Institution of Mining Engineers, in London, June 2, 1910, Dr. J. S. Haldane gave a demonstration of the use of small animals in testing for carbon monoxide, and of a new arrangement for enabling a man equipped with a rescue apparatus to test the air at any time. The experiments were as follows:

1. The fact that small animals may be safely used to indicate the presence of carbon monoxide was shown in a large iron air-tight chamber. 2. A new arrangement was demonstrated for enabling a man with a rescue apparatus to test at any point whether the air is respirable. 3. The improved form of the Hall-Rees apparatus for enabling men to escape from a sunken submarine was demonstrated in an experimental tank.

TO FRIENDS

RESIGNATION from Mines and Minerals in the month of June recalls some of the emotions of a June graduation not so long ago. Now, as then, the predominating one is that of regret at parting from steadfast friends. Relations with both the executive force of the journal and with hundreds of friendly correspondents have always been amicable and it will ever be a sincere pleasure to recall that they continued so to the end.

Did leisure time allow, the writer would gladly write a personal good-by to all the hundreds of friends whose contributions of articles and data have in such a large degree been responsible for the success of the western section of the journal. Truly it may be said that, whatever measure of success has been ours, that success is founded upon friendship. In lieu of a personal letter, manifestly impossible to send all those who have contributed to our columns at the writer's request, this editorial is dedicated—to friends in token of a sincere and lasting appreciation.

To friends—scattered from Alaska to Mexico, inclusive, and from coast to coast—yours be the credit. You knew the writer as a miner, a transitman, an assayer, a manager, and finally a "pen pusher." And if in his writings he reflected the enterprise, the foresight, the courage, and the magnificent achievements of the western engineers, it was because in all his vocations he absorbed the spirit that prompted you as well as the information you freely gave him. And lest a mistaken idea be gained that the writer proudly claims as friends only the foremost of the mining and metallurgical professions—a word further. Had the writer depended upon them alone his results had been far less than they actually were. It is to many a graduate student—a mere beginner in the arts—that the writer owes his fullest comprehension of far reaching engineering plans. It is to many a miner, readier with his good-natured tongue than with his pen, that he is indebted for his keenest insight into an accomplished work.

For all the thousands of miles traveled to visit the principal mines of the country, friends have never failed to make possible a rich compensation for strenuous effort. That compensation may be partially viewed in resulting articles scattered over 50 issues of Mines and Minerals, but it is the invisible recompense that goes with the writer into retirement—the memory of your glad-handed welcome and generous entertainment.

As in the past, so in the future, Mines and Minerals must depend upon its friends for its continued business expansion—the success that comes to it must be founded upon the success of its friends. So in extending his best wishes for the future prosperity of his friends in the field, he bespeaks the continued cooperation of them with his successor and with Mines and Minerals, and may the fruits of that friendship continue to enrich and ennoble the mining and metallurgical professions.

R. L. Herrick.

THE COXE AND FRITZ LABORATORIES

LEHIGH UNIVERSITY, a comparatively young educational institution, has made great strides in its progress toward the foremost of technical colleges in the United States. Founded by Judge Asa Packer in 1865, and guided by such men as Eckley B. Coxe, the father of coal mining, and John Fritz, the father of the steel industry, its success was assured in time, but not so rapidly as it has occurred. On June 11 the Coxe Mining Laboratory, so named by the trustees in memory of a trustee and friend, whose services to Lehigh are held in grateful remembrance, was opened.

On the same date the John Fritz Engineering Laboratory was opened. In the course of his remarks Mr. Fritz said: "How these gentlemen have turned out engineers with the things they have is more than I can comprehend."

Having been in touch with both the professors and the alumni of Lehigh University for the past 30 years, we are convinced that Lehigh's success is not due to superiority in courses of study; nor to the superiority of its professors; nor to the erudition of its graduates; but it is due to the united efforts of its alumni in pulling together for each other and their college.

From inquiries made we are able to state that Lehigh professors and assistant professors teach, and do not merely hear students recite, as unfortunately is so often the case in some colleges. In some technical schools, so far as teaching goes, the student would be just as well off reading the subjects at home as to pay for reading the subjects away from home. Any institution which expects to turn out finished pupils must employ teaching professors rather than listening professors.

We are indebted to Mr. Susan K. Huang, of Hankow, China, a student at Lehigh, for the illustrations of the Coxe and Fritz testing laboratories. The Coxe mining

Coxe Mining Laboratory

laboratory will contain in addition to a mining outfit, a milling outfit, by means of which students can become familiar with standard machines.

The Fritz laboratory will contain testing and other mechanical devices necessary to give the budding engineer an insight into practical matters, thereby enabling the recent college graduate to more readily attain to a living wage after graduation.

TEACHING FOREIGNERS ENGLISH

SOME have argued that mine foremen and others employing foreigners should learn the foreign languages in order to direct the men under them. There are two reasons particularly why this is not feasible. First, the mine boss is too busy to study, and second, he would be compelled to study all his life

John Fritz Laboratory

in order to learn the languages and dialects of the various nationalities coming within his jurisdiction. Italy alone has some 70 dialects and the Slavonic language is made up of dialects apparently.

It is proper, therefore, that the foreigner should be instructed in the English language and if the reader will turn to Doctor Peter Roberts' article on "Teaching English to Foreigners" he will find how readily this may be effectually accomplished.

MR. R. L. HERRICK, former Denver editor of Mines and Minerals, conceived the idea some years ago of awarding a thesis prize of $50 to the senior class of the Colorado School of Mines. The thesis that won the prize offered by Mines and Minerals in 1910 was entitled, "The Measurement of the Flow of Compressed Air by Means of an Orifice Meter." It was written by Jean McCallum and Duane Kelso, and will eventually appear in Mines and Minerals. If the plans of the editor can be formulated the prize will be increased in 1911 and be opened to students in all mining schools.

BOOK REVIEW

The Cyanide Handbook is the title of the latest on the cyaniding of gold and silver, by J. E. Clennell, of London. The book contains 499 pages, 10mo, is nicely printed and bound in the regular style adopted by the McGraw-Hill Book Co., who are the publishers. The price is $5.

The book is divided into nine parts headed General, Chemistry, Preparatory Treatment of Ore, The Dissolving Process, Precipitation and Smelting Process, Special Modification of the Cyanide Process, Assaying, Analytical Operations, and Metallurgical Tests. From the captions it is seen that the author is not dealing with the mechanical development of the process.

but with the chemistry entering into and needed in the economical working of the process; in fact, he intimates in his introduction that that is his object. As this is in no sense an elementary book, but one that requires the reader to be thoroughly posted in chemistry and the cyanide process, it seems as if there was too much padding for one thing and irrelevant matter for another. A cyanide man who does not know more about crushing and concentrating machinery than is given in this book would be *persona non grata*.

A chemist or assayer in a cyanide plant who could learn anything from the section on fire-assaying would, to use a "bull," not be there; *contra* there is not sufficient detail to teach one to be an assayer. No one knows better than Mr. Clennell the qualifications necessary for a position of this kind, or the needs of a cyanide mill man. Therefore we intimated that there was padding in the book. It is not, however, to be understood that the book is not a valuable addition to cyanide literature, on the contrary there is much between its covers that cannot be found in any other work on cyaniding, besides, the author has compiled and combined with his own other well-known cyanide men's practice. The section on special methods of assaying and the one on analytical operations will be helpful and a ready reference for mill men who desire to find what kind of ore they are to treat.—E. B. W.

We have received for review the sixth edition of Persifor Frazer's and Amos Peaslee Brown's TABLES FOR THE DETERMINATION OF MINERALS BY PHYSICAL PROPERTIES. The scheme for the first edition, 1874, was that followed by Albin Weisbach in his "Tabellen," 1866. The book is divided into three parts: Minerals of Metallic Lustre; Minerals of Sub and Non-Metallic Lustre; Minerals of Non-Metallic Lustre and White or Light Gray Streak. Two pages are given to columns, headed, Name, Lustre, Color, Streak, Hardness, Tenacity; Crystal System; Habit and Structure; Cleavage and Fracture; Chemical Formula; Remarks on Gravity, Reactions in Open and Closed Tubes Before the Blowpipe, and Associate Minerals. The book contains 125 pages, with flexible cover and is indexed. J. B. Lippincott Co., Philadelphia, publishers. Price $2.50. It is an excellent book for the mining engineer to use in field work.

THE APPALACHIAN MINES RECORD, published at Roanoke, Va., has just issued a new map and directory of all coal mines on the Norfolk & Western Railway. The location of each of the 169 mines is plainly shown by a number on the map referring to the list, which is printed beneath in the style of a calendar. The following details are given for each mine—all in one line across the sheet: Name of the company; name of branch line (if on one); main office of company; mine office; names and addresses of president and secretary, manager, mine superintendent, purchasing agent, and store buyer; station for local and for through passengers; shipping point for freight and express, and whether it is "prepay" or not; telegraph office; method of mining; class of mine; kind of haulage; grades of coal made; number of employes; production in 1909, and selling agents. The map is 24 in. × 36 in., mounted on cloth. The publishers announce that the information given has been gleaned since February 1, 1910, and is very complete. Price of the map is $3.75, postage paid.

COST OF MINING, by J. R. Finlay, Lecturer at Howard University on the Economics of Mining. This book is 12 mo, contains 415 pages, and 22 illustrations. As its name would imply, it deals with the economic side of mining, a subject on which too little has been written, and that at such wide intervals the student has received little benefit. The book is divided into 21 chapters as follows: I, Value of Mining Property; II, Factors Governing Variations; III, Partial and Complete Costs; IV, Statistics of Coal Production; V, Cost of Mining Coal; VI, Cost of Mining Lake Superior Iron; VII, Occurrence and Production of Copper; VIII, Lake Superior Amygdaloid Copper Mines; IX, Conglomerate Copper Mines of Lake Superior; X, Copper Mines on Fissure Veins in Montana, Australia, and Arizona; XI, Various Copper Mines of Arizona and Mexico; XII, Copper Mines in Various Other Districts; XIII, The Copper Mining Business in General; XIV, Lead; XV, Silver-Lead Mining; XVI, The Cost of Silver-Lead Mining; XVII, Zinc Mining; XVIII, Occurrence and Production of Gold; XIX, Quartz-Pyrite Gold Mines; XX, Cripple Creek, Kalgoorlie, and Goldfield; XXI, Silver Mining at Cobalt and Guanajuato.

MINING LAWS OF OHIO, 1910, compiled by George Harrison, Chief Inspector of Mines, Columbus, Ohio.

MARYLAND GEOLOGICAL SURVEY, Volumes VII and VIII, William Bullock Clark, Superintendent of the Survey, R. W. Silvester, secretary, Johns Hopkins University, Baltimore, Md. Volume VII is a resurvey of the Mason and Dixon line between Maryland and Pennsylvania boundary.

The Knox system of blasting is used in quarrying, and consists in drilling two holes in the rock, these holes being located along the line where a fracture is desired, and about 1 foot apart. Black powder is charged in the hole, the quantity being determined by the size of the rock mass it is desired to split off. Tamping is put in the hole, but is not placed in contact with the powder, a space of 1 to 3 feet being left between tamping and powder. This affords an air cushion, which in part receives the shock of the blast. The holes are fired and recharged several times, the result being the fracture of the rock along a line corresponding to the direction of the holes. In a thoroughly homogeneous rock this system works well, and much larger masses can be detached than by feather and plug work, and much more cheaply.

CORRESPONDENCE

Surveying

Editor Mines and Minerals:

SIR:—The length of the curve required by question of Gordon L. Cox, of Wasioto, Ky., in your July number, is readily found in this case, by taking one-quarter the circumference of the circle to the radius 50 feet, thus, $\frac{3.1416\times 50\times 2}{4} = 78.54$ feet for 90°, or the one-quarter part of a circle. The degree of curve, if referred to standard railroad methods of calculation, will equal the number of degrees between the two radii and a chord of 100 feet; in this case the chord of 100 feet will equal the diameter of a circle, and the degree of curve becomes 180°. The deflection angle is one-half the degree of curve, or by deflecting 90° from the tangent and measuring 100 feet for the chord, the arc of the angle included by the radii will include 180°.

Montcalm, W. Va. E. W. Bailey

Editor Mines and Minerals:

SIR:—The following is in answer to question asked by Mr. Gordon L. Cox, in your Correspondence Column of July, 1910, relative to 50-foot radius curve of 90 degree total angle: Total angle, 90 degrees; length of curve, 78.54 feet; degree of curve, 114° 35′ 24″; radius, 50 feet. Grenville Lewis

Pineville, Ky.

Thermochemistry of Anthracite

Editor Mines and Minerals:

SIR:—From a comparison of the relative ash contents and British thermal unit values of the deliveries of furnace coal to the various Government buildings at Washington, tabulated by Messrs. Randall and Holmes in your issue of August, 1907, it would appear that the ash does not act merely as a dilutent, for the lower ash coals show very uniformly a higher calorific value than they should as compared with the mean, and vice versa. It would be interesting to learn whether any of your readers have made a similar observation on other coals, or whether the above is merely a coincidence.

13 James Street, Cardiff R. T. Hancock

Determination of the Meridian

Editor Mines and Minerals:

SIR:—Mr. James Underhill, in common with a good many surveyors, should thank Professor Rowe for drawing his attention to the influence of altitude on the horizontal angle subtended by the sun's diameter. It is of great interest to note that the true position of the sun's center should be worked out separately for each observation, when these are taken to the limbs, and not calculated from the mean. The importance of this increases with increasing altitude and with increasing interval between observations in time. The correction must be worked out on the observed altitudes. At about 45 degrees the sun's semidiameter subtends a horizontal angle which increases or decreases nearly a minute with every interval of two minutes of time.

A clear conception of the effect of altitude can be obtained by imagining the transit set up at the radial center of an immense arch, the width of the arch being such that with the telescope level it subtends a horizontal angle of 32 minutes. If the leveled telescope is sighted to one edge of the arch and then slowly revolved upwards, the intersection of the cross-hairs will gradually leave the edge and travel toward the middle, to which it will point when the telescope is vertical. The horizontal reading has not altered all this time, and as a similar result is produced if the telescope is first directed to the other edge, it follows that the sun, which fitted into a space 32 minutes wide when on the horizon, would have to diminish in size as it rose in order to continue to do so, till it eventually became a mere speck at the zenith. As the sun of course does nothing of the kind, it follows that the horizontal angle subtended between its right and left limbs increases with increasing altitude.

It would be unfortunate if the respect which Mr. Underhill's opinion inspires among your readers should lead any of them to believe that doubled observations correct errors in the vertical angle due to faulty leveling of the instrument. They do not, of course, as any one can convince himself who will take the trouble to set up askew and try it. The only error in the vertical angle thus corrected is the index error of the vertical arc, and in this connection it may be useful to point out that in the plain theodolite, where the telescope reverses in the Y's, it will not even do this, unless the level of the telescope is so adjusted that the bubble remains in the center of its run when the telescope is reversed end for end. This adjustment is effected as follows: Level up the instrument in the manner described in Professor Rowe's article, lift telescope out and reverse. If the bubble moves, take any vertical angle by doubled observation to obtain the index error, which will be half the difference between the two readings. Set the vernier to this error, and with the telescope over one pair of main leveling screws bring the bubble into center by means of these. Lift out telescope and reverse, and bring the bubble back half way to center by these same screws and the remainder by the screws or nuts which attach the level tube to the telescope. If the collimation line has been previously adjusted in the manner customary with this class of instrument, that is to say, by twisting the telescope around in the Y's, this adjustment will not be thrown out. If, however, it has been adjusted by the more accurate method of sighting on to leveled pegs, it will now require altering.

As Professor Rowe says, errors in vertical arc produce an error of somewhat greater magnitude in the sun's azimuth. Errors in latitude or in declination produce their greatest effect near midday, but if of the same sign, tend to cancel each other. This is an additional reason for not trusting to observations which require the prismatic eyepiece. In doubled observations the sun should be observed in diagonally opposite quadrants if there is any doubt as to the cross-hairs being accurately at right angles to each other. Care should be taken that the horizontal cross-hair really is horizontal.

Cardiff, England R. T. Hancock

Lamp Burns in Water

Editor Mines and Minerals:

SIR:—We have a pump at the bottom of a slope which is about 5,000 feet long and delivers about 1,000 gallons per minute. The column pipe is a 10-inch pipe and it gets its water from the lower old workings. I can hold my naked lighted lamp right in the center of the discharge stream of water or I can take it right through the stream slowly and the light will continue to burn. I have held my light in the center of stream for a period of one-half minute time and it still burned. What is the cause of the lamp burning in the water? Student

Pumping

Editor Mines and Minerals:

SIR:—In answer to Wm. H. James' question on "Pumping," in the July number, I give the following solution: $400\times 60\times 24 = 576{,}000$ gallons = capacity of sump. While the sump is being emptied there is flowing into it $400 \times 60 \times 20 = 480{,}000$ gallons, or a total of 1,056,000 gallons to be pumped in 20 hours, making the capacity of the pump $\frac{1{,}056{,}000}{20} = 52{,}800$ gallons per hour, and $576{,}000 \div 52{,}800 = 10.91$ hours, nearly, say

11 hours it will take the pump to empty the sump if it is full and the supply cut off.

The dimensions of a pump to perform this amount of work will depend on the speed at which it is run, which for practical reasons should not exceed 100 feet per minute. The pump has a capacity of $52,800 \div 60 = 880$ gallons per minute. The following formula gives the diameter of the plunger and also makes allowance for slip and leakage past the glands: $5.535 \times \sqrt{\frac{800}{200}} = 11.6$ inches. But the size of the pump can be gotten by trial, thus: Assuming a common duplex steam pump, say 10 in. × 36 in., $10^2 \times 36 \times .0034 = 12.24$ gallons per stroke; $880 \div 12.24 = 72 \times 3 = 216$ feet. Making an allowance of 2 feet per minute for slip makes the speed for each piston equal $\frac{218}{2} = 109$ feet per minute, which is quite common practice. This trial gives the smallest size of plunger that should be used, as a larger size would give better results. The length of stroke is 36 inches, but the diameter of piston cannot be calculated from the question, as this depends on such factors as the vertical height to which the water has to be pumped, and the length of the discharge pipe, together with its diameter and the steam pressure carried. J. T. R.

Editor Mines and Minerals:

SIR:—I would offer the following in reply to Mr. Wm. H. James' question in the July issue of MINES AND MINERALS. The mine makes 400 gallons of water per minute, or $400 \times 60 \times 24 = 576,000$ gallons per day of 24 hours. The pump can empty the sump in 20 hours, $576,000 \div (20 \times 60) = 480$, hence, it delivers 480 gallons per minute. If the supply is cut off the pump can empty the sump, which is full, in 10 hours 54.54 minutes, for the pump can handle 480 gallons per minute, and the supply being 400 gallons per minute, taken together, will equal 880 gallons per minute, or $576,000 \div 880 = 654.54$ minutes or 10 hours 54.54 minutes. A double-action pump with 12-inch diameter plunger and 24-inch stroke making 50 strokes per minute would be able, theoretically, to handle 587 gallons per minute, therefore, a pump of the above dimensions should be sufficient to take care of 480 gallons per minute. E. W. BAILEY

Montcalm, W. Va.

MEETINGS OF INSTITUTES

MINE INSPECTORS' INSTITUTE

The second annual meeting of the Mine Inspectors' Institute of the United States of America, was held in Chicago, June 13–17, inclusive. A meeting of the Executive Board was held Monday, June 13, and by the evening of that day, delegates representing nearly every coal-mining state had registered. The local Committee of Arrangements consisted of the following inspectors, representing the full board of Illinois inspectors: James Taylor, of Peoria, chairman; Thomas Moses, of Westville, secretary; and John Dunlop, of Peoria, treasurer.

Tuesday, June 14, the Institute was called to order at 9.30 A. M. by President Geo. Harrison, of Ohio. The address of welcome on the part of the state of Illinois was given by Mr. David Ross, Chief of the Illinois Bureau of Labor Statistics. Corporation Council Bagby, of Chicago, extended to the Institute the welcome of the city of Chicago. To these addresses Mr. Harrison responded and then delivered his presidential address. Following this, came the appointment of the following committees.

Membership: Messrs. Epperson, of Indiana; Dunlop, of Illinois; Rhys, of Iowa. Executive Business: Messrs. Adams, of Pennsylvania; McDermott, of Montana; Hanraty, of Oklahoma. Constitution: Messrs. Moses, of Illinois; Grady, of West Virginia; Neill, of Alabama. Resolutions: Messrs. McDonald, of Ohio; Johnson, of Pennsylvania; Botting, of Washington.

The afternoon session of Tuesday was devoted to the reports of the secretary and treasurer, and to addresses by Mr. John H. Walker, President of the United Mine Workers of Illinois, and Mr. A. J. Moorshead, President of the Illinois Coal Operators' Association. A very lively discussion took place as to the advisability of endorsing some one for the head of the Bureau of Mines recently created under the Interior Department, but it was voted not to do so.

In the evening of Tuesday, a banquet and smoker was given at the Grand Pacific Hotel.

Wednesday afternoon was devoted to an automobile ride about the city of Chicago. In the evening a banquet was given at the Chicago Automobile Club, the host being Mr. W. W. Taylor, General Superintendent of the St. Paul Coal Co. After this banquet, the following papers and addresses were given: Discussion of the report upon uniformity of mine statistics; "Timbering in Metal Mines," by F. Cushing Moore, State Mine Inspector, Boise, Idaho; "Tests With Explosives in the Field," by Clarence Hall, Pittsburg, Pa.; an address by Mr. John Mitchell.

The program of Thursday was as follows: Address by Mr. G. A. Traer, of Chicago; "What Mine Inspectors Should Not Do," by Hon. David Ross, Springfield, Ill.; "Mine Ventilation," by J. B. McDermott, State Coal Mine Inspector, Helena, Montana; "The Ventilation of Safety Lamps," by E. A. Hailwood, Morely, England; "Mine Explosives," the general discussion being led by Mr. John Verner, of the state of Iowa. In the afternoon: "The Education of Mine Employes," by H. H. Stoek, Professor of Mining Engineering, University of Illinois; "Mine Fires," with general discussion, led by T. K. Adams, Mine Inspector, Mercer, Pa.; "Mine-Rescue Apparatus and Its Use by the Urbana Station, Illinois," by R. Y. Williams, Mining Engineer, Urbana, Ill. Evening—visit to Sans Souci Park. On account of the limited time and the absence of the writers, the reading of several of these papers was omitted and the papers ordered printed.

The closing meeting of Friday morning was devoted largely to business. The Committee on Constitution reported an amendment striking out Section 4. This section read as follows: "And such other professionals as majority of the members of the institute legalize as members for the best interest and advancement of the undertakings of the Institute." The constitution was also changed so that hereafter no officer excepting the secretary can succeed himself in office. Charleston, W. Va., was chosen as the place of meeting for the next annual meeting and the following officers were elected for the ensuing year: President, George Harrison, Chief Inspector Mines, Columbus, Ohio; First Vice-President, Thomas Moses, District State Mine Inspector, Westville, Ill.; Second Vice-President, John Verner, District State Mine Inspector, Charlton, Iowa; Third Vice-President, Robert Irving, District State Mine Inspector, Cayuga, Indiana; Treasurer, Thomas Hudson, District State Mine Inspector, Galva, Ill.; Secretary, James W. Paul, Mining Engineer, Pittsburg Pa.; Assistant Secretary, P. A. Grady, District Mine Inspector, Huntington, West Virginia.

COAL MINING INSTITUTE OF AMERICA

The summer meeting of the Coal Mining Institute of America, was held at Uniontown, Pa., June 28–29, by invitation of the Independent Coke Producers' Association. This meeting was probably the most successful in the history of the Institute, not only in point of numbers, broadness and variety of papers read, but in other matters of interest. President H. H. Stoek delivered an address on "Coal Mining in Illinois." The new constitution and by-laws were discussed and adopted after slight revision. Mine Inspector Thomas K. Adams read a paper on "Mine Fires and Their Prevention," in which he urged carefulness on the part of mine manager and mine boss.

An interesting paper was then read by Sion B. Smith, Esq. of Pittsburg, on the "Legal Responsibilities of Employers and Employes," in which he stated that with no indemnity fund for the injured, they or their families become local or state charges, and increase the taxes of those not especially interested in the mining of coal or making of coke. He suggested a provident savings fund based on wages of men, and a like sum by the company. Mr. F. C. Keighley was toastmaster at the lunch given at the Country Club. Dr. Peter Roberts, secretary of the Y. M. C. A., New York City, described his method of teaching foreigners English. His speech is given elsewhere, although it requires Doctor Roberts' personality to make it fully effective.

Professor Stoek said there had been an awakening in recent years on the scientific phases of coal mining. Prof. W. R. Crane, of Pennsylvania State College, spoke along educational lines. J. W. Paul, among other things said mine-rescue stations would be established in various parts of the United States within the next year. Editors H. P. Snyder and John O'Donnell, spoke briefly, then followed E. B. Day and J. B. Johnston of the *Coal and Coke Operator*. Doctor Johnston spoke on coke waste and made interesting references to the historical side of mining. Attorney James R. Cray, of Uniontown, spoke of the developments in the coke industry about Uniontown during his recollection.

On Wednesday morning the following papers were read: "Mine Layouts," by W. E. Fohl, Pittsburg. His proposed plan of shaft bottom caused some discussion, and will be continued later. W. M. Judd, a member of the engineering firm of W. G. Wilkins Co., Pittsburg, presented a paper on "Mining Towns and Mining Houses." H. N. Fitch, Breta, W. Va., read a paper on "The Systematic Handling, Disbursement, and Accounting of Mine Supplies." Wednesday afternoon a trip was made to the Continental Coke Plant No. 1, of the H. C. Frick Coke Co. The Institute was the guest of the officials of the company, who explained the most modernly equipped coking plant in the Connellsville region, and then took those who cared to go into the dark hole. The next meeting of the Institute will be held in December in Pittsburg.

HAULAGE-ROPE STRAINS

There is probably no greater strain placed upon a haulage rope than that which it is subjected to when starting a heavy load on a steep gradient in a reckless manner. When starting under such circumstances the rope is subject to such a tensional shock that the strands soon become broken, and much expense is then incurred in keeping the rope in repair. The life of the rope is also shortened, a new rope often being required.

To remedy this the rope should be started slowly, and the full pressure not put upon the engines suddenly.

In main- and tail-rope haulage the "shunts" or "stations" should not be made in that part of the road where the gradient is heaviest, but in a less gradient than any other part of the road, so that the load may be taken gradually.

Another common cause of great strains being placed upon haulage ropes, especially in endless-rope haulage, is that of allowing cars to leave the rails, owing to poor tracks. The cars in such cases either travel some distance over the ties or get fast in the timbers at the sides, or collide with the cars traveling in the opposite direction, before it is ascertained that they are off the rails; this subjects the rope to jerks that often prove disastrous to the life of the rope. Another method of straining ropes is to use pulleys, around which the rope has to pass, too small for the size of the rope. The following rules, if carried out, will greatly minimize the strains on haulage ropes, and lengthen the life of the rope:

1. Avoid jerking at starting, or when the engine cannot overcome the load. 2. Have all haulage roads kept in good condition, as upon the tracks depends the amount of strain to which the rope will be subjected and also the amount of output; badly laid tracks are detrimental to a large output. 3. In endless-rope haulage have **V** plates fixed in the roads at short distances apart, so that the cars will not travel far when off the rails. 4. Have pulleys large enough to insure a good turn being given to the rope. 5. Never run an endless rope empty, but keep a load upon it, if possible; this may not always be practicable. 6. Have engine powerful enough to move the load at any time

A NEW TRANSPORTATION SYSTEM

The Automatic Transportation Co., of Buffalo, N. Y., will soon complete the erection of their new system of transportation at Blossburg, Pa., which will be used to transport the output of several mines from the mountain side to the railroad. This transportation line is the first of its kind to be constructed in the state of Pennsylvania.

A new principle in the application of electricity to transportation of coal and ore from mines to railroad or smelters is successfully applied.

The system consists of parallel steel rails elevated from the ground on **Y**-shaped iron posts at a height of from 4 to 30 feet above the surface, as conditions require. The motored cars and carriers operate automatically on these rails at any

Motored Car and Track

desired rate of speed from 5 to 30 miles an hour. The motored cars haul several trailers. The standard gauge is 30 inches.

One of the important points of superiority that this means of transportation possesses is that it may be constructed over the roughest character of country where the problems confronting railroad building make the cost prohibitive. Its operation may be maintained at a minimum expense, and the line can be kept open under all weather conditions.

The ore cars with trailers convey the products of the mines at a high rate of speed, direct to bins or smelters, automatically dumping their loads, reversing and returning immediately to the starting point. The carriers have a capacity of several tons and will climb exceedingly heavy grades.

The important point wherein this system differs from all others in the adaptation of electricity to the problems of transportation is the fact that the carriers take the current into the motors direct from the rails upon which they travel, thus doing away with the third rail and the overhead trolley; another most important point is that all of the operations of transportation are accomplished automatically with the greatest exactness.

The company is closing several important contracts which include the moving of various ores as well as the products of coal mines. The headquarters of the Automatic Transportation Co. are at 2933 Main Street, Buffalo, N. Y., where an extensive factory has been erected. The officers of the concern are William C. Carr, the inventor of this system, president; Joel H. Prescott, secretary and treasurer.

THE MULGA MINE EXPLOSION

Written for Mines and Minerals

On April 20, 1910, an explosion occurred at the Mulga coal mine near Birmingham, Ala., in which 39 lives were lost.

Conditions Existing in the Mine. Probable Cause of the Explosion

Mulga is 12 miles west from Birmingham, on the Ensley Southern Railroad, and the mine is operated by the Birmingham Coal and Iron Co., a corporation which believes in protecting the lives of its employes by systematic work and modern methods. There are two timbered shafts, 720 feet deep, 385 feet apart and cutting two coal beds, the Pratt at 220 feet depth and the Mary Lee at 720 feet, although the latter was not being operated, the top bed only being worked. The shafts are equipped with structural-steel head-frames and double-decked cages. Electric haulage is used in the mine, which has been in operation about two years. The mine is ventilated by a Clifford fan, which at low speed produces 50,000 cubic feet of air per minute. About 10 per cent. of the intake air came through No. 1 shaft, and 90 per cent. through No. 2 shaft. According to Mr. James Hillhouse, Chief Inspector of Mines in Alabama, the mine is worked in two shifts, permissible explosives only are used, the mine being somewhat gassy, and a sprinkling system is installed, to keep down the dust.

The mine was badly wrecked by the explosion which, according to accounts, shot heavy objects out of the shaft high in the air. The cages in No. 1 shaft were wrenched from their guides and could not be used for some time. The cage in No. 2 shaft was at the bottom of the shaft at the time of the explosion, and was so fastened down that it could not be pulled up. The accident occurred at 9.10 P. M. and the fan was put in operation at 11.20 P. M., thus showing it was little damaged.

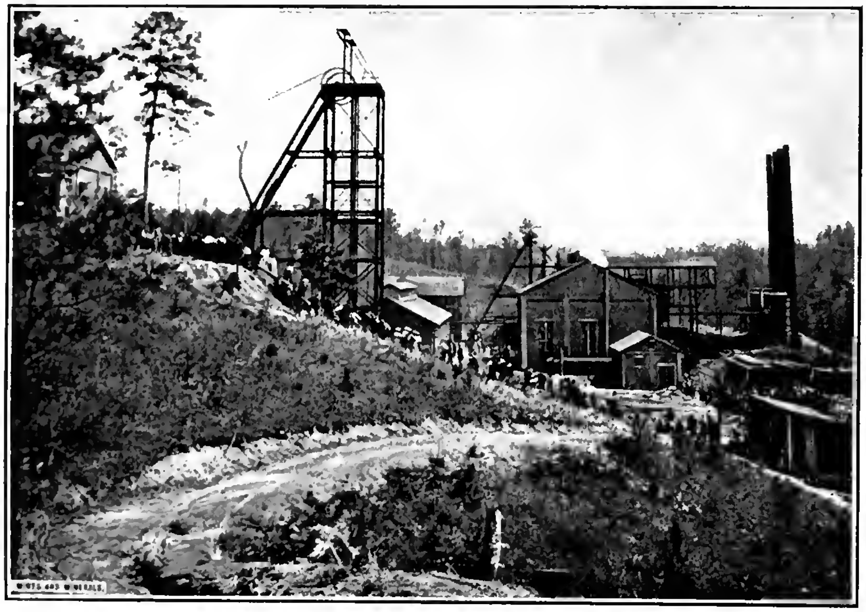

FIG. 1. MULGA MINE

When General Superintendent Hastings reached the shaft after the accident he found a natural air-current going in No. 1 shaft sufficiently strong to flatten out the flame of a driver's lamp, on all sides of the shaft. Immense volumes of smoke were coming from No. 2 shaft, and continued until 7 A. M. the next morning. The smoke smelled of fire and led the manager to believe that if there was fire it was close to No. 2 shaft, and this reasoning was given further weight by the reversal of the air-current from shaft No. 1 to No. 2.

The manager believed, and his belief was later substantiated, that the negroes would from impulse try to reach the shaft through which they entered the mine, and if any of the men reached No. 1 shaft between the time of the explosion and the time when the fan began to operate it would have been death to all had No. 1 shaft been made the upcast.

Arriving at this decision, which was perfectly sound under the premises, and bearing in mind that explosions travel towards the intake, the fan was reversed when repaired and No. 2 shaft made the upcast. Two hours after the explosion, Mr. Johns, the mine foreman, accompanied by another man, went down No. 1 shaft in a bucket and explored for 700 or 800 feet, east, west, north, and south of the shaft without helmets. They then went to No. 2 shaft, and released the cage which was fastened by some timbers that were driven in by the explosion. This occurred about 5 A. M. and Mr. Johns realized that by this time all those that were in the mine when the disaster occurred were dead. By this time assistance had arrived from the Pratt mines, Ensley, Wylam, and Blossburg and all other mines in the vicinity of Mulga. An advance guard with safety lamps and a relief party of 6 or 8 men was organized who went in seach of the dead.

The plan advised by the inspectors was to turn all air into each heading separately and explore them separately. This plan was carried out by cloth brattices carried to the face of each entry. These relief parties worked in alternate shifts of two hours, until they had aggregated 6 hours out of 12 when they were relieved. The position of the bodies represented by the crosses on the map, Fig. 2, would indicate that the men attempted to retreat from the afterdamp or were killed immediately by the concussion. On account of the mine being well ventilated considerable damage was done inside the mine and bodies that were not burned, were badly mutilated. The last of the bodies was removed Sunday evening, April 24, four days after the explosion.

On Monday, April 25, four days after the explosion and after all bodies had been removed, Chief Mine Inspector J. J. Hillhouse and his assistant Robert Neill, accompanied by J. J. Rutledge of the United States Geological Survey, entered the mine for the purpose of ascertaining the cause of the explosion. They attempted to locate a windy shot, but were unable to do so as all coal was found undermined, and the shot firer was found where no mining was going on. Portions of two boxes of permissible explosives with the 15 sand dummies used for tamping were found intact. Firing was done in this mine by connecting the detonator wires with the electric trolley wires, and no indications that this had been done could be found. At the time of the explosion two coal cutting machines were at work undermining and men were engaged in loading the "buck dust" or cutter chips from the machines. This was done daily and, as a further protection against dust explosion, sprinklers were used.

The inspectors having satisfied themselves that the cause of the explosion was not a "windy shot," next turned their attention to the gas. They found some at the extreme points of operation, but the accumulation may have taken place after all the brattices had been blown out by the force of the explosion.

Mr. Hillhouse states that the explosion seemed to have greatest force in locations known to be free from gas and dust, and that ponds of water standing in several places were covered with a solid crust of dust. He gives it as his opinion that a

small body of gas was ignited in some part of the mine, and the flame traveled until it met the dust from the machines, which was suspended in the mine atmosphere, and igniting this increased the force of the explosion. Morgan Johns who was night fire boss and shot firer at Mulga reported at 6:30 p. m., three hours before the explosion, that he found some gas in four headings, but that he left all working places free from gas. He then returned to the mine and was found dead on a haulage heading, showing that no shots had been fired by him at 9:15, the time the explosion occurred. The report sent to Northern newspapers that the government officials were in charge of the mine was wrong, the Alabama State Mine Inspectors were in charge until after the mine was cleaned up and their reports made.

Mulga was a modern mine and a model one. Mine Inspector Neill made an investigation two days before the explosion occurred and found matters satisfactory.

Mulga No. 1 shaft is 15 ft. × 26 ft. in size over all and is divided into three compartments, the north compartment being the upcast air shaft. The other two compartments are used for hoisting coal. The air compartment is 8 ft. 4 in. × 13 ft. 8 in., and the hoisting compartments are 7 ft. 4 in. × 13 ft. 8 in. inside dimensions. Double-decked steel cages are used in the hoisting compartment, the upper deck carrying the loaded car of coal, and the lower deck returning the empty car to the line. No. 2 shaft is similar to No. 1, except the over all dimensions are 13 ft. × 26 ft., instead of 15 ft. × 26 ft. The north compartment at No. 2 shaft is the intake or downcast for the ventilation current. The tipple is equipped with a Heyl-Patterson rotary dump and an endless-belt picking table of steel, together with the necessary coal and rock chutes, etc. No. 2 shaft has a steel head frame and steel cages similar to No. 1 shaft, but no tipple and is used only for ventilation and to hoist men. East of each shaft is located a hoist house, 50 feet square, built of brick with concrete foundations and floors, and structural steel roof trusses. Each hoist house contains two first-motion Vulcan hoisting engines with cylinders 26 in. × 42 in., with coned winding drums having a capacity of 800 feet of 1½-inch wire cable.

The fan house near No. 1 shaft is constructed of brick and concrete. The fan way is built of concrete and connects with the air shaft below the surface of the ground. The top of the air compartment of the shaft is covered with an explosion door. The fan is 15 feet in diameter and driven by a 250-horsepower (230 volts) General Electric motor. There is also an 18″×24″ 155-horsepower engine to drive the fan in emergencies.

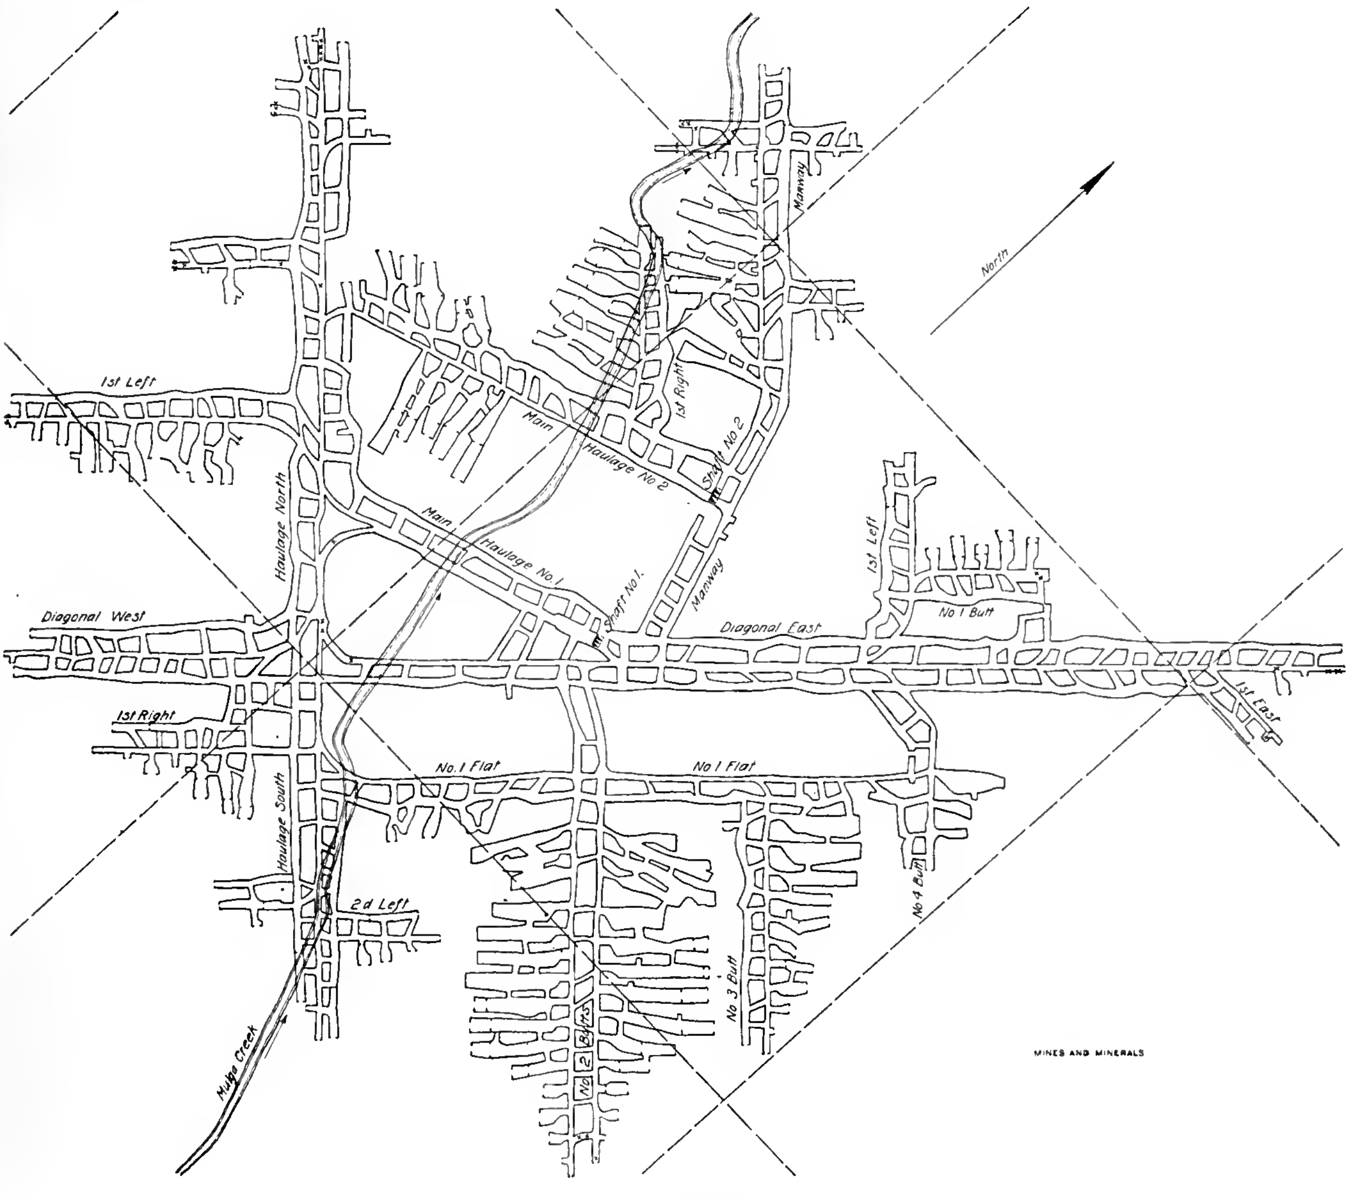

Fig. 2. Map of Mulga Mine

MECHANICAL STOKERS AND HAND FIRING

Results of Tests on Manning Boilers With Taylor Underfeed Stoker and Hand Firing

There has been much written and tabulated on fuel tests, but seldom are comparative tests between stokers and hand firing made and tabulated. It is well known that under certain conditions mechanical stokers are preferable to and more economical than hand firing, but just how much more economical is a question that can only be determined by actual tests. There have been instances where mechanical stokers have been discarded and hand firing substituted, the latter being more economical owing to the kind of coal used for steam raising. There have been cases where preference was given to underfeed rather than overfeed stokers, after the latter had been fully tested. Most engineers and coal consumers are familiar with the underfeed type of mechanical stoker, with its automatic rams, also with the overfeed stoker with its rocking grate and again with the moving chain grate stoker, each type having distinguishing names; it is assumed in this synopsis of comparative tests that the reader is familiar with the constructive details of the ordinary forms of mechanical stokers. The comparative tests were made at the Nashua Mfg. Co., Nashua, N. H. Robert Amory, Jr made the tests, using four boilers, and his results are tabulated below:

Principal conditions governing the trial. Ordinary running conditions of plant with average firing load on at 6 A. M., and off at 6 P. M., pumps, blowers, and stoker feed stopped from 12 to 12:50 P. M.

Stoker Test

Kind of fuel........George's Creek, Cumberland, Jackson Co.
Kind of boiler....Standard "Manning" type mounted on brick setting, fitted with one two-retort Taylor Gravity Underfeed Stoker and forced draft
State of weather..............Cloudy at first, clearing later
Method used in test...Alternate method A. S. M. E. Code 1899
Date of trial... ....November 29, 1906
Duration of trial.........7 A. M. to 6 P. M., 11 hours (figured on basis 10.2 hours, standby losses included)
Stoking surface.. ....Width 3 ft. 10 in.; length, 6 ft., 0 in. Area, 23 00 sq. ft.
Height of furnace..............................7 ft. 8½ in.
Approximate air spaces (stoker)...................136 sq. in.
Ratio of stoking surface to air opening..................24.36
Water-heating surface.......................1,300.17 sq. ft.
Superheating surface..........................453.43 sq. ft.
Ratio of water-heating surface to grate surface...........56.5
Ratio of stoking surface to minimum draft area.........4.68

Hand Fire Test

Kind of fuel..........George's Creek, Cumberland, Jackson Co.
Kind of furnace.......Regular circular water leg Manning type
State of weather........Overcast and damp in morning, later clear and cold
Method used in test..Alternate method A. S. M. E. Code 1899
Date of trial............................December 7, 1906
Duration of trial................7 A. M. to 6 P. M., 11 hours (figured on basis 10.2 hours, standby losses included)
Grate surface.....width circular length...area...28.27 sq. ft.
Height of furnace ....4.76 in.
Water-heating surface...................... 1,300.17 sq. ft.
Superheating surface,.........................453.43 sq. ft.
Ratio of water-heating surface to grate surface.......45.9 : 1
Ratio of minimum draft area to grate surface........1 : 5.48.

Average Pressures

	Stoker Test	Hand Firing
Steam pressure by gauge, pounds	113.06	110.05
Force of draft between damper and boiler, inches of water	.25	.39
Force of, or blast in ash pit, inches of water	2 00	

Average Temperatures

	Stoker Test	Hand Firing
Of external air, degrees F.............	39.0	21.5
Of fireroom, degrees F...............	73.4	67.5
Of steam, degrees F..................	386.7	365.6
Of feedwater entering boiler, degrees F..	104.7	101.0
Of escaping gases from boiler, degrees F	468.7	480.5

Fuel

	Stoker Test	Hand Firing
Size and condition....................	Run of mine good condition	Run of mine good condition
Weight of coal as fired, pounds.........	20,483	21,492
Percentage of moisture in coal, per cent.	2.60	2.60
Total weight of dry coal consumed, pounds..........................	19,950	20,933
Total ash and refuse..................	1,541	1,102
Quality of ash and refuse..............	Soft and clean	Light and full of coke
Total combustible consumed, pounds....	18,409	19,831

Proximate Analysis of Coal

	Stoker Test	Hand Firing
Fixed carbon, per cent.................	78.00	78.00
Volatile matter.......................	13.28	13.28
Moisture.............................	1.00	1.00
Ash..................................	7.72	7.72

Fuel Per Hour Per Boiler

	Stoker Test	Hand Firing
Dry coal consumed per hour, pounds....	489.000	527.000
Combustible consumed per hour, pounds	451.000	486.000
Dry coal per square foot of grate surface per hour, pounds..................	21.260	18.640
Combustible per square foot of water heating surface per hour, pounds.....	.347	.374

Calorific Value of Fuel

	Stoker Test	Hand Firing
Calorific value by oxygen calorimeter per pound of dry coal, B. T. U...........	14,790	14,790

Quality of Steam

	Stoker Test	Hand Firing
Percentage of moisture in steam.......	None	None
Number of degrees in superheating, degrees F.........................	40.9	21.4

Water

	Stoker Test	Hand Firing
Total weight of water fed to boiler, pounds	198.895	180.233
Equivalent water fed to boiler from and at 212 degrees (K 1.154), pounds.....	229.580	(K1.158) 208.660
Water actually evaporated, corrected for gauge level, pounds.................	199.141	180.012
Factor of evaporation.................	1.178	1.169
Equivalent water evaporated into dry steam from and at 212 degrees, pounds	234.447	210.548

Water Per Hour

	Stoker Test	Hand Firing
Water evaporated per hour corrected for quality of steam, pounds	19.500	17.760
Equivalent evaporation per hour from and at 212 degrees, pounds	22.984	20.642
Equivalent evaporation per hour from and at 212 degrees per square foot of total heating surface, pounds	3.250	2.960

Horsepower Per Boiler

	Stoker Test	Hand Firing
Horsepower developed, (34½ pounds of water evaporated per hour into dry steam from and at 212 degrees, equals 1 horsepower)	166.5	149.6
Builder's rated horsepower	150.0	150.0
Percentage of builder's rated horsepower developed, per cent	111.0	99.8

Economic Results

	Stoker Test	Hand Firing
Water apparently evaporated under actual conditions per pound of coal as fired, pounds	9.71	8.37
Equivalent evaporation from and at 212 degrees per pound of coal as fired, pounds	11.45	9.81
Equivalent evaporation from and at 212 degrees per pound of dry coal, pounds	11.75	10.06
Equivalent evaporation from and at 212 degrees per pound of combustible, pounds	12.73	10.62

Analysis of Dry Gases

	Stoker Test	Hand Firing
Carbon dioxide (CO_2)	8.86	8.10
Oxygen (O)	11.08	12.12
Carbon monoxide (CO)		1.39
Hydrogen and hydrocarbons } Nitrogen (by differences) (N)	80.06	78.39
	100.00	100.00

Calculations From Gas Analysis

	Stoker Test	Hand Firing
Pounds air per pound of combustible, pounds	22.01	21.1
Pounds air per pound of carbon, pounds	26.05	25.6
Dilution per cent. (excess air) per cent	125.50	122.0

Heat Balance

	Stoker Test	Hand Firing
Heat absorbed by water, per cent	76.74	65.68
Heat lost in flue gases, per cent	14.02	13.30
Heat lost by incomplete combustion { on grate / by CO		10.72
Heat lost by evaporation of moisture in coal	.715	.715
Radiation, conduction and unconsumed hydrogen in flue gases	8.52	9.58
	100.00	100.00

Stokers and Fan Blower

	Stoker Test	Hand Firing
Steam used per pound of steam evaporated by boilers per cent. (assumed from Quincy Point). (Test probably too high) per cent	3.2	

The increase in economy of the Taylor stoker plant as compared with the hand-fired plant is 16.84 per cent.

If anything, this figure should be increased, as the hand-firing tests fires were very dirty at the end, as shown by the light ash; there was about 250 pounds of ash in each fire at the end.

CHARGING BLASTING HOLES

Written for Mines and Minerals

The use and abuse of explosives is attracting as much, if not more, attention than any one subject now being considered by mining men, whether considered from the standpoint of the miner or the operator. Elaborate and costly experimental plants have been installed within a few years, by the manufacturers of explosives and by the United States Geological Survey at the Pittsburg Testing Station, to determine the properties of the common explosives used in mining and to demonstrate the proper method of using them. The charging and tamping of the holes drilled to break down coal or rock in a mine are matters of interest and importance, but too often these operations are poorly done, due to negligence, carelessness, or inexperience. It is impossible to see inside a drill hole that has been charged, to determine if the fuse has broken or kinked, the cap pulled out of the cartridge, or to discover other possible accidents that will occur to every practical man. In order to enable the students in mining engineering at the University of Illinois to practice charging holes and then have the charge inspected and criticized, a charging box or "artificial hole" has been built. This is shown in the accompanying illustration and consists of a block of timber 8 inches square and 4 feet 6 inches long, with a hole 2 inches in diameter bored in the center. This block is sawed through the center, hinged and held firmly by clamps while the hole is being charged. It is then opened and the charge easily inspected. By varnishing and greasing the hole, the tamping is prevented from sticking to the wood when the top is raised.

Apparatus to Demonstrate Loading of Holes

The "hole" is set on wooden horses and by raising one horse a hole inclined upward or downward can be obtained. Students are required to charge the hole, using different kinds of tamping, different explosives, and all of the ways of firing by squib, fuse, and electric detonators. Sand or sawdust is used to represent black powder and dummy cartridges of inexplosive dope to represent the nitroglycerine explosives. The charge is examined and criticized by the class and by the instructor.

An experienced miner and former mine manager who was showing a class of students how to load the hole was very much surprised to find upon opening the box that the fuse was kinked into an S shape and broken.

By the use of this box, the effect of using different kinds of tamping can be easily shown, the rate of burning of fuse in a hole can be tested and other experiments with explosives demonstrated much better than in the darkness of a mine where the inside of the charged hole cannot be seen.

A glass tube was first thought of, but the glass breaks readily, is hard to clean from the tamping for another charge, and moreover, as the inside can be seen during the tamping, the actual conditions are not represented nearly as well as with the block.

The blasting box or "hole," which can be easily made and is inexpensive, is adapted for demonstrating to inexperienced men at a mine the proper method of charging. It can also be used for demonstration purposes before mining institutes, etc.

USE CARE IN THE PURCHASE OF BRATTICE CLOTH

Brattice cloth is a comparatively inexpensive item of mine equipment, and as a rule the quantity, weight, and quality furnished by purchasers who buy from sample is not carefully looked into.

Our attention has recently been called to an instance wherein the purchaser of a quantity of brattice cloth, which was quoted at an abnormally low price, preserved the sample sent him. When his order was filled he compared the cloth received with the sample and found that it was of lighter weight, and on measurement the shipment was found to be of less yardage than was charged.

Naturally, no responsible business house will be guilty of such practices, but all sellers of mine equipment are not responsible. Reputable houses, such as those who advertise in Mines and Minerals, welcome the most rigid inspection of the brattice cloth they furnish. It is a rigid rule with Mines and Minerals to deal only with reputable concerns and the utmost care is used before accepting advertisements. This rule has been so well enforced that during the past 20 years there have been but three advertisements thrown out of our columns on account of methods of business that were not strictly honest. Two of these three were doing a legitimate business when their advertisements were first secured, but the third was purely dishonest from the start. The latter, however, did not fool our management only. The advertisement appeared for months in the columns of several mining journals after Mines and Minerals and one other reputable publication threw the advertisement out, and published an expose of the methods of the parties advertising.

EVOLUTION OF MINE HAULAGE

Written for Mines and Minerals, by E. B. W.

(Continued from July)

Different Systems of Endless and Tail-Rope Haulage. Aerial Tramways. Cableways

From primitive methods of mineral transportation, described in the June issue of Mines and Minerals, to the rope haulage described in this article, some years have intervened. Just the year wire-rope haulage was introduced is not known to the writer but he assumes it was between 1870 and 1880. However, since its introduction it has proved both economical and satisfactory and there are conditions where it cannot be replaced to advantage. Some 30 years ago the North of England Institute of Mining Engineers had an excellent paper on underground haulage and from this the assumption is that it was first introduced in that country.

Fig. 38. Endless-Rope Haulage

The two most generally adopted systems are known as the endless-rope and main-and-tail-rope systems, and in coal mines which have low entries and in coal mines which are fiery, these systems offer advantages that other systems of haulage lack.

The endless-rope system, as its name suggests, uses an endless rope which is kept running continuously in one direction by a pair of drums geared together and set tandem. The drums, which are comparatively narrow, are provided with grooves in which the rope runs in its traveling on and off. Two drums are necessary to supply sufficient frictional grip to drive the rope when the trip is attached, and, further, a tension wheel in the rear of the drums is required to take up slack due to the stretching of the rope. The rope winds around the drums several times, then half around the tension wheel (which is weighted and movable back and forth as occasion demands) and then back to the drums and off. To use this system to the best advantage a double track is essential, also a grade which is fairly uniform and in one direction, although with the top grip illustrated in Fig. 38 this is not absolutely necessary.

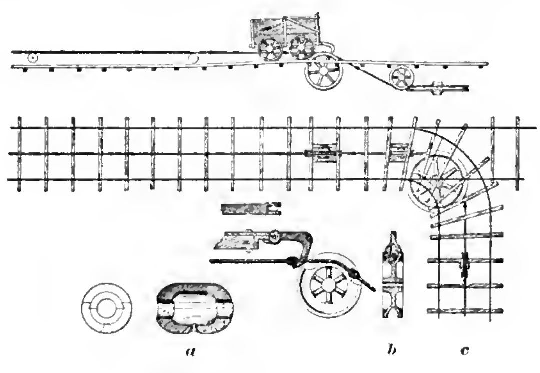

Fig. 39

Where cars are hitched to ropes traveling underneath them, the grips are clamps, which move with the rope. On down grades the clamp holds back the car with a jerk, and on reverse or up grade the car gives another jerk on the rope, thus injuring the rope, particularly where several cars are coupled together. If the trips could be spaced at regular intervals so that the load on the haulage engine could be uniform, this system would be ideal, but owing to the delays in gathering cars and the irregularity in unloading, this is not possible. It is possible to work cross-entries by the endless-rope system as well as main entries if sheave wheels and gearing are arranged for the purpose.

The horsepower required for an endless-rope system may be calculated from the formula

$$\text{H. P.} = \frac{l}{u\,33000}\left[o\left(1+\frac{2\,W_1}{c}\right)+2WV\right]$$

In this formula l = length of haul; V = speed of rope per minute; o = output of mineral per minute; W_1 = weight of empty cars; c = capacity of car in pounds; W = weight of rope in pounds per foot; $u = \frac{1}{40}$ of the total weight to be moved = tension. The horsepower found by the above formula should be doubled to allow for extra pull in case of stoppage.

The Gunckel endless-rope system of haulage consists of an endless-wire rope with hollow, oval, steel knobs a, Fig. 39, attached at intervals. An iron rivet is driven through the rope and knob, after which the hollow is filled with Babbit metal to prevent the ball from slipping. The grip used is shown at b, while at c is shown the means adopted to carry the rope under the track and around a sheave at curves.

One of the difficulties of endless-rope haulage is overcome by placing the rope above the cars. When this system is practiced the cars do not need to be run in trips, and as the cars and rope move slowly there is a minimum of wear and tear. The "grip" for cars being hauled by this overhead system is shown attached to the front of a car in Fig. 40. The empty cars are taken off by simply raising the rope and placing it in a pulley overhead, and as the cars approach this point the rope gradually lifts out of the grab. Where there is any unevenness in the road so that sheaves must be

used to keep the rope from the roof, the plan shown in Fig. 41 was found to overcome the difficulty at the DeBeers Diamond Mine, in South Africa. The two sheave wheels are fixed with hardwood bearings on the ends of two angle irons, which are pivoted on a center shaft of the wooden frame like a balance.

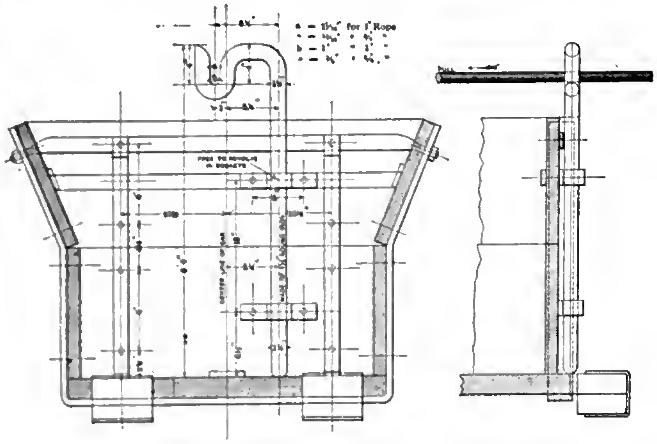

Fig. 40. Grip for Endless Rope

The grip on taking the first wheel lifts it up and depresses the second, thus allowing the car to pass under the first one. When the car passes under the second wheel it raises that and

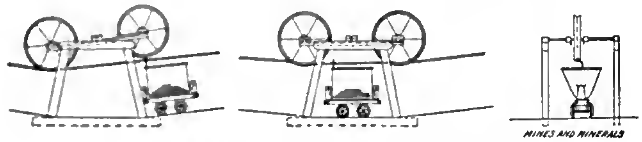

Fig. 41. Arrangement of Sheaves to Keep Rope from Roof

depresses the first wheel. The same arrangement can be used on an incline of 1 in 12 without the rope lifting from the grip.

Much has been said for and against tail-rope haulage, but even then it is preferred, because it may be installed where there are undulating grades, and where for certain reasons the

Fig. 42 Cutting off Cars from Tail-Rope

haulways cannot be continued in a straight line. In tail-rope haulage there are two winding drums on the same power shaft, but so arranged that they revolve in opposite directions. The cars are run in trips and the system may be either single or double tracked, but usually the former. The haulage or main rope is attached to the front end of a loaded trip, while the tail-rope is attached to the rear end of the trip and draws along behind as the loaded cars move to the shaft. As the trip moves either way, one rope plays from its drum while the other is wound on the drum. Fig. 42 shows a car runner cutting off a loaded trip outside the Klondyke coal mine, in Maryland. Whenever an empty trip goes into the mine the tail-rope, which passes half around a pulley at the end of the system, acts as the haulage rope for the empty cars.

On curves, or where it is desirable to carry either main rope or tail-rope across the track, a series of horizontal cast-iron guiding sheaves are used. On curves, a special arrangement such as that shown in Fig. 43 is introduced to carry the main rope. In this particular case the side pull from the main rope is resisted by a series of wooden drums, while the tail-rope is carried on the side near the roof of the mine. Various methods for making attachments to cars and for coupling ropes, when the system is used for side-entry haulage, have been devised. Various kinds of rollers, sheave wheels, and methods of placing them have been tried, so that to go into the details of this matter would be out of the province of this article. Various modifications to the system have been introduced, such as third-rail tail-rope haulage, district tail-rope haulage, etc. The horsepower for the haulage engine of a tail-rope system is found from the formula

$$\text{H. P.} = \frac{f(W_1 N + W_r)\,v}{33000}$$

In which f = the coefficient of friction = tension = $\frac{1}{40}$ the weight of the load to be moved: W_1 = weight of a loaded car in pounds; W_r = total weight of the rope in pounds; v = speed of the rope in feet per minute; and N = number of cars. The rope couplings are attached to the trip which prolongs the life of the rope, in fact it is customary to use old hoisting ropes that have been condemned, as tail-ropes and even for haulage ropes.

One of the most pronounced improvements in mine haulage is that of aerial or wire-rope tramroads, which have made it possible to work mineral deposits which were practically inaccessible. The flexibility of aerial tramways is such that they may be used for carrying supplies to the mine as well as ore from the mine. There are cases where mine cars are carried over aerial tramways and then hauled on surface roads to their destination. Mine timbers, powder, fuel, etc., are also carried from the valley up into the hills, by this means, crossing rivers, valleys, and hills in the ascent. There must be a loading station and an unloading station, and between them a system of towers to support the carrying rope. Aerial tramways are of three kinds, the Bleichert system requiring a stationary and traveling rope, and the one-rope, or Halliday, system, and the cableway. The aerial tramway operated by the Montana Coal and Coke Co. is an excellent illustration of the flexibility of the aerial tramway. For many years the coal was brought from the mines at Aldridge by means of a stream of water confined in a wooden flume lined with sheet iron.* The distance traversed was 1¾ miles with a drop of over 1,000 feet. It was decided to open two new mines and adopt the aerial tramway system of transportation, using three separate lines.

The No. 1 line is 4,000 feet in length and is operated by gravity, conveying the coal from the Newton Mine to the discharge station or coal bins at Electric, 900 feet lower in elevation. See Fig. 44.

The No. 3 line has a total length of 7,200 feet and connects the Foster Mine with the washer at Aldridge, as well as with the terminal of No. 2 line which carries the coal from the loading station, Fig. 45, 7,800 feet, dumping it into coal bins at Electric. The No. 2 line overcomes an elevation of 1,200 feet and traverses a very rough country. The loading terminal consists of a bin of about 100-ton capacity, the bottom of which is so arranged that the coal is delivered in equal quantities to the automatic loader. This loader, shown above the bucket in Fig. 45, is constructed with two pockets of about 12.5 cubic feet

* Mines and Minerals, Vol. 29, p. 531. Robert M. Magraw.

capacity, one on each side of the bucket, each delivering the coal automatically to it without stopping the line or detaching the bucket from the traction cable, although the speed is checked somewhat during the operation. The bucket, after passing around the grip wheel, engages, by means of a short shaft placed horizontally through the trolley frame, two levers which are attached to the loader. This loader is pushed along by the bucket a distance of 12 feet, during which time the gates on the loader are raised automatically, thus discharging into the bucket from both sides and ensuring an even load. The buckets have a capacity of 25 cubic feet, or 1,250 pounds of coal, and are so spaced that when one is loading another is dumping. The usual speed of the buckets is about 250 feet per minute. The No. 2 line crosses a deep gulch, the length of the span being 1,250 feet, the vertical height of the rope at the center being 300 feet. Owing to the length of No. 2 line, 7,800 feet, it was necessary to erect a tension station to break the strain on the track ropes, and to permit of greater ease in taking up the slack resulting from expansion. The two down-hill cables are anchored at this station, the two from the up-hill end being held taunt by weight boxes. Fig. 46 shows the tension station, a high tower and a hill-side tower on No. 2 line.

The tramway described is constructed on the Bleichert system, introduced into this country many years ago by the Trenton Iron Co. Patent locked wire-rope is considered to be the best for this kind of tramway, owing to the comparative smoothness of its exterior, which prevents wear both of rope and trolley wheels. The calculation for the sag in the rope between towers is somewhat complicated, but according to J. H. Janeway, Jr.,† there are but two problems in curves. The first is that of a long curve unloaded from one support on a height to another, maybe 2,000 feet or more away, but subject to a tension coefficient which will be greater than can happen in practice, to ensure the cable always remaining in the saddle. This curve is broken up by interposing intermediate supports making shorter spans, and the use of a span of 500 or 600 feet to avoid several supports. The curve will have practically the form of a parabola, the formula of which is

$$x^2 = \frac{l^4 W^2}{4(T^2 - l^2 W^2)}$$

in which x = deflection at the center or versed sine; l = one-half the span; W = the weight of the rope per foot; T = tension in rope at supports.

This formula is for curves whose supports are on the same level. For curves whose supports are on different levels Rankin's reasoning from Fig. 47 is employed. In the figure, $a\ b\ c$ is the curve of a parabola, with b the lowest point, then s is the span between two points whose coordinates are $x_1\ y_1$ and $x_2\ y_2$. From the equation of the parabola $y^2 = 2\ p\ x$ – in which $2\ p$ = parameter of the curve.

$$y_1^2 = 2\ p\ x_1 \text{ or } y_1 = \sqrt{2\ p}\sqrt{x_1} \qquad (1)$$

and

$$y_2^2 = 2\ p\ x_2 \text{ or } y_2 = \sqrt{2\ p}\sqrt{x_2} \qquad (2)$$

but $s = y_1 + y_2$ in the figure, therefore $= \sqrt{2\ p}\,(\sqrt{x_1} + \sqrt{x_2})$ or by dividing, $\sqrt{2\ p} = \frac{s}{\sqrt{x_1} + \sqrt{x_2}}$. Substituting for $\sqrt{2\ p}$ this value in equations 1 and 2

$$y_1 = s\frac{\sqrt{x_1}}{\sqrt{x_1} + \sqrt{x_2}} \text{ and } y_2 = s\frac{\sqrt{x_2}}{\sqrt{x_1} + \sqrt{x_2}}$$

Making W and T functions of each other and making the proper substitution in the formula, x or the center deflection is determined and a curve plotted from the well-known property of the parabola

$$x : x^1 = y^2 : (y^1)^2$$

† MINES AND MINERALS, Vol. 24, April, 1904, p. 423.

The supports are now located and their heights scaled and marked.

The second problem in curves is that of a long or short single span with one or more carriers on the cable. The weights of the carriers are considered as uniformly distributed loads and

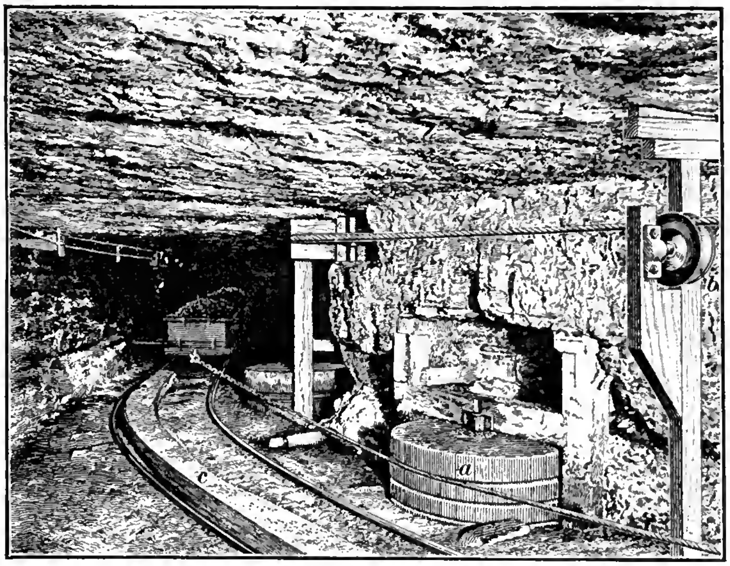

FIG. 43. HAULAGE AROUND CURVES

the solution is as before, bearing in mind that the tension for reasons stated must be less than the actual.

An approximate formula for a single center load is

$$T = 2\,\frac{l + y\ W}{\left(\sqrt{\frac{f^2}{1 + 2\ f^2}}\right)}$$

in which T is the tension of the rope at supports; l = concentrated load; f = ratio between x and y; and W = weight of the rope per foot.*

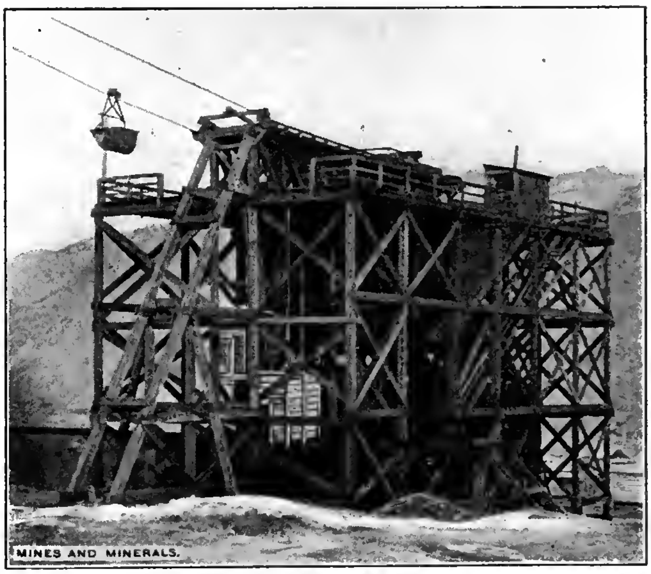

FIG. 44. LOWER DISCHARGING STATION, AERIAL TRAMWAY

The Halliday wire-rope tramway consists of one movable rope from which the buckets are suspended by goose-neck hangers. If the grades are less than 1 to 4, the box-head hangers, Fig. 48, are used, friction being sufficient to prevent slipping;

* The derivation of this formula is given in MINES AND MINERALS, Vol. 24, p. 425.

if, however, the grades are as much as 1 to 4, clamps must be used to prevent slipping. The clamp hanger is shown in Fig. 49. It has a shank *a*, strap *b*, key *c*, and bolt and nut *d*, in order to surround and take firm grip on the rope. The rope and grip travel over the tower sheave wheels, as shown in Fig. 50, which is a tower placed on an eminence. If the grade is 8 degrees or more, the system, being on the endless-rope plan, will move by gravity and necessitate grip wheels supplied with brakes at the terminals. If, however, the grade is undulating, or less than 8 degrees, this system, like the Bleichert, must be driven by power. The cost of wire-rope tramways is practically the same as ordinary surface tramways where the ground is not exceedingly rough. The cost of running a wire-rope tramway depends upon the conditions which it must surmount, and the tonnage carried daily.

An article on rope haulage would be incomplete without some reference being made to the Lidgerwood cableway. This arrangement consists of a wire-rope runway, a carriage, a car, a hoisting rope, and haulage rope. The car is loaded, hoisted to the carrying rope, where it joins the carriage, and from this point on the former fall rope becomes the haulage rope. The first installation of this system was introduced at the Tilly Foster iron mine, near Brewsters, N. Y., where 300,000 cubic yards of rock overburden was removed in order to reach the body of magnetite beneath. The appearance of the mine after the ore was uncovered is shown in Fig. 51.

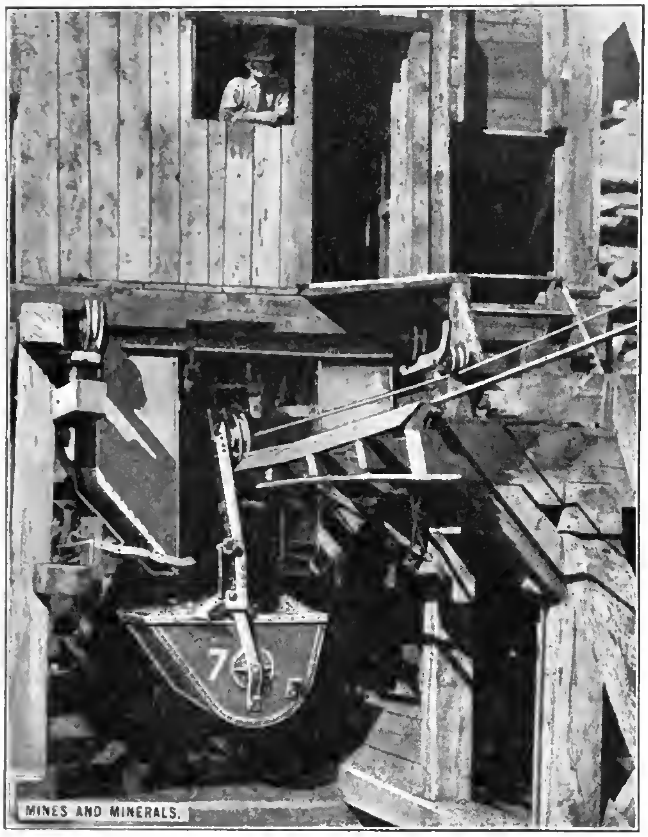

Fig. 45. Loading Station, Aerial Tramway

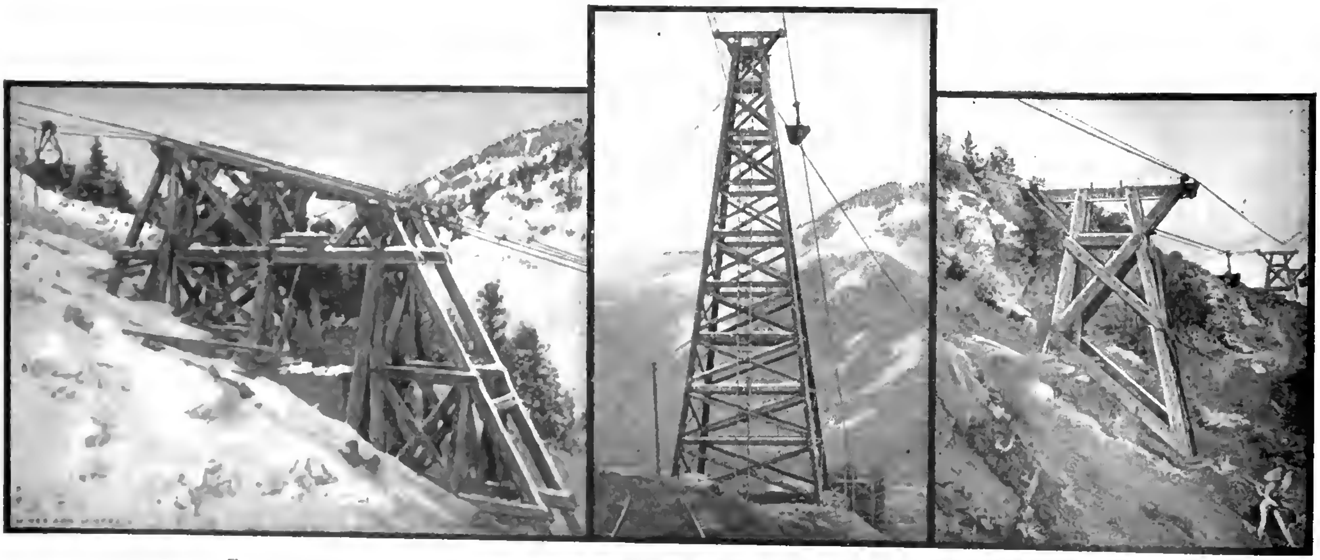
The cableway was invented by Pluchet in 1851, and 11 years later it appeared in the slate quarries in Pennsylvania,* but not with the present improvements in carriage, fall block, head towers, etc. At the Tilly Foster Mine about 600,000 tons of ore were recovered; also by this apparatus dams are constructed, ships unloaded, material transferred across rivers, placer mines worked, coal and iron ore beds stripped; in fact it may be applied to a very large number of useful purposes with economy, particularly in quarrying. The longest cableway constructed on this system had a span of 2,140 feet. It was used in the construction of a dam at Glens Falls, N. Y., and was capable of handling a load of 6 tons. Its value is increased in quarrying by its hoisting up an incline as well as carrying, which feature, in some cases, is almost a necessity.

(*To be continued*)

COAL NOTES

Coal lands are being staked between Mattagami and Missinaibi rivers, near Hudson Bay. The *Cobalt Nugget* says: "To any one but a lumber jack or an Indian it's worth all the coal concessions in the country to wallow in the muskeg around Hudson Bay and be eaten up day and night by flies. There's a fortune waiting for the man who can invent the dope that will stop a mosquito."

We would suggest the plan adopted in Cuba, for killing fleas; viz., first catch them and next put camphor on them. After they are released and attack the next person their bite is harmless.



Tension Station *High Tower* *Hillside Tower*

Fig. 46 Wire-Rope Tramway

*Spencer Miller, Mines and Minerals, Vol. 24, p. 411.

The production of both iron, and consequently coke, has increased over the boom year of 1906 about 10 per cent. The Connellsville coke region produces about 400,000 tons of coke weekly. Recent long-term coke contracts were consummated at prices around $2 per ton. When this price is compared with the recent price paid for Connellsville coal land; viz., $3,300 per acre, it seems ridiculous. The price is the highest ever paid, and figured out, makes each ton of coal in the ground worth about 30 cents, and the coal for a ton of coke worth about 50 cents.

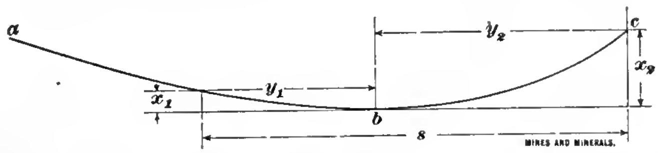


Fig. 47

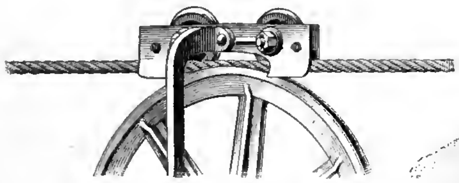

Fig. 48. Box Head for Hanger

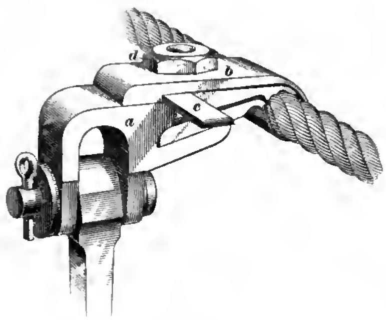

Fig. 49. Grip

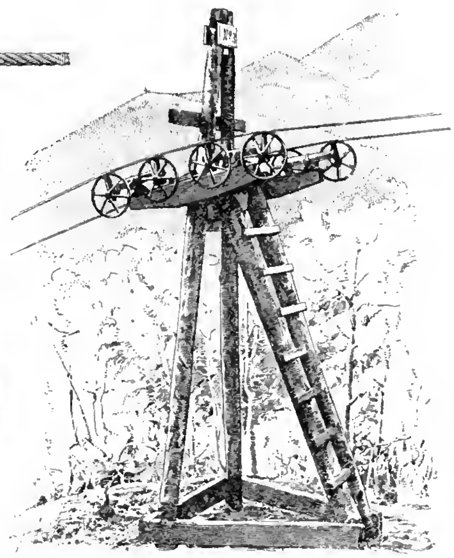

Fig. 50. Tramway Tower

The coal and coke shipments over the Norfolk and Western for the first six months in 1910 were 2.5 million tons more than in the first six months of 1909.

Pottsville, Penna., capitalists who control the Majestic collieries at Majestic, Ky., just across Tug River from War, W. Va., on the Norfolk & Western, according to well-authenticated advices are preparing to spend $600,000 upon their land and operation. A modern steel tipple is now under construction, and other improvements are to be added at once. When these are completed the company will have a daily output of 40 cars, which is among the largest in the lower field. This company controls a coal area of about 10,000 acres on which development has already disclosed several very fine beds measuring from 5 to 8 feet in thickness. It is understood to be the policy of the management to push the work as rapidly as possible, and increase the initial output of the property.

During the first five months of 1910, the Pennsylvania Railroad shipped 28,050,212 tons of coal and coke over the lines east of Pittsburg, which is an increase of 3,868,052 tons compared with the same period in 1909.

A collier entered a book shop, somewhere in England, with his wife and asked: "Can you give me an arithmetic for use in the mine?" The clerk was sorry he could not, and the miner said: "Do you ken what I mean. It is a thing for calculating; something to check the foreman." The clerk again told him he had not got such a thing; and then the collier, looking at his wife in a sheepish sort of way, said: "Man, you have got it in the window." The clerk asked him to point it out—and the collier, taking him into the street, pointed out, "Pitman's Arithmetic."

Drilling for oil in Nescopeck Valley, near Hazleton, Pa., is being prosecuted. "It is said that several bottles of oil have been taken from springs in the neighborhood of the place now being drilled."—*Hazleton Sentinel.* Parenthetically, oil has not been found in the Blue Ridge in paying quantities and it is not likely that it will be, owing to the metamorphic changes in rocks and the dynamic disturbances that occurred in times past which prevented its accumulation.

The trouble between the coal operators and miners over the scale in the Pittsburg district seems to be nearing an end. Motormen are to receive an increase of 10 cents, making their wages $2.80. Wiremen are similarly increased making their wages $2.70. Day laborers also receive an increase. A complete check-off system is established including the collection of an initiation fee. An increased pay of 5 cents per inch for thick slate is allowed. There is to be no charge for safety lamps; three-fourths entry prices for four-run places; no increase in the price of fuel for the home; and no increase in rent for miners' houses.

According to the *National Labor Tribune*, Chairman M. H. Taylor has been placed in an embarrassing position by the quarrels between the miners over their labor union officers, which made it appear as if he was assisting one miners' faction in preference to another. When the quarrel was cleared up, Mr. Taylor found it comparatively easy to treat with the miners' officers. The settlement of the local scale is said to be satisfactory to both miners and operators.

The miners working for the Pennsylvania Coal Co. not being connected with the United Mine Workers, could not be controlled when they decided to strike. The coal company and

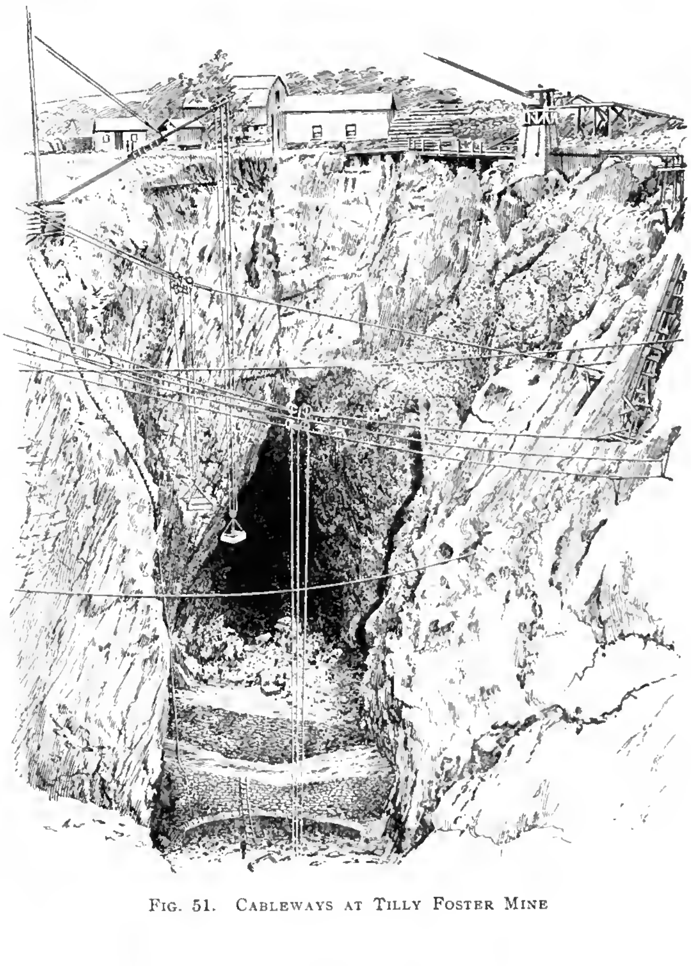

Fig. 51. Cableways at Tilly Foster Mine

unions were in the position of not being able to comply with the award of the Anthracite Coal Commission. After much entreaty on the part of the officers of the United Mine Workers and citizens, the men agreed to place their grievances before the Conciliation Board, and to work pending the decision. The Board was able to obtain concessions at once from the coal company which are satisfactory to the men.

The fiscal year of the Mining Department of West Virginia closed June 30 without one life being lost by an explosion of any kind. Heretofore the mine explosions from gas and dust have attracted the attention of the world. Mines that were thought to be model ones in every particular were visited with the greatest accidents, and the toll of human life was appalling. There were the usual number of deaths from fall of coal and slate. Greater care is being exercised in the mining department, and a higher standard of efficiency is being required among the men that have direct charge in the operation of the mines. Now, all of the mine foremen and fire bosses have to be examined in order to be eligible to hold their positions. The examination is a searching one along practical lines, and any one failing in the test cannot become a fire boss or a mine foreman.

Coal-mine fatalities in the United States in 1909 were fewer than in 1908, notwithstanding an increase of approximately 10 per cent. in the quantity of coal mined. The figures compiled by Edward W. Parker, statistician in charge, Division of Mineral Resources, United States Geological Survey, show the total number of deaths from coal-mine accidents in 1909 to have been 2,412, against 2,450 in the preceding year.

During the last five years the annual reports of the Geological Survey on the production of coal have contained a chapter on coal-mining accidents, their causes, and their relations to the number of men employed and the tonnage produced. These statistics are compiled almost entirely from statements furnished by State Mine Inspectors. It is expected that statistics of mine accidents in future years will be compiled by the new Bureau of Mines. The most serious catastrophe which occurred during the calendar year 1909, was the fire at the Cherry Mine of the St. Paul Coal Co., at Cherry, Bureau County, Ill. It has been reported that in that disaster 393 men were burned or suffocated. The statistics of the holocaust are not, however, included in the preceding general statements, for the reason that the reports of the State Mine Inspectors of Illinois are made for the fiscal year ended June 30, and as the Cherry disaster occurred in November it will be included in the statistics for the fiscal year ended June 30, 1910.

The most serious single accident included in the statistics presented in this statement was an explosion at the Lick Branch colliery of the Pocahontas Consolidated Collieries Co., near Bluefield, W. Va., on January 12, 1909. In that explosion 65 men were killed and 1 was injured. Another explosion had occurred in this mine about 2 weeks before, in which 51 lives were lost. The Lick Branch explosion of January 12 was the only one of serious proportions in West Virginia during the year.

An explosion in mine A of the Chicago and Cartersville Coal Co., at Herrin, Ill., on December 28, 1909, killed 8 men and imperiled the lives of 400 others.

Twelve men were killed by what is supposed to have been an explosion of dynamite in one of the mines of the Cambria Steel Co., near Johnstown, Pa., October 31, 1909.

On April 9, an explosion of dynamite killed 7 miners and injured several others at mine No. 37 of the Berwind-White Coal Co., near Windber, Pa.

On January 25 4 men were killed and 8 injured in Washington mine No. 5 of the Piedmont and Georges Creek Coal Co., in Maryland, as the result of a collision between two trips of coal cars.

On March 19, 5 men were killed and 20 injured in an explosion at the Sunnyside Mine of the Sunnyside Coal and Coke Co., in Vanderburg County, Ind. Twenty nine men were in the mine at the time of the explosion, and all but 5 escaped.

An explosion which caused the death of 20 men occurred on January 10, in the mine of the Zeigler Coal Co., at Zeigler, Franklin County, Ill.

What is supposed to have been a dust explosion occurred in April at the Short Creek Mine of the Birmingham Coal and Iron Co., in Jefferson County, Ala., and killed 18 men.

PETROLEUM DEPOSITS ABOUT TAMPICO, MEX.

Most of the capital employed in the petroleum and asphalt industry near Tampico, Mexico, is American, and the company most heavily interested, and in fact the pioneer in this field, is the Mexican Petroleum Co., an American concern, with headquarters at El Ebano. This company now has over 30 producing wells, a large number of storage tanks all of its departments specially equipped with modern facilities for handling the output, and it is now building a pipe line 62 miles to run from its new fields in the state of Vera Cruz to Tampico. The handling of the most of its output does not require a pipe line, as the wells are conveniently located to rail or water transportation. The output is consumed by the Waters-Pierce refinery, of Tampico, and by the National Railroad of Mexico, from 50 to 55 cents gold being paid for the crude product. Other prominent American operators in this section are the Harriman interests, the Mexican Fuel Oil Co., the Mexican Fuel Co., C. H. Rathbone, and the McKay interests, a collateral branch of the Rio Bravo Oil Co. S. Pearson & Sons (English) are also operating near Tuxpam and building a 6-inch pipe line to run from their fields to Tuxpam. The well belonging to the latter and the Pennsylvania Oil Co., which was brought in on July 4, 1909, at Dos Bocas, about halfway between Tampico and Tuxpam, and which later was completely destroyed by fire, has been pronounced by several experts to have been the greatest well that has ever been known in the history of the oil industry of the world, its output having been estimated from 300,000 to 500,000 barrels daily.

The wells in the vicinity of Tampico range in depth from 800 to 2,500 feet and vary in production from 100 to 2,000 barrels daily. The oil is heavy and viscous and is mostly used in its crude state as a fuel. Under distillation, about 30 per cent. fractionates into good grades of naphthas and illuminants. The heavy or malthitic product is converted into asphaltum by the removal of a 10 per cent. distillate. These asphaltums, for which there is a good demand, delivered in Mexico City, sell for $40 gold per ton. Their exportation, mostly to Germany, is also increasing.—*United States Consular Report.*

PERSONALS

Edgar G. Tuttle, E. M., consulting engineer, is now permanently located at 30 East Logan Street, Germantown, Pa.

L. E. Yoder, chief engineer and superintendent of The New River Collieries Co., Eccles, W. Va., has resigned his position and will resume duties as chief engineer of The New River Co., with offices at Harvey, W. Va.

J. B. Tyrrell has been elected a fellow of the Royal Society of Canada.

J. H. Dietz, formerly mining engineer for the Central Coal and Coke Co., of Kansas City, and for the past 7 years consulting engineer of the United Iron Works, Joplin, Mo., has recently assumed the position of general manager with the Eagle Foundry and Machine Co., of Fort Scott, Kans.

Ernest Russell Woakes left for the Caucasus on July 17 to examine mines on behalf of Messrs. Hooper, Speak, and Fielding.

J. P. Hutchins writes from St. Petersburg, where he is on mining business, "that concomitants essential to doing business in Russia consist in drinking much tea and smoking many cigarettes."

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

Mine Inspectors' Examination Held at Scranton, Pennsylvania, May 25, 1910

QUES. 1.—(*a*) What gases are found in anthracite coal mines? (*b*) How do they affect the lives and safety of men employed in the mines? (*c*) Give the symbols, specific gravity, and properties of each gas. (*d*) Where would you look for each; how is the gas produced; does it affect combustion, and how?

ANS.—These questions can be answered together more concisely by stating the properties and effects of each gas in order. Methane or marsh gas (CH_4), specific gravity .559, is a colorless, odorless, and tasteless gas; combustible, but will not support combustion or life; it suffocates when breathed pure, and extinguishes flame; when mixed with air it can be breathed with impunity but the mixture, in certain proportions, is inflammable or explosive. Marsh gas is to be sought at the roof, or the face of rise headings, or in void places or close to large feeders. The gas issues from the coal or other strata, having been produced in the formation of the coal. Carbon monoxide (CO), specific gravity .967, is a colorless, odorless, and tasteless gas; combustible, supports combustion, extremely poisonous, forms an inflammable or explosive mixture, in certain proportions, with air. This gas is to be sought in poorly ventilated workings in proximity to and in old abandoned places; it is produced by gob and mine fires, or by combustion of carbon in a limited supply of air, or by the explosion of powder in blasting. Carbon dioxide (CO_2), specific gravity 1.529, is a colorless, odorless gas, with slight acid taste; it is not combustible, and will not support combustion or life; it suffocates when breathed, dims and extinguishes flame, and reduces the explosiveness of firedamp mixtures. This gas is to be sought near the floor and in low or dip workings, and in poorly ventilated or abandoned workings; it is produced by the burning of lamps, breathing of men and animals, or any combustion of carbon in a plentiful supply of air. Hydrogen sulphide (H_2S), specific gravity 1.1912 is a colorless gas, having a bad odor like that of rotten eggs. It is combustible, but does not support combustion or life; extremely poisonous, and mixed with air is inflammable or explosive. It is to be sought in damp workings where the coal contains sulphur balls or pyrites; it is produced by the decomposition of pyrites in presence of moisture.

QUES. 2.—State briefly but thoroughly.(*a*) What obligations are imposed on the operator by the mine law? (*b*) What on the mine inspector, and what are his duties? (*c*) What on mine officials? (*d*) What on all employes? State the act, date, article and section, in all cases where memory serves you.

ANS.—The mine operator is requred by law (Art. 3) to furnish an accurate map of the mine as surveyed, and extended at least once in every six months, and to keep one copy at the colliery and file one copy with the mine inspector; also (Sec. 10), to leave a barrier pillar of sufficient width to render the mine safe from inundation by water accumulated in adjoining mines; also (Art. 4), to provide two openings not less than 150 feet apart at the surface, and 60 feet apart under ground, available for each seam in which more than 20 persons are employed; also (Art. 6), to provide suitable wash house at request of 20 employes (Art. 7), a colliery ambulance and two stretchers (Act 1901), waterproof and woolen blankets, olive and linseed oil, bandages, etc., in a suitably clean, lighted, and ventilated room in the mine, (Art. 10) adequate ventilation in the mine, (Art. 11) all necessary timber, ties, rails, etc.; also (Art. 12), to use every precaution to ensure the safety of workmen and employ a competent mine foreman to take charge of the mine. (*b*) The mine inspector (Art. 2, Sec. 11) must enter and examine each mine in his district, and carefully inspect all the workings and the machinery and other appliances in use, methods of ventilation, lighting, and drainage, and inquire into matters relating to the health and safety of the workmen; (Art. 3, Sec. 5) accept, or reject as inaccurate, all mine maps sent him; (Art. 8, Sec. 3) act as member of examining board to examine and certify men for the positions of mine foreman and fire boss; (Art. 13) attend inquests, and investigate all mine accidents, collect and record evidence respecting cause of same; (Art. 15) apply for injunction, at the court of the district, to stop the operation of any mine that does not comply with the mine law, after giving the operator of the mine 24 hours' written notice of his intention; (Act 1901, Sec. 4) visit the medical room of each mine in his district to see that they comply with the law. (*c*) The mine foreman (Art. 12, Rule 3) is charged with all matters pertaining to ventilation; (Art. 10, Sec. 15) the weekly measurement and recording of the quantities of air in circulation; (Art. 11) the supply of all timber, ties, rails, etc., to the men as needed; (Art. 12, Rule 4) the weekly examination of all accessible parts of abandoned places in the mine; the examination, by himself or assistants, of all working places, (Rule 5) daily, before each shift, in mines generating gas, and (Rule 12) each alternate day while the men are or should be at work; (Rule 13) the daily examination of all slopes, shafts, roadways, signal apparatus, pulleys, timbering, etc.; and (Rule 8) he must use every precaution to ensure the safety of the men. (*d*) (Art. 12, Rule 14) Every miner is made responsible for keeping his place securely timbered. (Rule 24) Any employe must report to the mine foreman or other person in charge any danger he may discover in any part of the mine.

QUES. 3.—The diameter of the cylinder of an engine is 16 inches, length of stroke 30 inches, indicated steam pressure 100 pounds, piston speed 225 feet per minute; what is the horsepower of the engine?

ANS.—Assuming the given steam pressure is the mean effective pressure as calculated from an indicator card, the indicated horsepower of the engine at this speed is

$$H = \frac{100(.7854 \times 16^2)225}{33{,}000} = 137 + \text{H. P.}$$

QUES. 4.—What recommendations would you make to secure a large quantity of air in a mine, with the least possible resistance; and how would you handle the air to secure the best possible results?

ANS.—Reduce the resistance by removing every obstruction to the flow of the air-current, and enlarging all cross-cuts, and shortening the distance the air must travel wherever practicable. Clean up the air-courses and avoid standing empty and loaded cars in the airways, where they seriously obstruct the free movement of the air. Also, split the air wherever the conditions will justify doing this, thereby reducing the velocity of the current and the mine resistance.

QUES. 5.—Consider an airway 8 ft.$\times$10 ft. and 5,000 feet long; (*a*) what must be the length of a (similar) airway 6 ft. $\times$8 ft. in section in order that it will have the same rubbing surface? (*b*) If a pressure of 5 pounds per square foot is required to create a certain velocity in the 8'$\times$10' airway, what pressure per square foot will be necessary to produce the same velocity in the 6'$\times$8' airway?

ANS.—The given airways are not *similar*, as the question states; because their corresponding sides are not proportional. But taking the sizes as given, (*a*) the rubbing of the first airway is $2(8+10)5{,}000 = 180{,}000$ square feet; and since the perimeter of the second airway is $2(6+8) = 28$ feet, the required length of this airway, for the same rubbing surface would be $180{,}000 \div 28 = 6{,}428.57+$ feet. (*b*) For equal rubbing surface and equal velocity, the pressure varies inversely as the area; or the pressure ratio is equal to the inverse area ratio. Hence, calling the required pressure x,

$$\frac{x}{5} = \frac{8 \times 10}{6 \times 8} = \frac{5}{3}; \text{ and } x = \frac{5 \times 5}{3} = 8\tfrac{1}{3} \text{ lb. per sq. ft.}$$

If, however, the airways are assumed as of equal length, for

equal velocities the pressure varies as the perimeter and inversely as the area; or, the pressure ratio is equal to the product of the perimeter ratio and the inverse area ratio; thus,

$$\frac{x}{5}=\frac{2(6+8)}{2(8+10)}\times\frac{8\times 10}{6\times 8}=\frac{7}{9}\times\frac{5}{3}=\frac{35}{27}$$

$$x=\frac{5\times 35}{27}=6.48 \text{ lb. per sq. ft.}$$

Ques. 6.—State what measures you would adopt to prevent the occurrence of mine fires from any cause, condition, or circumstances. Should a serious fire occur in the mine, in your efforts to extinguish it, what general points would you observe for the protection of life, limb, and property?

Ans.—Permit no combustible material such as hay, oil, powder, etc. to be taken into the mine except what is required for immediate use, and permit no such material to be placed where it will be exposed to the open lights of workmen. Give strict orders that all supplies of hay, oil, powder, etc. must be taken at once to their destination on arrival in the mine. All powder must be contained in secure metallic cases. Shaft and slope bottoms must be lighted by stationary lamps or electric bulbs; no open lights should be allowed either here or in the mine stables. Allow no accumulations of oily rags or waste in the pump room or lamp station. Where electric power is used particular attention must be given to the arrangement of the switchboard and to the wiring. Enforce strict regulations in regard to the handling of powder in preparing a blast. In blasting in a gassy mine arrangements should be made to have the face examined after the firing of a blast to ascertain that no gas has been fired. Should a serious fire occur in the mine, the men must be notified to withdraw by some safe route if possible. At the same time active measures must be taken to prevent the smoke and gases of the fire being carried into the workings, and get water on the fire by a line of hose laid in the entry; or bring the chemical engine into action. The fire must, in general, be fought from the side toward the air, so as to avoid exposing the men to the poisonous gases and smoke. By what means the smoke and gases may be kept from entering the workings, whether by short circuiting the air, or slowing down, stopping, or reversing the fan, will depend wholly on the conditions existing in the mine, location of the fire, and the headway it has gained.

Ques. 7.—If you were assigned a colliery of 400 acres with five veins, the third and fourth being mined, and the fifth or bottom vein just being opened, and you were about to mine pillars; state briefly what restrictions you would impose for the safeguarding of life, limb, and property, there being no unusual conditions.

Ans.—Assuming that the workings in the third and fourth veins have been systematically planned so that the pillars in the lower seam stand vertically under those in the seam above, the work of drawing back pillars in these two veins should begin in the third vein where the entries and chambers have reached their limit. If the two veins are separated by only a few feet of rock the pillar work in the upper vein should be kept a few yards in advance of that below and this work should proceed uniformly in each vein. Only the most experienced miners should be employed in drawing back the pillars, and they should keep a careful watch for gas, loose top, fault lines in the roof and other dangers incident to the work. As far as practicable the condition of the abandoned workings in the overlying veins should be ascertained and special attention should be given to timbering so that the miners will be warned of any approaching fall of roof in time to escape.

Ques. 8.—(a) What kind of explosives are used in the anthracite mines? (b) What powders are best adapted to various conditions of mining? (c) How should they be handled, stored, etc.? (d) What is meant by permissible explosives?

Ans.—(a) Black powder and dynamite of different grades. (b) Black powder is best adapted to shooting coal, because its action is not as sudden as that of detonating powders (dynamite), and the coal is not as badly broken. The grade or strength of the powder should be adapted to the hardness of the coal. Dynamite or some special kind of detonating powder is used in breaking rock. (c) All explosives should be handled with the greatest of care, and kept in a suitable case or box in a safe place in the mine. Powder must be stored on the surface, in a building set apart from other buildings, and designed for the purpose. No person may have more than one keg (25 pounds) of powder, or what is required for the day's work, in one place in the mine. No lamps or other fire may be brought nearer than 5 feet to any open box or can containing powder. (d) By permissible explosives is meant such explosives as have passed the government tests and been entered on the list of so-called permissible explosives published by the government.

Ques. 9.—How many and what are the essential features of a good safety lamp?

Ans.—The essential features of a good safety lamp may be classified under five different heads; namely, (1) *Simplicity of construction* to facilitate cleaning and avoid mistakes in assembling the parts, and not invite the curiosity of the user or require special oil or special equipment in the lamp room or special intelligence on the part of the user. (2) *Security of the lamp* against damage by accident, improper handling, strong air-currents, sudden exposure to gas, tampering and curiosity. (3) *Good illumination* to assist work and inspection of mine, roof, timbering, etc., and constancy of flame. (4) *Correct indication* of gas and dust, or explosive condition of air by maintaining the same condition within the combustion chamber as exists outside the lamp, by the free admission of air at or below the flame, thus producing an upward circulation, which avoids the tendency of the lamp to smoke, and prevents the products of combustion descending to the flame. (5) *Lightness and portability* of the lamp.

Ques. 10.—Assume that a large territory of a certain mine has collapsed; men are entombed; an inflow of 18,000 gallons of water per hour seriously handicaps the work of rescue, and must be pumped out by a shaft 225 feet deep, with a steam pressure of 50 pounds available at the foot of the shaft. Assuming a piston speed of 110 feet per minute, find the horsepower, size and proportion of a direct-acting steam pump required for this work.

Ans.—To allow for breakdowns and repairs, or a possible increase of demand on the pump, assume all the pumping is done in 20 hours out of 24, or in $\frac{5}{6}$ of the time, making the required discharge in this case $\frac{18,000\times 24}{20\times 60}=360$ gallons per minute. This would require a column pipe having a diameter of $.25\sqrt{360}=4.75$, say 5 inches. Allowing 25 feet over the depth of the shaft to cover the suction and discharge ends, the total length of pipe is $225+25=250$ feet. The total head under which the pump must act is the depth of the shaft to the coal, plus the suction head or depth to low-water line in sump, plus the friction head, which is the extra head required to overcome the resistance of the pipe. The friction head in this case is

$$h_f=\frac{f l G^2}{8 d^5}=\frac{.01\times 250\times 360^2}{8\times 5^5}=\text{say } 13 \text{ ft.}$$

Then, assuming a suction head of say 17 feet, the total head against which the pump must operate is $225+17+13=255$ feet. For this head and an available steam pressure at the pump of 50 pounds, the ratio of the diameter of the steam end to that of the water end is

$$\frac{D}{d}=.7\sqrt{\frac{h}{p}}=.7\sqrt{\frac{255}{50}}=1.58;$$

or

$$D=1.58d$$

This allows for an efficiency of 75 per cent. at the steam end, and .85 per cent. at the water end of the pump, which is good practice. The diameter of the water end allowing this efficiency is

$$d=5.37\sqrt{\frac{G}{S}}=5.37\sqrt{\frac{360}{110}}=9.7, \text{ say } 10 \text{ in.}$$

The diameter of the steam end is then

$$D = 1.58 \times 10 = 15.8, \text{ say } 16 \text{ in.}$$

The horsepower of the pump when doing this work would be

$$H = .00034\ Gh = .00034 \times 360 \times 255 = 31.2 \text{ H. P.}$$

Assuming a 24-inch stroke the pump is making $110 \times 12 \div 24 = 55$ strokes per minute.

Ques. 11.—If you were to make an outside inspection of an average anthracite colliery, state what points would receive your careful attention, and in what features would you be particularly interested? Assume the breaker is over the shaft.

Ans.—It would be important to ascertain the location, character, and equipment of the second or escape opening, and its relation to the hoisting shaft and the breaker building as well as all the other buildings and supply yards that form the surface plant. Also, the methods of lighting, heating, and ventilating the breaker, and the power employed in operating the machinery therein should be carefully investigated. All safety and other appliances should be thoroughly inspected and approved or condemned; this includes brakes on winding drums, safety blocks and catches, cage guides, wings or keeps, gates at top of shaft, signal apparatus, speaking tubes, hoisting ropes and sheaves, hand rails, danger signals, electric wires. The boiler plant should be inspected and the date of the last boiler inspection ascertained; the mine map should also be examined and the data of its latest extensions observed. The age of breaker boys should be noted to see that none are illegally employed.

Ques. 12.—(*a*) If you had reason to question the strength of a boiler to carry, say 100 pounds pressure with safety, in what manner would you satisfy yourself? (*b*) Would you recommend water glasses or gauge cocks on a boiler, and why? (*c*) In what manner could you determine that the steam gauge was recording the pressure correctly? Give a formula by which to calculate the position of the ball of a safety valve so that the boiler will blow off at a given pressure.

Ans.—(*a*) The pressure a cylindrical boiler will stand with safety when the same is in good condition and properly set may be calculated when the thickness and strength of material and the diameter of the boiler are known, by the formula $p = 2$ (thickness$\times$safe strength)$\div$diameter in inches. Thus, a 5-foot steel boiler made of plates $\frac{3}{8}$-inch thick and having a safe strength of 10,000 pounds per square inch, if all right, should withstand safely a pressure of $p = 2(\frac{3}{8} \times 10{,}000) \div 5 \times 12 = 125$ pounds per square inch. However, where any doubt exists as to the strength of a boiler the mine inspector should order its use discontinued until examined by a competent boiler inspector. (*b*) Gauge cocks are preferable to water glasses because of the liability of the latter being broken or becoming clogged, and giving a false indication of the water level in the boiler. (*c*) Multiply the weight (w) of valve, valve stem, and lever by the distance (d_1), in inches, from their center of gravity to the fulcrum of the lever; in like manner, multiply the weight (W) of the ball by the distance (d), in inches, from its point of support to the fulcrum; add these two products together and divide their sum by the distance (d_2), in inches, from the valve stem to the fulcrum. The quotient obtained will be the total upward pressure of the steam on the valve. Finally, divide this total pressure by the area (A) of the valve, in square inches, and the quotient will be the pressure in pounds per square inch at which the valve should blow off. If everything is working correctly the gauge will indicate about this pressure when the valve is blowing off. Expressed as a formula this rule is

$$p = \frac{wd_1 + Wd}{d_2 A}$$

Ques. 13.—If you were conducting a search party through very old and extensive workings and suddenly found yourself bewildered when about to return to the shaft, describe how you would proceed to ascertain the right way back. Assume you have with you the mine map, compass, tape, protractor, and scale, and have found and identified one station at the point where you became bewildered.

Ans.—Set up and level the compass at the point found, and having set off correctly the declination of the needle turn the compass sights in the line of the true meridian. Now spread the map on the floor so that the meridian of the map corresponds with that determined by the compass. In this position the map shows correctly the lay of the workings. Having identified the point found in the mine as a station on the map proceed to measure the bearing and length of any course that is most convenient to travel, leading in the general direction outby or toward the shaft, and establish another point in the mine. With the protractor and scale draw this course on the map, starting from the station found, and mark on the map the point established as substation 1. Having set up and leveled the compass now at substation 1, sight back to the last preceding point and read the needle to detect any possible error due to local attraction. Continue to survey and plat on the map each course leading outby till some place is arrived at that can be recognized.

Ques. 14.—Describe the dangers that attend the use of electricity in and about mines and state the suggestion you would make to safeguard the workmen.

Ans.—The chief danger lies in the liability of workmen or mules to come in contact with live wires or some tool or machine or other metal that is charged with the electric current, and receive therefrom a fatal shock. This danger is greatly increased in the dark and uncertain passageways of mine workings, and the occurrence of roof falls and settlements that often displace the conducting wires and render roads and passages dangerous. There is also danger from short circuiting of currents, blowing out of fuses and sparking of commutators and electric connections by which gas may be ignited or a fire started. To safeguard life use a 250-volt direct current for haulage and permit no travel on the haulways; place conspicious warnings at all road crossings and elevate the trolley wire, at these points out of harm's way; also place danger signals at the mine entrance and the inside parting where trips are made up. Insulate all high-tension transmission lines for conducting power units into the workings and protect these as well as possible against accident.

Ques. 15.—What does the anthracite mine law require in case it is found impracticable to keep the mine free from an accumulation of gas or water?

Ans.—Article 12, Rule 8, of the laws require the person who is in charge of the mine at the time such danger prevails, to use every precaution to ensure the safety of the workmen, and to withdraw every man from the mine, or such part thereof as is found to be dangerous, except those required to remove the danger; and not permit them to return to the mine until the same has been examined by a competent person and reported safe.

(*To be concluded in September*)

LOSSES IN ELECTRIC TRANSMISSION

When figuring upon the installation of an electric transmission plant it is necessary to allow a sufficient factor for losses. An authority gives these as follows: Loss due to friction of steam engine, 10 per cent.; loss in belting between engine and generator, 3 per cent. If direct-connected this is not figured. Loss in generator, 10 per cent.; loss in line, 10 to 20 per cent.; depending on its length, size of conductor, care in building line, etc.; loss in motors, 12 to 20 per cent. depending on kind used and service required by them; 5 to 10 per cent. loss between the brake horsepower and the machine to be driven, to which may be added the loss in the machine itself due to friction. Total efficiency, 50 per cent., taking the lowest estimate of loss. Where the distance is short and great care is taken in making the installation the actual efficiency may be increased to 60 per cent.

THE ILLINOIS COAL FIELD

*Written for Mines and Minerals, by H. H. Stoek**

History and Geology. Trade, Inspection and Mining Districts

Very few Americans probably realize that the great prairie state of Illinois ranks second only to Pennsylvania as a producer of coal. The traveler through Pennsylvania and West Virginia feels instinctively on account of the mountains about him that he is in a mining region, even were he not visibly reminded of it in many sections of these states by the ever-present pall of smoke by day, and the pillars of fire by night, from the coke ovens. Moreover, in these states, the main transportation lines pass directly through the mining section. Not so in Illinois, however, for the traveler to the Far West who goes by way of Chicago usually passes through only the northern part of Illinois, which is the only section not

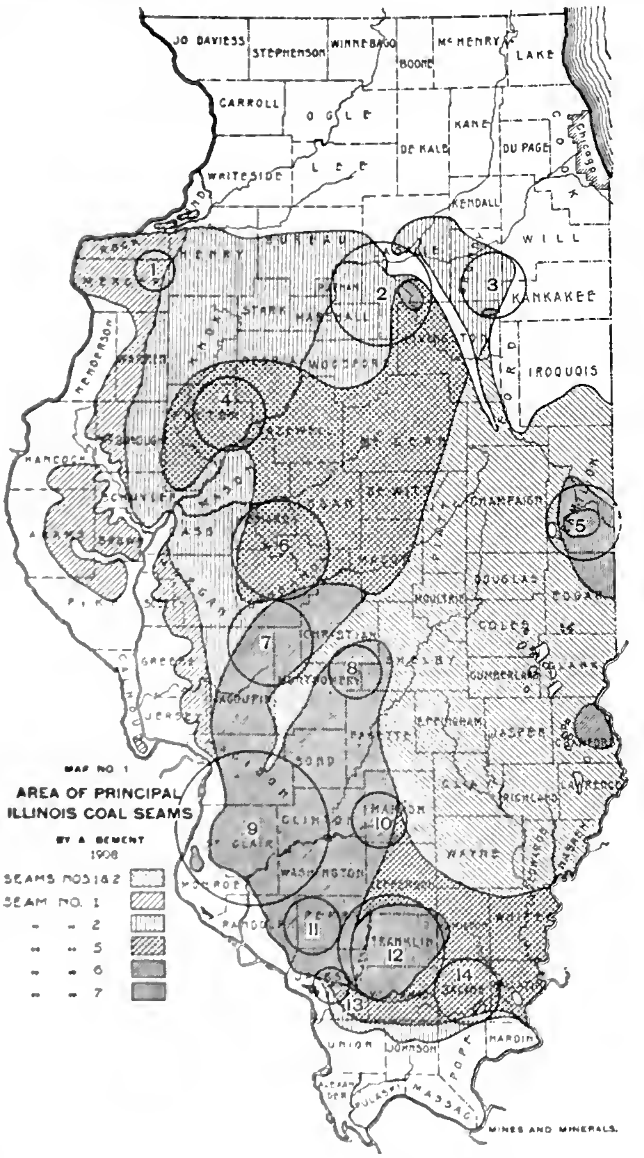

Fig. 1. Map of Illinois Coal Fields

1 Rock Island; 2, Northern; 3, Wilmington; 4, Peoria & Fulton; 5, Grape Creek, 6, Springfield, 7, Virden, 8, Pana; 9, Central Illinois, 10, Centralia; 11, DuQuoin, 12, Williamson and Franklin; 13, Big Muddy; 14, Saline

underlaid by coal. The traveler going southward or southwestward from Chicago to St. Louis or one passing through the southern or central part of the state realizes to some extent that he is passing through a country which has a covering of golden grain and a lining of black diamonds, but even here the surface indications of mining are small compared with those seen in a country where the coal is coked, or in the anthracite region of Pennsylvania where the surface equipment is so much more elaborate.

In Illinois, King Coal cannot be the same despot that he is reputed to be elsewhere, but must reckon with the fair goddess of agriculture who rules over surface lands worth frequently $200 and more per acre, while the coal rights underneath these same lands may be worth only from $10 to $100 per acre.

Coal-bearing rocks underlie three-fourths of the state of Illinois, being under 85 of the 102 counties, the greatest area of bituminous coal in any single state of the United States. The barren areas include a narrow strip along the Mississippi River, a small section in the extreme south, or Egypt, and about one-fifth of the area of the state along the northern boundary.

According to E. W. Parker's "Coal Statistics," "probably the earliest mention of coal in the United States is contained in the journal of Father Hennepin, a French missionary, who as early as 1670 reported a 'cole' mine on the Illinois River above Fort Crevecoeur, near the site of the present city of Ottawa. Father Hennepin marked the location of the occurrence on the map which illustrates his journal. It is also probable that, outside of anthracite mining in Pennsylvania and the operations of the Richmond basin in Virginia, Illinois holds the record for priority of production. The earliest statement that we have in regard to actual mining in Illinois is that coal was produced in Jackson County in 1810 from a point on Big Muddy River. A flatboat was loaded with coal at this place and shipped to New Orleans, but the quantity is not stated. Again, it is reported that in 1832 several boat loads were sent from the same vicinity to the same market. Another record is found stating that 150,000 bushels "or 6,000 tons of coal were mined in 1833 in St. Clair County and hauled by wagons to St. Louis. From 1840 to 1860 the bureau of statistics of the state is without any reliable data in regard to the coal-mining industry, although some scattering statistics are found in the geologic reports published by the state government." Mining is carried on in 52 counties and coal probably occurs in 33 other counties, where it has not as yet been developed. The production of coal from Illinois since 1900 has been as follows in short tons:

Year	Quantity
1900	25,767,981
1901	27,331,552
1902	32,939,373
1903	36,957,104
1904	36,475,000
1905	38,434,363
1906	41,480,104
1907	51,317,146
1908	47,659,690

Illinois has ranked second among the coal-producing states for 23 years excepting in 1906, when on account of a strike in the state, West Virginia secured second place.

Several estimates of the original amount of coal in Illinois before mining began are as follows:

	Tons
F. W. DeWolf, Acting State Geologist	136,960,000,000
M. R. Campbell, U. S. Geological Survey	240,000,000,000
A. Bement	201,299,808,000

Of this amount, according to Mr. DeWolf, 1,041,060,000 tons have been mined and wasted up to the close of 1907, this estimate assuming that 62 per cent. of the coal is recovered in the mining. The output for 1908 was 47,659,690 tons; which is 62 per cent. of 76,870,467. Adding this to the above estimate gives a total of 1,117,930,467 tons to the end of 1908, or a production of about ½ of 1 per cent. of the original content of coal in the state.

The following table gives the production by counties for 1908:

*Professor of Mining Engineering, University of Illinois

Coal Productio of Illinois in 1908, by Counties, in Short Tons

Bureau	1,512,971

There has been a gradual change southward in the center of production and now the counties having the greatest production are in the southern part of the state.

The following table shows the counties having the greatest outputs during the last 20 years:

Counties Leading in Production From 1881 to 1909—Chronological Arrangement

Year	County	Tonnage	Year	County	Tonnage
1881	La Salle	624,900	1895	Macoupin	1,948,992
1882	La Salle	2,365,000	1896	Macoupin	2,097,539
1883	Macoupin	1,233,200	1897	Vermilion	2,000,623
1884	Macoupin	1,164,409	1898	Sangamon	1,763,863
1885	St. Clair	1,202,187	1899	Vermilion	2,221,867
1886	Macoupin	1,085,539	1900	Sangamon	2,519,911
1887	La Salle	1,125,235	1901	Sangamon	2,919,223
1888	St. Clair	1,184,579	1902	Sangamon	3,672,987
1889	Macoupin	1,202,187	1903	Sangamon	4,386,526
1890	Macoupin	1,369,919	1904	Sangamon	4,516,358
1891	St. Clair	1,595,839	1905	Sangamon	4,395,050
1892	Macoupin	1,823,136	1906	St. Clair	4,168,019
1893	St. Clair	2,133,870	1907	Williamson	5,266,452
1894	St. Clair	1,623,684	1908	Williamson	5,367,140

A number of detailed descriptions of the Illinois coal fields have appeared within the past few years, notably, "A Study of Illinois Coal," which appeared in the Transactions of the American Institute of Mining Engineers, Volume XL; another detailed article by Mr. A. Bement, of Chicago, appeared in the Journal of the Western Society of Engineers for June, 1909*. These articles and the reports of the Illinois Geological Survey have been largely used in preparing the following data, and direct reference will be made to them when it is possible to do so without tedious repetition. The writer is also indebted to Mr. F. W. DeWolf for many suggestions and for notes not included in the papers mentioned.

Illinois constitutes the major part of the eastern interior coal field. Of the total area of the eastern interior field, 48,500 square miles, Illinois is estimated to have 35,600, Indiana, 6,500 and Kentucky 6,400 square miles. Before taking up the Illinois field in detail, it is advisable to describe briefly the general characteristics of the entire eastern interior field. The general outline is regular and there are only a few outlying coal areas which are found, mainly toward the northwest. The field may have originally been more extensive, having continued eastward in Kentucky and westward into Missouri, where it may originally have joined the western interior coal field. If this connection originally existed, it has been eroded through the Mississippi Valley.

*Mines and Minerals, July, 1910.

The stratigraphy of the field as a whole has not been worked out sufficiently to definitely subdivide it, and the principal subdivisions now used are based upon state lines, and within the states by commercial or labor districts. Unfortunately, the coal beds have been differently numbered by the State Geological Surveys of Illinois, Indiana, and Kentucky. In Illinois the coal beds are numbered from 1 to 16, 1 being the lowest and bed No. 7 being the highest now worked to any extent, though in Shelby County a bed 2 feet thick and called No. 14 is worked for local trade in a small way. In Indiana, the coal beds are numbered from I to VIII with minor beds marked VI*a*, etc. In Kentucky, the beds are both numbered and lettered, the numbers beginning at the bottom and continuing upward to 12, Nos. 9, 11, and 12 being the principal beds worked. The letters extend from top downward and bed A is the same as bed 12.

At the northern end of the junction between Illinois and the Indiana fields, according to Ashley, No. 6 of the Illinois section seems to correspond with No. IV of the Indiana section. According to DeWolf, toward the south No. 5 Illinois and No. V Indiana are the same. It has not yet been certainly determined if No. 6 Illinois and No. 11 Kentucky are equivalent to No. VI Indiana, or if No. VI Indiana and No. 12 Kentucky are equivalent. A large amount of study and field work have been devoted to the several parts of the eastern interior coal field during the past few years by the State Geological Surveys of Illinois, Indiana, and Kentucky, and the results are being prepared for publication, so that within a comparatively short time, this subject should be cleared up considerably.

The coal-bearing rocks of the eastern interior field belong to the coal measures or Pennsylvanian series of the Carboniferous. The rocks between the coal beds are sandstones, limestones, and shales. The sandstones are not constant in thickness and do not, therefore, give good reference lines, but the limestones, although thin and impure are sufficiently regular to serve as reference planes. DeWolf says: "Probably most of the Pennsylvanian rocks constitute interfingering lenses of comparatively local extent."

The total thickness of the Pennsylvanian rocks probably exceeds 2,000 feet, but around the edges of the basin much has been removed by erosion, and in a large part of Illinois, the basal division is thin or absent. David White, who has contributed largely to recent studies of it, has shown that the earliest beds in Illinois were deposited in a restricted area in the southeastern counties of the state and that the favorable conditions for deposition of the coal measures gradually spread over the state, overlapping the eroded surface of the rocks, which are progressively older to the north.

Ashley says: "The coal measures of the eastern interior coal field rest unconformably on the underlying formations. At the southern margin of the field they lie on the Chester or Kaskaskia limestone, which, in Southern Illinois, has a thickness of 800 feet. Northward, along both the eastern and western borders of the coal field, the Chester thins out, having been eroded before the coal measures' rocks were deposited, and the latter rest on successively lower members of the lower Carboniferous, first, upon the St. Louis, and, as the northern end is approached, upon the Keokuk and the Knobstone. Finally at the northern edge of the field, the Devonian and Lower Silurian formations underlie the coal measures, and consist of alternating beds or lenses of shale and sandstone with which are thinner strata of limestone, coal, and fireclay."

There are three general divisions of the coal-bearing rocks:

First, the base of the measures is a massive sandstone of same age as the Pottsville formations of the Appalachian field. To it belong the Millstone grit of the early Illinois geologist and the Mansfield sandstone of Indiana. According to DeWolf, in Illinois, this section has a thickness of 650 feet or more in Johnson and Hardin counties, but diminishes rapidly in the west and north,

being nearly or quite absent over much of the state. Coal No. 1 of the western counties lies near the top of this formation. Lower coals occur in Southeastern Illinois and Western Kentucky, and some of these were formerly mined.

The second division in Illinois extends from coal No. 9 to coal No. 6, of the western and northern counties, and thus includes all the seams mined for shipment in the state. It is dominated by shale and contains a subordinate amount of sandstone. In age, it corresponds pretty closely to the Allegheny formation or Lower Productive measures of Pennsylvania, since coal No. 6 lies at or near the Upper Freeport, and No. 2 near the Kittanning horizon. This formation extends over nearly the whole area, but its lower beds are not well known in the central part of the basin. At Peoria the total thickness is about 200 feet and at Mattoon it appears to be 300 feet. In Jackson County it is 350 feet thick.

The third and topmost division in Illinois is dominated by shales, and contains no coals of present importance, though some are locally mined on a small scale. This portion of the rocks corresponds to the Lower Barren measures of Western Pennsylvania. It occupies much of the coal area, and reaches its greatest thickness (1,200 feet or more) in the vicinity of Hamilton and White counties. From 275 to 350 feet above its base occurs the Carlinville limestone, which, in the earlier state geological works, was accepted as a dividing line between the upper and lower coal measures.

The Illinois coal field is spoon shaped, the beds dipping gently toward a long axis which lies a short distance west of La Salle, and continues a little east and south to the southwest county of Indiana. According to DeWolf, "the deepest part of the basin is in the vicinity of White County, and from here the strata rise more rapidly to the south than to the north, averaging over considerable distance 40 feet, and locally 100 feet per mile.

The sides of the spoon show some minor longitudinal folds, notably the anticline which runs from LaSalle through the Illinois oil field toward Princeton, Ind., a steep monocline at Duquoin, and a gentle anticline at Belleville. The southern margin of the basin shows numerous minor faults and at least one of consequence, which runs west and a little south from Shawneetown, and has a down-throw to the north of over 1,000 feet. This separates the greater part of the basin from a narrow southern belt of rugged country, characterized by massive sandstones, but containing local areas of thick coal. Igneous dikes and other features along the southern margin of the basin indicate that the structure of the coal field is in part related to the orogenic movements of Southern Illinois and Western Kentucky."

Trade, Inspection, and Mining Districts.—The geological structure of the coal field has largely determined the mining centers, as the first mining has been carried on around the edge of the basin where the coal could be most easily reached. The central part of the basin will probably not be developed to any great extent while there is an abundance of coal about the edge of the basin.

The following brief notice of the several districts will be useful in understanding the references to the different localities and districts of the state.

The state is divided into districts upon several bases as follows:

1. For mine inspection purposes.
2. Geographically, for trade reasons.
3. For labor agreement between the coal operators and the United Mine Workers.

For mine inspection purposes:

District No. 1.—Grundy, Kankakee, La Salle, Putnam, and Will counties, Hector McAllister, Inspector.

District No. 2.—Bureau, Fulton, Henry, Knox, Mercer, Rock Island, and Warren counties, Thomas Hudson, Inspector.

District No. 3.—Livingston, Logan, McLean, Marshall, Menard, Peoria, Stark, Tazewell, and Woodford counties, John Dunlop, Inspector.

District No. 4.—Brown, Cass, Morgan, Sangamon, Scott, Hancock, Schuyler, and McDonough counties, Thomas Weeks, Inspector.

District No. 5.—Christian, Edgar, Macon, Moultrie, Shelby, and Vermilion counties, James Moses, Inspector.

District No. 6.—Calhoun, Green, Jersey, Macoupin, and Montgomery counties, James Taylor, Inspector.

District No. 7.—Bond, Clinton, Madison, Washington, and Marion counties, W. W. Williams, Inspector.

District No. 8.—Randolph, and St. Clair counties, Walton Rutledge, Inspector.

District No. 9.—Franklin, Gallatin, Jefferson, Perry, Saline, Wabash, and White counties, ———, Inspector.

District No. 10.—Jackson, Johnson, and Williamson counties, Thomas Little, Inspector.

In the paper by Mr. Bement already referred to, he divides the state into districts geographically as shown in Fig. 1, and the relative importance of these districts as shown by the output for 1908 is also shown by the numbers.

The districts as set by the Mine Operators and District No. 22 of the United Mine Workers of America for making trade agreements are as follows:

First District.—Bureau, Grundy, Kankakee, Livingston, La Salle, Marshall, McLean, Will, Woodford, Putnam, and Kendall counties.

Second District.—Vermilion County.

Third District.—Brown, Cass, Logan, Mason, and Menard counties; that portion of Macon county lying south of Logan County and west of an extension south of the east line of Logan County; and that part of Sangamon County lying north of a line from east to west, between Chatham and Springfield, located as development of the respective coal seams may indicate.

Fourth District.—Christian, Shelby, Scott, and Morgan counties; that part of Macon County lying east of an extension south of the east line of Logan County; Montgomery County, except mines on the Clover Leaf Railroad as far east as and including Coffeen; also so much of the northwest corner of Macoupin County as to include the mines on the C. & A. R.R. to and including Carlinville, also that part of Sangamon County between Chatham and Springfield not included in the third district.

Fifth District.—Monroe and Randolph counties; that part of St. Clair and Clinton counties south of, but not including the B. & O. S. W.; that part of Washington and Perry counties west of, but not including the main line of the Illinois Central Railroad; also Edwardsville, Glen Carbon, and points intermediate to St. Louis, on the same line of railroad in Madison County.

Sixth District.—Marion and Jefferson counties, and that part of Washington and Perry counties east of and including mines on the main line of the Illinois Central Railroad.

Seventh District.—Wayne, Edwards, Wabash, White, Hamilton, Franklin, Jackson, Williamson, Saline, Gallatin, Hardin, Pope, Johnson, Union, Massac, Pulaski, and Alexander counties.

Eighth District.—Rock Island, Mercer, Henry, Stark, Knox, Warren, Henderson, Peoria, Fulton, McDonough, Hancock, Schuyler, and Tazewell counties.

Ninth District.—Calhoun, Green, Jersey and Bond counties; all of Macoupin County except that part of the northeast corner which includes the mines on the C. & A. R.R. to and including Carlinville; that part of Clinton and St. Clair counties north of and including mines on the B. & O. S. W.; all of Madison County except Glen Carbon and Edwardsville and mines intermediate to St. Louis; also mines on the Clover Leaf Railroad in Montgomery County to and including Coffeen.

ENGINEERING OF MODERN COAL PLANTS

*By Howard N. Eavenson**

This paper will be a general description of the plants of the United States Coal and Coke Co., giving their main features.

A Description of the Plants of the United States Coal and Coke Company

On December 31, 1901, the Pocahontas Coal and Coke Co. executed a lease to the Illinois Steel Co., which was subsequently assigned to the United States Coal and Coke Co., for a portion of their territory containing 50,000 acres of the No. 3, or Pocahontas, seam of coal, 5 feet or over in thickness. The lease contained an agreement that the lessee was to begin work at once, and was to construct 3,000 coke ovens, and to reach an output of 1,500,000 tons of coke at the end of 3 years. Work upon the surveys was started in January, 1902, and construction work on plants Nos. 1, 2, and 3, consisting, as projected, of 950 ovens, was started in May. This work was pushed as rapidly as possible upon these three plants, and in February of the following year, work was started upon Nos. 4, 5, 6, and 7 plants, composing a total, as projected, of 1,100 ovens. In November, 1903, work was stopped upon Nos. 4, 5, and 6 works, and only 100 ovens completed at No. 7 works, which were charged from No. 6 mine. During 1904, a portion of the plants originally projected at Nos. 4 and 5 works were completed and placed in operation, and in 1904, plants Nos. 6 and 7 were completed and plant No. 8 started and completed, making at that time a total of 2,151 ovens. For various reasons, chief among which was the probability of the speedy development of the by-product oven, the original number of ovens was not completed. In the late fall of 1906, the construction of four new plants, Nos. 9, 10, 11, and 12, was authorized, and the construction of these plants was completed last year. The latter four plants are for coal-loading purposes only, and no ovens are projected or intended for them.

With the exception of plants Nos. 1 and 2, all of the mines of the company are drift mines. The No. 1 plant was originally intended to be a drift mine, but on account of a rock fault encountered in what was at that time supposed to be the No. 3 seam, but which was really the No. 4 seam, it became necessary to abandon this plan and to sink a shaft to the No. 3 seam, whose existence in good condition had been found by drilling. The No. 2 mine was originally opened as a drift mine, with a wooden tipple. In 1905 a fire entirely destroyed this tipple, and as it was found necessary, by that time, to use picking tables to clean the coal, the new steel tipple which replaced the wooden one, was built much higher on account of the crushers and picking tables, and a slope was driven to the coal seam a short distance below the original pit mouth. The height of the coal seam above the valley at the various plants varies from good tipple height, at No. 3 works, to an elevation of 600 feet at No. 12 works.

As originally stated, when the first work was started, the largest seam, and in fact, the only one which had been opened in the vicinity of the first operations, was supposed to be the No. 3, or Pocahontas, seam, and work was started with this idea. Subsequent prospecting, however, in the vicinity of No. 4 plant showed the existence of two seams, the lower one of which was found to be identical with the Pocahontas, or No. 3 seam, and the upper one was found to be the No. 4 seam, about 75 feet above the Pocahontas seam. More thorough prospecting demonstrated the fact that, at least along the outcrop, the No. 3 seam had thinned to not more than 3 feet in thickness for a considerable distance on Tug River, and practically the entire length of Sand Lick Creek, one of its main tributaries. Careful prospecting with the diamond drill confirmed the outcrop work, and it was found that this thinning was not merely a local condition, but that over a very large portion of the area which was supposed to contain the No. 3 seam over 5 feet thick, that this seam was less than 4 feet thick. Fortunately, however, over practically all of this same territory, the No. 4 seam, which is of no commercial importance along Elkhorn Creek, excepting in the immediate vicinity of Kimball, had thickened and had become a valuable seam, although it carried more partings than the No. 3 seam, and was also handicapped with what is called a "black-rash" roof. This rash ranges in thickness from a few inches to 2 or 3 feet, averaging about 18 inches. It is composed of thin layers of slate and coal interstratified, is very brittle, and is entirely too high in ash to allow its use in making coke. In some localities both the No. 3 and No. 4 seams are in good condition, and the area of good No. 3 seam coal at No. 1 mine is overlaid with a considerable area of good No. 4 seam coal, and both veins are worked to the shaft. The No. 3 mine is working the No. 4 seam of coal in the territory in which No. 10 mine is working the No. 3 seam, and at No. 11 mine both the No. 3 and No. 4 seams are being worked to the same tipple. The No. 4 seam reaches its greatest development on Sand Lick Creek, and the Nos. 2, 6, 7, and 8, and 9 mines are all working this seam, which ranges in thickness from 6 to 8 feet under the rash roof. At the 12 plants of the company there are 14 mines, of which six are working the No. 3 seam and eight are working the No. 4 seam. At No. 3 and No. 11 mines, in the No. 4 seam, the coal is the thinnest, averaging about 4 feet 8 inches in thickness. The No. 12 mine in the No. 3 seam is the thickest of any, averaging a little over 8 feet. The average thickness of all the coal now being worked is about 5 feet 10 inches. The quality of the clean coal in the two seams is very much alike. The No. 4 seam is a little lower in volatile matter, and a little higher in ash than the No. 3 seam immediately below it, and is a better coking coal, the yield being somewhat better and the structure and looks of the resultant product being considerably better.

The ovens, which have been constructed are of the beehive type, the first ones being 12 feet in diameter. Later this size was increased to 12 feet 3 inches, and the last ovens built were made 13 feet in diameter. A few experimental ovens were made 11 feet in diameter, and practically every type of beehive oven has been tested to see if the structure and yield of the coke could be improved. A number of ovens were built with a flue around the outside of the oven into which air was forced and from which it passed through holes in the crown brick to the crown of the oven. Other ovens were tested with flues under the bottom of the oven, the air entering at the crown, passing over the coal in the oven, thence by a flue at the back under the bottom of the oven and escaping through a chimney. It was found that none of these types gave any better results or any improved yield over the beehive oven when properly operated. An experimental oven was built 16 feet in diameter and still another 25 feet in diameter was tested. Both of these ovens made very good coke, but as they were constructed about the time the last of the ovens were built, no practical results have followed from their test. All of the ovens are charged by electrically driven larries, the current used on the trolley being the same as in the mines, 275 volts. At all of the coke plants, coke-drawing machines have been, or are being, installed, and a little more than two-thirds of the ovens are now drawn by machine. Twelve of these machines use the familiar wedge, which passes under the coke. One employs a scraper which goes into the oven on top of the coke, is forced down through it and operates practically as a hand scraper does. Still another machine which was developed at Gary, uses a shovel, which is forced through the coke and which discharges automatically into a conveyer, from which it passes to a shaking screen and thence to the cars. Fourteen machines are in operation, and four of the plants are entirely machine operated.

As soon as operations were started at the various plants, it was realized that some method must be employed for cleaning the coal, and a Bradford breaker was installed for this pur-

*West Virginia Coal Mining Institute, June, 1910.

pose at the No. 3 mine. After considerable experimenting with this machine, however, it was found that it would not take out the rash, and that in taking out the bone partings which were in the coal, a very considerable amount of coal was wasted. An experimental picking table was then installed at the No. 6 mine, and the results of this were so satisfactory that as rapidly as possible picking tables were installed at all the tipples, the coal in each case being dumped into a small hopper, and being fed from that to the tables. At the last plants, however, it has been found advisable to install bar screens for removing slack from the coal, allowing this to run to a separate conveyer and the coarser coal to be spread on the picking tables. This is a more satisfactory arrangement than to attempt to pick the run-of-mine coal without screening. All of the coal shipped is loaded as run of mine, and no effort is made in the tipple to keep the slack separated from the coarser coal, as it is all run into the same chute and thence into the bin.

The volatile matter in the coal at the eight coking plants does not exceed 18 per cent., and at the No. 1 mine it is as low as 16 per cent.; in fact, the coal which is being coked at our plants is the lowest-volatile coal which is being coked anywhere in the world, either in beehive ovens or by-product ovens, without the addition of some coal of higher volatile matter. On account of this low volatile matter, the coal does not fuse readily, and in order to get a coke of desirable structure, it is necessary to crush the coal. At each of the permanent tipples at each of the coke plants, duplicate crushers are installed through which all of the coal for the ovens passes. The crushers are of the hinged-hammer type. The first screens that were used to regulate the fineness of the coal were bar screens having ¾-inch spaces. It was found at once that this coal was not fine enough to obtain the best results, and after a number of experiments with different kinds of screens, a perforated screen ¼-inch in thickness, having ¼-inch round holes, spaced $\frac{7}{16}$-inch on centers was adopted as a standard. The result of a large number of determinations of the fineness of the coal through these screens is as follows:

Per cent. remains on				Per cent. passes through	
½-inch	¼-inch	$\frac{1}{16}$-inch	....	$\frac{1}{16}$-inch	....
.70	2.23	14.31	....	82.77	....

The crushers are all driven by electric motors, the first ones being belt driven. So much trouble was experienced with bearings and belts with this arrangement, however, that one of the motors was direct-connected to the end of the crusher shaft by a flexible coupling. The results were so satisfactory that all of the crushers are now driven by direct-connected induction motors having a speed of 720 revolutions per minute.

When work was started on the first plants, it was decided to install a central power plant, generating three-phase alternating current at 6,600 volts, and two 400-kilowatt generators, each driven by direct-connected cross-compound engines, were installed in the power plant. On account of the large amount of power consumed in crushing, it was soon found that the power plant, as originally proposed, would be entirely too small, and in 1904 a 750-kilowatt unit, direct-connected to a cross-compound engine was installed. In 1905, a duplicate of this was put in and in 1907, when the four new plants were started, a Westinghouse low-pressure turbine and Westinghouse high-pressure turbine were installed, each of these units being 1,000 kilowatt, and of course, each of them operating condensing.

On account of the scarcity of water, cooling towers were installed to cool the condensing water, and with the exception of a short time during the winter seasons, these towers have been in continual operation. The original boiler installation was four 300-horsepower, horizontal, water-tube boilers. With the additional power units, five 520-horsepower boilers were installed. These are being fired by Jones underfeed stokers, which are supplied with coal from an overhead bin filled by a larry. Duplicate pumps and feedwater heaters are also in operation. The rated capacity of the boiler plant is 3,000 horsepower, and the rated capacity of the power plant is 4,300 kilowatts. Every piece of apparatus at the entire 12 plants, with the exception of the hoisting engine and the fan at No. 1 shaft, is driven by current from the central station. Substations are located at each of the mines in which are installed 15 150-kilowatt rotary converters, furnishing direct current at 275 volts for the locomotives, mining machines, coke-drawing machines, mine pumps, etc. The direct-current load is about 26 per cent. of the current generated, induction-motor load being 74 per cent. In all, there are in addition to the rotary converters,* 8,483-horsepower induction, 6,964-horsepower direct-current motors, and 485-horsepower lighting transformers, a total of 15,932 horsepower, being supplied from the power house. These motors are classified as follows:

Alternating Current

	Horse-power	Per Cent.
Crushers	2,475	15.5
Fans	2,580	16.2
Pumps, outside	1,035	6.5
Compressors	420	2.7
Picking tables	289	1.8
Shops	174	1.1
Conveyers	420	2.6
Exciters	415	2.6
Spares, etc.	675	4.3
Lighting transformers	485	3.0
	8,968	56.3

Direct Current

	Horse-power	Per Cent.
Locomotives	3,215	20.2
Larries	380	2.4
Coke machines	568	3.6
Pumps, mine	260	1.6
Forge blowers	41	.3
Mining machines	2,440	15.3
Hoists	40	.2
Spares	20	.1
	6,964	43.7

The amount of current being generated is approximately 1,200,000 kilowatt hours per month, and the load factor is 39 per cent. The power consumption per net ton of coal produced is 4.7 kilowatt hours. The ratio of motors installed to generator capacity of power plant is 278 per cent., and the boiler capacity is 419 per cent. As previously stated, there are substations at each of the mines, nine of these stations containing one converter and three of them having two each. The substations are usually located at the drift mouth, and in most cases the motor driving the mine fans is in the same building. Usually the power transformers for reducing the high-tension current to 440 volts are located in these substations, although at some of the works it is more economical to have these transformers located closer to the tipples than to the substations, and in these cases they are located in separate buildings. The current is conveyed to the different substations from the power house by wooden pole lines, excepting in the case of the line from the central station to No. 6 works, where, for a distance of 7,000 feet, a very heavy galvanized steel tower line has been constructed. This line carries now two separate circuits, one for Nos. 6 and 7, and the others for Nos. 8 and 9 mines, and provision is made for a third circuit to proposed plants on the waters of Dry Fork. The wooden poles are located from 100 feet to 150 feet apart, while the steel towers are about 520 feet apart. The voltage used on the transmission lines is 6,600 volts, excepting on the line to No. 12 works, where 22,000 is used, the step-up being made by oil-cooled transformers in the power plant. The distance of this transmission is approximately 9½ miles. All of the transmission lines are calculated for 5 per cent. line loss.

The mines are all ventilated by fans, and excepting in the case of No. 8 mine, where two small wooden fans are in use, these are Clifford steel fans. Five of them are 20 feet diameter by 6 feet wide, one is 16 feet diameter by 6 feet wide, and six are 13 feet diameter by 6 feet wide. The delivery of these fans is, at full capacity, from 300,000 to 400,000 cubic feet of air per minute against a mine resistance of 4 inches. Excepting one fan at No. 1 shaft, all of these are motor driven, seven being belt driven, and five being direct connected. In every case the motors are two-speed induction motors, being run usually for 4 or 5 years at the lower speed before increased size of the mine demands the full capacity of the fan. The direct-connected fans are driven by motors having a capacity of 150 horsepower at 120 revolutions, and 300 horsepower at 240 revolutions per minute. These, of course, are now being operated at the lower speed. On account of the large percentage of induction load, the power factor conditions at the central station are not as good as they should be, and during this summer, two synchronous motors, to be used as rotary condensers and also to drive two of the mine fans, are being installed. The motors will be direct-connected to the fans by flexible coupling, will be self-starting, and will each have a capacity of 400 kilowatts. The useful work in each case will be about 200 horsepower, leaving the remaining capacity to improve power factor conditions. The motors are to operate at 187 revolutions per minute, and will replace two of the belt-driven units.

The gauge of track in all of the mines is 48 inches, and the original intention was to keep all of the mine cars uniform, the capacity selected being 93 cubic feet. On account of the low coal at Nos. 3 and 11 mines, however, it has been necessary to put a smaller car at these places, and at these two mines, cars having a capacity of 62 cubic feet are in use. These smaller cars have 14-inch wheels, all of the larger ones having 18-inch wheels and all $2\frac{3}{16}$-inch cold-rolled steel axles. The No. 11 mine is equipped with steel cars throughout, and at No. 9 mine, about one-half of the cars in use are steel of the semicylindrical type. At No. 10 mine a few steel cars are being tested, but at the remaining mines the cars are all of wood.

At six of the mines steel tipples have been erected, and two more are under construction this year to replace temporary tipples at Nos. 4 and 5 mines. At No. 3 mine a wooden tipple was erected originally on account of the time necessary to secure the steel, and at No. 8 mine a wooden tipple was erected to work out a small piece of coal which could not be conveniently worked to the permanent steel tipple which will be erected later. At Nos. 11 and 12 mines, the life of the plants are not sufficient to justify steel tipples. All of the tipples use Phillips automatic cross-over dumps and in every case the coal is dumped into a small hopper and from thence passed to the picking tables, all of which are 4 feet wide and are motor driven, running at a speed of 50 feet per minute. These picking tables at all of the coal plants feed directly into the chutes and then into the bins; at the coke plants the coal is fed from the picking tables to chutes to the crushers and from thence to the bins. At the No. 2 mine the dump is located at the foot of the slope, from which point an overlapping bucket conveyer carries it about 260 feet to the tipple. This conveyer is on a grade of 40 per cent. At No. 9 plant the difference in elevation between the mines on opposite sides of the hollow is so great that the coal from one is brought directly to the top of the tipple, while the coal from the other one is lifted to the same elevation by a rubber-belt conveyer 210 feet long, on an incline of 28 per cent. At No. 12 mine the coal is 600 feet above the loading point, and about 1,200 feet horizontally from it. The dump and picking tables are located at the top of the hill and the coal is brought down the hill by means of three retarding conveyers which discharge into each other and into the bin. At all of the later bins the gates are operated by compressed-air cylinders, and, as the bins are just the length of a car, it is no trouble to load a car of mine-run coal in 5 minutes. The air cylinders are controlled by three-way valves, operated by levers.

Excepting for the first two openings, which were timbered on account of lack of time, all drift mouths and all fan openings are arched with concrete.

At all of the coke plants the water supply for the ovens is obtained from the river or from the branches on which the plants are located when these afford water. The water is pumped from the streams by direct-connected motor-driven centrifugal pumps to large steel storage tanks. All plants have an auxiliary deep-well supply, which is used during the dry months of the late summer and fall. Three of the plants have deep-well pumps, but at all of the others air lifts are used, the water being blown into small tanks, from which the centrifugal pumps handle it. At four of the plants, large sumps have been excavated in the rock and concreted. In these the ground and stream water collects, and the well water is blown. At Nos. 9, 10, 11, and 12 works, the water supply is for house use only, and at these plants nothing but deep-well water is pumped.

The houses erected for the miners are all well built, of good size and conveniently arranged. They range in size from a single two-room house to a double five-room house, but by far the greater number are single three-room or double three-room houses, as this type seems to appeal more to the miners in this field than any other. Most of the houses are plastered, about 60 per cent. have water in the kitchen, about 80 per cent. are lighted by electricity, and a large percentage are fenced. The foremen's houses and houses of a better grade are built with cellars, bath rooms, and all the usual modern conveniences. At Gary a number of the better grade of houses are heated by steam from the main boiler plant. Prizes are offered each year for the best kept gardens and the best display of flowers around the houses. The lighter side of life has not been entirely neglected and at different works are ball grounds, tennis courts, etc., and at Gary the company built and operates a bowling alley and pool room. Under a lease from the company, a skating rink has been built and is operated at Gary, and furnishes a very convenient place for dances and meetings of all kinds. A moving-picture show was established by a lessee of the company, but this venture did not prove a success financially and has been abandoned. A bank has been organized by the employes of the company, and in a little over 3 years its savings account, on which interest is paid semiannually, shows deposits of more than $70,000 by the miners and other employes around the works.

WEIGHT OF FULMINATE OF MERCURY

The importers, E. I. du Pont de Nemours Powder Co., contended that the weight of fulminate of mercury on which duty was assessed was excessive. Protest was sustained. No attempt was made to weigh the article exclusive of the water accompanying it, on account of its highly explosive nature. Duty was therefore assessed upon the invoice weight of the merchandise. The merchandise was imported in canvas bags, which were themselves contained in rubber bags. These rubber bags were placed inside of small casks and each of these casks was contained in a larger cask. Water was placed in the rubber bags so as to prevent friction in transportation, and thereby prevent explosion. The decision says:

The invoice weight of the merchandise is shown to be 12,000 pounds. The weight of the fulminate after the extraction of the water is shown to be 11,661 pounds and 15 ounces, showing a difference between the article containing the water and without it of 338 pounds 1 ounce. The importers claim that no duty should be assessed on this amount of water. We think the contention is well taken and therefore reverse the decision of the collector and authorize a reliquidation of the duty so as to make an allowance by way of reduction from the invoice weight of 338 pounds.

TEACHING ENGLISH TO FOREIGNERS

By Peter Roberts *

A Practical Method for Use of Adult Foreign-Speaking Persons

The great need of the foreign-speaking mine workers is a working knowledge of English. They are anxious to understand the boss, to learn the art of mining, and know how to best preserve life and limb. A system which gives these men a working knowledge of English quickly and interestingly must commend itself to employers in the mining industry; such a system is the one issued under the caption: "English for Coming Americans."

Children of every nation learn with equal ease their mother tongue. They can do it because they depend wholly upon the organ of language—the ear, and practice their vocal organs to reproduce what they hear. This is nature's way to give her children practical knowledge of language; no sooner does a child learn a word or sentence than he uses it to make known his daily wants. By the time he is four or six years of age he can talk fluently, he understands what he is told, and when he begins his school life the teacher has a medium of communication through which knowledge may be given the child.

The foreign-speaking, when they come to America, are like the babe, deaf and dumb to the English language. They possess the organ of language—the ear; they have articulating organs. What they need is a wise and sympathetic teacher to train their ears to the English sound and help them to adjust their vocal organs to utter it. This is what the mother does, and every normal child talks; if it were systematically done with the foreign-speaking in the mines, every one of them would talk and understand every-day English within six months.

The foreign-speaking is like the child—in not knowing our language; but unlike him in possessing a mature intellect. Children's books don't interest him; lessons for children do not appeal to him. He has a logical mind, his daily life is rich in experience, he is employed in a specific industry, and he lives in a society that carries on its affairs by every-day English. These facts should be taken into account when we plan to give this man a working knowledge of English. The lessons should recognize the laws of logic; they should appeal to the adult mind; they should hitch on to his daily experience; they should pertain to the work he does; they should contain every-day English, such as is heard in the shop and on the street, in the mill, and in the mine.

The preparatory course in "English for Coming Americans" comprises 30 lessons, divided into three series:

A.—Domestic:

1. Getting up in the morning.
2. Getting wood to light the fire.
3. Lighting the fire.
4. Preparing breakfast.
5. Table utensils.
6. Eating breakfast.
7. A man washing.
8. A family of eight.
9. Welcoming a visitor.
10. Going to bed.

B.—Industrial:

1. Going to work.
2. Standing a prop.
3. Guarding against fire.
4. Cleaning and loading coal.
5. Drilling a hole.
6. Preparing a cartridge.
7. Fixing and starting a shot.
8. A man injured.
9. Looking for work.
10. Quitting work.

C.—Commercial:

1. Writing a letter.
2. Buying stamps.
3. Buying a ticket.
4. Going by train.
5. Pay day.
6. Buying a hat.
7. Going to the bank.
8. Sending money to the Fatherland.
9. Buying a lot.
10. Building a house.

Each lesson deals with every-day experiences, the sentences are simple but practical, the lessons conform to the laws of economics, the industry is carefully studied in the second series and the scholars are taught how to perform work as well as how to talk English. A new lesson is given each evening and the men are brought under new relations so that their interest is held.

A sample lesson will illustrate how the lessons are built. Take lesson first in Series *A*:

GETTING UP IN THE MORNING

awake	I awake from sleep.
open	I open my eyes.
look	I look at my watch.
find	I find my watch.
see	I see what time it is.
is	It is six o'clock.
must get up	I must get up.
throw back	I throw back the bed clothes.
get out	I get out of bed.
put on	I put on my pants.
put on	I put on my stockings and shoes.
wash	I wash myself.
comb	I comb my hair.
put on	I put on my collar and necktie.
put on	I put on my vest and coat.
open	I open the door of my bedroom.
go down	I go down stairs.

The language is simple, given in sentence form, which is the unit of language; it deals with a daily experience which it clothes with a new garment; the words are such as men use a thousand times a day, and the adult is interested and his attention held.

In our classes no books are given the pupils. Before the learner sees a word or writes a word of the lesson, he knows it all and can rehearse it as the teacher goes through the pantomime suggesting the various stages in the act of getting up. When the pupil is able to do this, he is given a sheet containing the lesson and he reads it. On the reverse side of the sheet the lesson is in script, and he writes it out copying from the sheet. Then the lesson is reviewed and comments such as "good," "that's right," "splendid," "fine," "first-rate," etc., thrust in by the teacher as the scholars rehearse, so that soon the pupils learn the proper use of these words and bring them to practice.

How long will it take a foreign-speaking man to learn such a lesson? About 30 minutes. Our classes last about an hour and a quarter, and if the teacher knows his business there is not a dull moment in the session. The scholar begins to talk the very first lesson and when he is through he has more than 50 English words which he can pronounce and use correctly in the connection in which he learned them. In subsequent lessons he meets words he knows, but under different relations, and he is interested in meeting old friends in new connections. The teacher reviews each lesson as he goes along, so that soon teacher and pupil converse in simple sentences, and by the time the 30 lessons are completed, the scholars will have command of between 600 and 700 words, used daily in the affairs of life. With this equipment he will be able to understand the foreman, do his work more intelligently, know the routine of the industry in which he is employed, and be better able to take care of life and limb in hazardous work.

*An address delivered before Mining Institute of America, June 28, 1910, at Uniontown, Pa

The system of teaching is not a philosophical scheme although based on sound philosophy. It has been in practice for two years, and last year nearly 10,000 men learned the English language by it. There are around each colliery in the country men who are able to take this system and by it teach English to the foreign-speaking employe in the mine. All that is needed is an organized effort. If the men in charge of the mining industry say, "it will be done," within a year every man now employed in the mines would have a working knowledge of English, and once this is realized the new men of foreign speech, entering the industry, can easily be taken care of.

I cannot point out the beneficent results that would follow. A few may be mentioned: fewer accidents; less destruction of property; less friction between employes; better understanding between employer and employe; the disappearance of the straw boss, the interpreter, the demagogue, and racial cliques; greater intelligence, better understanding of American industrial methods, and a sense of greater responsibility in social, political, and moral affairs.

COLLIERY SURVEY NOTES

Written for Mines and Minerals, by Ralph Shumway *

As a comparison with Mr. Harrison's system of note-keeping, described in the December, 1909, issue of MINES AND MINERALS, the following system may be of interest:

Method of Recording Notes Used by the Rocky Mountain Fuel Company

This form of notes is now being used very satisfactorily in all of our mines in Colorado. It is only intended for double-entry system of mining with room-and-pillar work; with all entries and rooms carried on sights.

Three sets of books are necessary to complete the record of the mine surveys. These books are standard I. P. loose-leaf books, provided with indexes and sheets which have been printed with the forms shown in the succeeding sketches. These three sets are:

1. Room books, using sheets shown in Fig. 1.
2. Entry books, using sheets shown in Fig. 2.
3. The office record, sheets shown in Fig. 3.

In using the room books, we record certain definite information at every extension of all working rooms. This information would be the pluses on all cross-cuts either from the mouth of the room or from the survey station in the room; the thickness of pillar at every cross-cut and the width of both rooms at every cross-cut, also the plus to the face of the room and the coal measurements at the face. The outline form, as printed on the room sheet, is intended to be used only where the rooms are run regularly. In some cases rooms are cut up very badly, necessitating the use of free-hand sketching, which is usually done on the opposite side of the page.

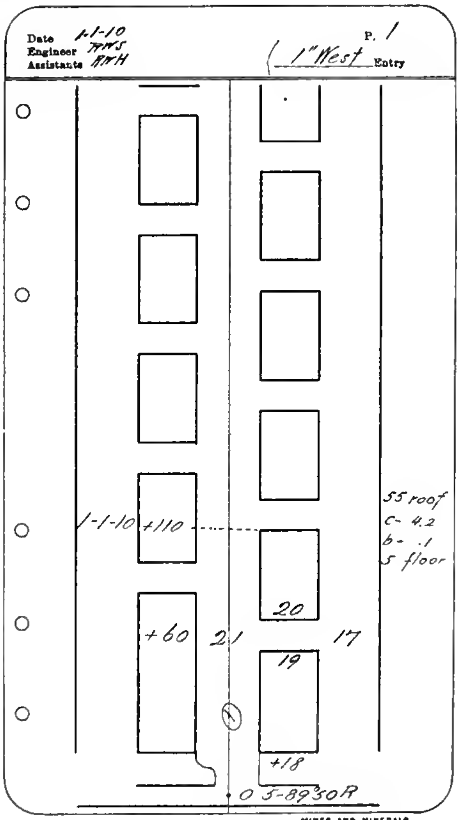

FIG. 1

In entry work the angles are read by deflection and doubled at each station. The record at each station includes the description of the station, needle course, vertical angle, including H. I. and F. S., horizontal angle, and slope measurement. The

FIG. 3

slope measurement is read going in the entry and again on leaving the entry. As side notes to the regular transit notes, are measurements of the thickness of coal at the face, including all impurities; the width of entry; the pluses on all cross-cuts and rooms; the thickness of pillar at the cross-cuts and the center to center of the entries. As in the case with the room notes, the printed form is used only in routine double-entry work. In case of cut-offs or single entries, sheets similar to Fig. 1 are used with sketch and the same notes, as described above, using the dividing line as the survey line.

In transferring entry notes to the office book, the essential notes of the transit survey are copied and the latitude and departures figured in the office book. This does away with the greater part of the labor of preparing an office copy. If it is necessary to use the latitude and departures at the mines, the office book can be taken along. In that case all the notes are in the field at one time, which is somewhat objectionable, but with a small engineering force it is found that the small amount of labor in copying notes more than compensates for this objection.

The advantages of loose-leaf notes are: All entry and room notes are continuous; compactness; ready accessibility; clearness, as it reduces to a minimum the necessity for free-hand sketching; readiness of expansion, as in the case of royalty measurements; a minimum amount of copying of notes.

As each entry or room is completed, the complete notes for it can be filed in the office under similar indexing.

THE ACID SPECIFIC-GRAVITY TEST

Written for Mines and Minerals, by A. Langerfeld

Amount of Impurities Allowed in the Various Sizes of Anthracite. Methods of Testing for Them

Anthracite to be marketable must be sized and cleaned. At every colliery there is an inspector who examines each car loaded for shipment, to ascertain its fitness for market. If he finds the coal contains too much rock, slate, or bone, or that it is rusty or muddy looking, or contains over or under sizes, he condemns the car, and the coal must be run through the breaker again.

For the sake of uniformity certain percentage quantities of coal under or over the size being shipped are made allowable; also certain percentage quantities of impure coal called "bone," and of slate or rock.

These are as follows:

1. Steamboat. Very little of this size is now made, and some collieries make none at all. The size is generally larger than 6 inches and every piece must be clean coal, and not much under size. It must be free from mud or discoloration.

2. Lump coal at some collieries is from 3-inch to 6-inch diameter, and at others, from 4-inch to 5-inch diameter. All pieces must be nearly pure coal, not much under size, and all free from discoloration.

3. Broken, or grate coal, must pass over about 2¼-inch round or 2¾-inch square holes, and the largest pieces must pass through about 4½-inch round or 4-inch square holes. It may contain an unobjectionable admixture of larger or smaller pieces; 1 per cent. of pieces of slate or rock (stones), and 2 per cent. of pieces of bone.

Pieces of material containing less than 40 per cent. carbon are classed as "slate," and pieces containing hardly any carbon are classed as "rock." Pieces containing from 40 per cent. to 65 per cent. of fixed carbon are classed as "bone," and pieces containing over 65 per cent. of fixed carbon are classed as coal. At some collieries 70 per cent. carbon, instead of 65 per cent., is classed as coal. The inspectors use their judgment in deciding the quality of each piece, but if a dispute arises, samples of the disputed kinds of pieces are sent to a chemist and analyzed. A sample piece of the analyzed quality is then kept on hand for comparison. This is generally accomplished by comparing the colors and apparent specific gravities by holding the pieces in the hand.

There is generally a close agreement between inspectors as to the quality of a car of coal, or of any one piece, but not always. One piece of coal in my possession was pronounced good enough to pass as coal by one inspector, as bone by another inspector, and as slate by another one. But this is a peculiarly exceptional piece. Sometimes there is an equally wide difference of opinion as to the quality of an entire car of coal, for instance, a car of washery buckwheat coal was billed by the inspector as containing 8 per cent. slate, but at the destination the receiving inspector stated it contained 40 per cent. slate. This is an exceptional case, due to discoloration after drying, but it proves that for small sizes of coal the "hand test" alone is unreliable, and therefore the more positive specific-gravity test is in use at some collieries.

Egg coal which is next smaller in size to broken coal varies at different collieries. The smallest pieces pass over 2-inch square holes and over 2¼-inch to 2⅝-inch round holes; the largest pieces pass through 2¾-inch square holes or 3¼-inch round holes. Egg coal may contain up to 5 per cent. oversize and 10 per cent. undersize; also 2 per cent. slate or rock and 2 per cent. bone. It must be fairly free from mud or discoloration.

Stove coal passes through 2-inch to 2⅛-inch square holes and over 1⅜-inch square or 1½-inch round holes. It may contain 5 per cent. egg and 10 per cent. chestnut; also 4 per cent. slate or rock and 3 per cent. of bone. This appears to be a transposition of percentages because there is always more bone than slate in anthracite, but the standard specifications are written that way for this size. Stove coal must be free from mud, and fairly free from discoloration.

Chestnut or nut coal passes through 1⅜-inch square holes or 1½-inch round ones, and over ¾-inch square holes or ⅞-inch round ones. It may contain 5 per cent. oversize and 10 per cent. of undersize, called pea coal, and 5 per cent. of undersize called buckwheat No. 1. It may contain 5 per cent. slate or rock and 5 per cent. bone. Chestnut coal must be free from mud and discoloration.

Pea coal passes through ¾-inch square holes or ⅞-inch to $\frac{15}{16}$-inch round holes and over ½-inch square holes or $\frac{9}{16}$-inch to ⅝-inch round holes. It must not contain an objectionable quantity of larger sizes, over 15 per cent. of buckwheat No. 1, 5 per cent. of the size termed rice, nor more than 10 per cent. of slate or rock, and not much more bone than slate. Its color must be fairly bright.

Buckwheat No. 1 passes through $\frac{7}{16}$-inch to ½-inch square or $\frac{9}{16}$-inch to ⅝-inch round holes, and over ⅜-inch to $\frac{5}{16}$-inch round holes or ¼-inch square ones. It may contain an unobjectionable admixture of oversize but not more than 15 per cent. of smaller coal, nor more than 15 per cent. of slate or rock, and not so much bone as to make the mass look dull in color. It must be washed free from mud and not contain more than 2 per cent. of ashes if it is washery coal. Ashes are also counted in as part of the allowable slate.

Buckwheat No. 1 is the largest size to which the specific-gravity test is applied. One large coal company has adopted the rule that from 15 per cent. to 18 per cent. of the pieces in buckwheat No. 1 size may be heavier than 1.7, so that in an "acid test," made by throwing a sample into a liquid of 1.7 specific gravity, at least 82 per cent. of the sample will float.

Rice coal passes through $\frac{5}{16}$-inch to $\frac{11}{32}$-inch round or ¼-inch square holes, and over $\frac{3}{16}$-inch round or ⅛-inch square ones. The quality of rice coal is not specifically defined, but must present a good appearance and be free from mud. It is generally understood that it may contain up to about 20 per cent. slate. Rice coal is sometimes subjected to the acid test, and is then generally allowed to contain up to 25 per cent. of pieces heavier than 1.7.

Barley coal passes through $\frac{3}{16}$-inch round or ⅛-inch square holes and over $\frac{3}{32}$-inch round holes. It must present a fairly bright appearance and is not generally tested specifically.

Culm or "gun powder" size is all that passes through $\frac{3}{32}$-inch round holes. It is also called slush. Lately it is being burned in many of the steam plants near the mines, and in some chemical works; some of it is also being used for making briquets.

Birdseye coal is a mixture of rice and barley sizes. Chestnut and larger sizes are called "prepared sizes." Pea is in a class by itself, while buckwheat, rice, and barley, are called steam sizes.

When a car of coal contains considerably less slate or rock than the maximum allowable percentage, then for each per cent. less slate 2 per cent. more bone is generally permissible in that car. Approximately the percentages of the different sizes produced in a breaker are: Steamboat, little; lump, 3 per cent.; broken, 10 per cent.; egg, 13 per cent.; stove, 20 per cent.; nut, 19 per cent.; pea, 18 per cent.; buckwheat No. 1, 10 per cent.; rice, 3 per cent.; and barley, 4 per cent. These percentages depend on the hardness and friability of the coal, and also on the demand for prepared sizes. Often there is no demand for stove and larger sizes which are produced in the mines, and then it becomes necessary to break and so reduce them to nut size. The percentage of coal lost by this method of reduction varies from 5 per cent. to 8 per cent. of the coal mined. This totals an enormous loss during a year, which will, it is to be hoped, be reduced to less than 2 per cent. by the use of modern breaker machinery.

The impurities contained in anthracite are slate, rock,

fireclay, pyrite, and bone. Rock is any kind of stone nearly free from coal; fireclay is also nearly free from carbon; slate may contain as much as 40 per cent. coal; pyrite is generally diffused through pieces of coal and slate, or occurs in small cubical crystals. In some coal beds there are occasional pieces of pure white stone which are principally either lime or magnesia. This is generally produced by percolation into cracks or fissures.

Fireclay is usually immediately below the coal, but it also occurs in bands in the coal. Therefore it comes into the breaker and is classed as slate or rock. It varies in hardness from clay to slate and in specific gravity from 1.9 to 2.5 according to the quantity of coal it contains. Slate in the anthracite measures varies in specific gravity from 1.75 to 3, according to the admixture of carbon or pyrite.

The rock varies in specific gravity from 2.5 to 4, according to the admixture of pyrite.

Pieces of pyrite run from 3 to 5 in specific gravity according to the proportions of coal and slate they contain.

The specific gravity of the lightest pieces of pure Bernice anthracite is only 1.38, but most of the hard anthracite runs from 1.45 to 1.5. Analyses made by Pennsylvania Second Geological Survey give the specific gravity of hard anthracite at from 1.54 to 1.68. This is inclusive of bone and slate, producing from $5\frac{1}{2}$ to $13\frac{3}{4}$ per cent. of ash. The specific gravity of bituminous coal is often only 1.27.

Pieces of anthracite containing only 65 per cent. of carbon theoretically vary in specific gravity from 1.77 to 2.72, because pieces consisting of 65 per cent. of the lightest pure anthracite of 1.38 specific gravity and 35 per cent. of the lightest slate of 2.5 specific gravity, have a specific gravity of 1.77, and pieces consisting of 65 per cent. of anthracite of 1.5 specific gravity and pyrite of 5 specific gravity, have a specific gravity of 2.72. There are few such heavy pieces that could be classed as coal, but in the Buck Mountain coal bed there are many pieces of passable coal whose specific gravity is nearly 2, which in weight is equal to much of the light slate. For this reason a specific-gravity test usually differs materially from a hand test depending on looks and feeling. There is generally a difference of from 3 to 5 per cent. between a hand test and an acid test of buckwheat No. 1. The hand test is usually lower for impurities than an acid test, because many pieces are specifically as heavy as slate and will therefore sink with slate, while in appearance they are good coal. For this reason an acid test made by floating the coal in a heavy liquid only is not very definite. It only shows the percentage of pieces which are lighter than the liquid used, and the percentage of pieces that are heavier. The lighter pieces are sure to be coal, but of the heavier ones some are usually also passably good coal containing some sulphur and iron, or other substances whose specific gravity is higher than that of coal. The method of testing coal by floating it has been called the acid test because sulphuric acid, properly diluted with water, was mostly used as the heavy liquid.

When a dry sample of coal is tested it will show a considerably smaller percentage of slate than when tested damp, because dry slate is lighter than damp slate; and when a wet sample is tested, the adhering water reduces the specific gravity of the liquid, and therefore shows a larger percentage of pieces over 1.7 than the same sample would show dry or damp. In order to obtain uniformity the sample should be wet and the liquid should be tested for its specific gravity after putting in the sample of coal, and then brought up to 1.7 specific gravity before taking out the sample.

If in a piece of coal containing pyrite the coal part has a specific gravity of 1.5, then only 6 per cent. of pyrite makes the specific gravity of this piece 1.71, and the piece will sink in a 1.7 liquid. The acid test applied to such a piece therefore classes it as slate or refuse. But any inspector would pass such material as good coal by its appearance. Similarly a piece containing only 3 per cent. of pyrite and about 11 per cent. of slate would sink in a 1.7 liquid although it contains 86 per cent. of coal and is therefore commercial coal. A piece containing only 1 per cent. of pyrite and about 18 per cent. of slate would also sink in a 1.7 liquid although it would contain 81 per cent. of coal and is therefore also commercial coal. Such a piece of coal is classed as slate or refuse by an acid test, but would be classed as coal by a hand test.

These are the reasons why there is generally a difference of several per cent. between an acid test and a hand test, and why the hand test is more nearly correct. But a hand test is not as uniform as an acid test, because a hand test is a matter of personal judgment of the inspector, and this is almost sure to vary as much as anything else that depends on the personal equation, as illustrated by the tests mentioned for the car of buckwheat coal. As a rule the difference in hand tests is less than 1 per cent. for prepared sizes and seldom over 3 per cent. for steam sizes.

For testing steam sizes the greatest advantage of the acid test is that it can be made very quickly, while a hand test of a sample containing so very many small pieces takes considerable time.

The quickest and best way to test steam sizes is to first separate all the pieces lighter than 1.7 by floating them, and then pick the heavier pieces over by hand to complete the separation of all the pieces that are commercial coal. In most cases the retesting by hand of the pieces heavier than 1.7 gives about the same result as an acid test in a 1.75 liquid.

When coal is tested only for slate, or pieces heavier than 1.7, the test does not show the actual quality of the coal, because the percentage of bone also makes a material difference in the heating quality of anthracite. But there is a far greater variety of bone than there is of slate. It is claimed that certain kinds of bone actually produce more heat when burned than pieces of pure coal, generally called "glassy" coal. Glassy coal is jet black and lustrous. Until a few years ago the so-called "blue" coal was all classed as bone. "Blue" coal is dull black, bluish black, or grayish. It occurs in all grades from nearly pure coal to nearly all slate. It is a substance in which coal and clay or other materials are homogeneously mixed, and it often contains considerable pyrite and some graphitic coal. Blue coal is therefore always heavier than glassy, or pure coal, and its specific gravity is from 1.5 to 2. When it contains no iron or sulphur its acid test agrees closely with a hand test, but when it contains considerable pyrite or other heavy materials, its specific gravity is increased far more than its appearance as being bone or slate. The variance in classification between such blue coal tested by specific gravity and by appearance is therefore greater than for bone, in which the slate occurs in layers.

In order to ascertain by specific gravity the percentage of bone or bony pieces in a sample of coal, it is necessary to use two heavy liquids; one for floating coal, and one for floating bone and sinking slate.

To do this it must first be decided what the specific gravity of the heaviest pieces of coal may be, and then the liquid for floating this coal should be a little lighter. Having already adopted 1.7 as the limit for pieces passable as coal and good bone of buckwheat size, it is necessary to adopt a lighter liquid than this for floating only coal, because in testing buckwheat all the coal and fairly good pieces of bone are classed as coal. So far none of the coal companies have used two heavy liquids for one test, but they will probably do so when coal prices go higher for steam sizes, because the consumers will be more particular about wanting to know the quality of the coal.

A piece containing 66 per cent. of coal of 1.45 specific gravity and 34 per cent. of slate of 2.5 specific gravity will have a specific gravity of 1.8 theoretically, but the actual specific gravity of a piece of that composition or quality is usually considerably less than that. The reason for this is the presence of from 4 to 6 per cent. of moisture and some occluded gas. If only $\frac{1}{10}$ per cent. of marsh gas of about .00065 specific gravity

(water being unity) is in a piece containing 66 per cent. coal, 5 per cent. water, and the rest slate, then the specific gravity of this piece is only 1.74. In practice, all the pieces that float in a 1.75 liquid are classable as either coal or good bone in buckwheat No. 1 size, and this generally gives a test of about 3 per cent. less slate than a test in a 1.7 liquid. In view of the fact that pieces containing from 40 to 65 per cent. of pure coal are classed as bone, the liquid for floating bone should be at least 1.8, because a piece containing 40 per cent. of pure coal, or fixed carbon as is usually said, of 1.4 specific gravity, 6 per cent. moisture of 1.1 specific gravity, $\frac{1}{10}$ per cent. marsh gas of .00065 specific gravity (water unity), and the rest slate of 2.5 specific gravity, would be of 1.973 specific gravity. A liquid for floating this would therefore have to be of about 1.98 specific gravity. In practice it is not necessary to make the liquid quite so heavy. This is probably because there is always some air in the crevices and recesses in pieces of anthracite. For testing with two liquids it has been found that 1.85 and 1.65 gravity gave good results.

Experiments made to test coal for specific gravity by displacement in water were not successful, because when a number of small pieces are immersed in water it is almost impossible to force all the air bubbles from between the pieces and out of the crevices in the pieces, and the presence of a small quantity of air makes such a test very inaccurate.

The rule for calculating the specific gravity of material containing various substances is simple if the quantity or proportion of each substance and the specific gravity of each are given. It is as follows:

RULE.—Divide the weight of each ingredient by the weight of the whole piece, and multiply each quotient by the specific gravity of the respective ingredients. Add these products together. Divide this sum into the weight of the piece. The quotient gives the specific gravity of the piece.

EXAMPLE.—A piece of bone weighs $2\frac{1}{2}$ pounds and contains $\frac{1}{2}$ pound slate of 2.5 specific gravity, and $\frac{1}{10}$ pound of pyrite of 5 specific gravity. The remainder, 1.9 pounds, is coal of 1.45 specific gravity.

$$\frac{1}{2} \div 2\frac{1}{2} = \frac{.5}{2.5} = \frac{.1}{.5} = \frac{1}{5} \text{ and } \frac{1}{5} \times 2.5 = .5$$

$$\frac{1}{10} \div 2\frac{1}{2} = \frac{.1}{2.5} = \frac{1}{25} \text{ and } \frac{1}{25} \times 5 = \frac{5}{25} = \frac{1}{5}$$

$$1.9 \div 2\frac{1}{2} = \frac{1.9}{2.5} = \frac{19}{25} = .76 \text{ and } .76 \times 1.45 = 1.102$$

$.5 + .04 + 1.102 = 1.642$ and $2.5 \div 1.642 = \frac{2.5}{1.642} = 1.523$, the specific gravity of the piece.

By simple equation any one unknown ingredient can be found. If it is desired to find out how much of any one ingredient must be added to give the composition a certain specific gravity, the calculation is easily obtained from the formulas:

$m_1 + m_2 = 100$, and $S_1 m_1 + S_2 m_2 = S_3$,

m_1 and m_2 are the percentages of the materials in the composition, and S_1 and S_2 the respective specific gravities. S_3 is the specific gravity of the composition. Then: $m_1 = 100 - m_2$, $m_2 = 100 - m_1$, and then $S_1 m_1 + S_2 (100 - m_1) = S_3$.

There are many ways of making heavy liquids or solutions. The cheapest is sulphuric acid diluted with water, but it is so dangerous to handle and destroys so much, that it is better to use something else. The next cheapest heavy liquid is a saturated solution of calcium chloride with enough zinc chloride added to give the double solution the desired specific gravity. A saturated solution of commercial calcium chloride at a temperature of about 65 degrees has a specific gravity of 1.41, and a saturated solution of commercial zinc chloride 1.85 to 1.9. The specific gravity of a saturated solution of calcium chloride can be raised to 1.55 by adding zinc salt, but no higher, except by warming it and keeping it warm. It is most convenient to use only zinc chloride, and this is not expensive.

The Thoulet solution described in MINES AND MINERALS of April, 1910, has a specific gravity of 3.2, which is more than is required for coal, bone, or slate. It also costs very much more than zinc chloride.

A saturated solution of copperas with 1 part common salt for 25 parts of the copperas will make a heavy solution if kept hot, but is only heavy enough for floating coal, and not bone.

COAL MINING IN INDIA

Statistics which have been published by the Board of Trade relating to coal mining in India show that the quantity produced has steadily risen since 1886. In 1878 the total amounted to 1,015,210 tons, whereas in 1908 it had increased to 12,769,635 tons. Up to 1905 the Raniganj field held the premier position as regards quantity, but it is now second, its output in 1908 being 4,221,781 tons, or 33 per cent. of the year's total. The Jherria fields had the largest production in 1907, and in 1908 it increased its lead by yielding nearly $6\frac{1}{2}$ million tons, or about half the total production. About 90 per cent. of the coal mined in India during 1908 was produced in Bengal. The remainder was raised principally in Nizam's Territory, Assam, and the Central Provinces. During the years 1904-5 to 1908-9 the exports, including bunker coal, amounted to 7.28 per cent. of the production.—*London Times.*

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates:

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED JUNE 7 TO JUNE 28, 1910, INCLUSIVE

No. 960,867. Giant powder cap, James Henry Fahy, Goldfield, Nev.

No. 960,852. Mine car wheel, Thomas Donohoe, Avella, Pa.

No. 960,958. Coal-mining machine, Lotte Kovatch, Oliveburg, Pa.

No. 960,782. Feeder for tube mills, Everest A. Baylis, Madera, Mexico.

No. 960,441. Production of fine metal tungsten, Elihu Thomson, Swampscott, Mass.

No. 960,940. Art of constructing tunnels in the earth, George W. Jackson, Chicago, Ill.

No. 961,298. Prospector's needle, Dell W. Jewell, Kalamazoo, Mich.

No. 962,040. Apparatus for electrical treatment of ores, William B. McPherson, Los Angeles, Cal.

No. 962,383. Process of treating ores, Elizabeth Barnston Parnell, Carshalton, England.

No. 961,846. Sink-and-float testing apparatus, George R. Delamater, Strong, Colo.

No. 962,493. Method of making sulphuric acid from smelter gases, John Parke Channing and Frederic John Falding, New York, N. Y.

No. 962,612. Means for extracting gold from river beds, John H. Batten, Jamestown, Cal.

No. 962,636. Gold-saving apparatus, William H. Hackney, National Soldiers Home, Cal.

No. 963,002. Mine ventilating apparatus, William Dunn, Wheatland, Pa.

No. 962,678. Ore concentration, Henry Livingstone Sulman, Henry Howard Greenway, and Arthur Howard Higgins, London, England.

No. 962,990. Ore concentrator, Seth R. Swain, Denver, Colo.

No. 962,998. Ore, mineral, and coal breaker, Isaac Christ, Tamaqua, and Henry K. Christ, Mahanoy City, Pa.

No. 962,575. Ore separating or concentrating machine, Walter R. Lins, Philadelphia, Pa.

THE WIND ROCK COAL MINE

*By W. S. Hutchinson**

The Wind Rock Coal and Coke Co. derives its name from Wind Rock, Anderson County, Tenn., which is about 4½ miles north of Oliver Springs. Wind Rock No. 1 Mine is on the southern edge of the Wartburg coal basin, at an elevation of 2,400 feet above the sea level. Its location commands a splendid outlook over the valley to the south. Wind Rock can be reached from Khotan, on the L. & N. Railroad, or from Oliver Springs, on the Southern Railroad.

Undermining by Continuous-Cutting Machines. Use of Coal-Loading Machine. Haulage Systems

The mine was opened in the early part of 1904 by the Wind Rock Coal and Coke Co., composed of Knoxville business men who were considerably delayed in the development of the property by encountering a split in the coal bed composed of hard fireclay, which has since been exploited and found to be confined to 200 acres. The extent of the split, which is lenticular in shape, with its major axis line approximately parallel to Walden's Ridge, was ascertained by driving a pair of entries on the bottom bench of coal. Its maximum thickness was found to be 35 feet. Further exploiting was carried on by skirting the edge of the split and by outcrop prospecting. In 1905 the Wind Rock Mine was purchased by the Bessemer Coal, Iron, and Land Co., of Birmingham, Ala., which now operates the property, consisting of 4,000 acres, as measured within the 30-foot crop line. The entrance to the mine is shown in Fig. 1.

Fig. 1. Entrance to Wind Rock Mine

Geology.—The seam of coal operated probably belongs to the lower Kanawha measures and is known locally as the Dean seam. It is high in the mountains and extends throughout the Wartburgh coal basin, having extensive workable areas in Campbell, Anderson, Morgan, and Scott counties in Tennessee, and also in Bell County, Kentucky.

The inclination of the seam is from 1 to 2 per cent. to the northwest, which is practically in the same direction as the course of the main entry of the mine, shown in Fig. 1, which unfortunately furnishes a grade against the load. This, however, is unavoidable, because the location of the railroad relative to the mine and tipple renders this arrangement necessary. The average height of the coal bed on the entire property, as determined by outcrop openings and prospect holes, differs slightly from the thickness of the coal in the mine proper, which averages 4 feet 9 inches. The roof is exceptionally good, being of solid blue slate from 15 to 30 inches in thickness; and the floor is a massive sandstone formation. At certain points in the mine a soft, white, fireclay, which lies just below the coal, causes trouble and expense by softening and heaving the floor of the excavation as increasing pressure comes on the pillars. This condition of creep seems to be unavoidable, and is not uncommon in mines.

* Knoxville, Tenn.

The analysis of the coal is as follows: Moisture, 1.90 per cent.; volatile matter, 38 per cent.; fixed carbon, 56.64 per cent.; ash, 3.46 per cent.; sulphur (taken separately), 59 per cent,

Coal from this mine is an excellent steam fuel and the entire output is readily disposed of to the railroads in Georgia and Florida.

Mining System.—The mine is developed on the room-and-pillar system, as indicated by the plan, Fig. 2. The main entries and air-course are driven almost due northwest. On the main entry, all cross or butt entries were turned off at right angles to the main entry, but considerable trouble was experienced from cracks in the roof, causing bad top in the butt entries.

Later this trouble was successfully avoided by turning all cross-entries at an oblique angle to the main entries. On entries next to the outcrop, rooms and pillars are each 21 feet wide, with the room necks 21 feet long by 10 feet wide. On all other entries the rooms are driven 30 feet wide with 25-foot pillars, and room necks 10 to 12 feet wide and 21 feet long. In all cases from 150 to 250 feet of solid coal (depending on the amount of cover) is left on each side of the main entries before the first rooms are turned on the various cross-entries.

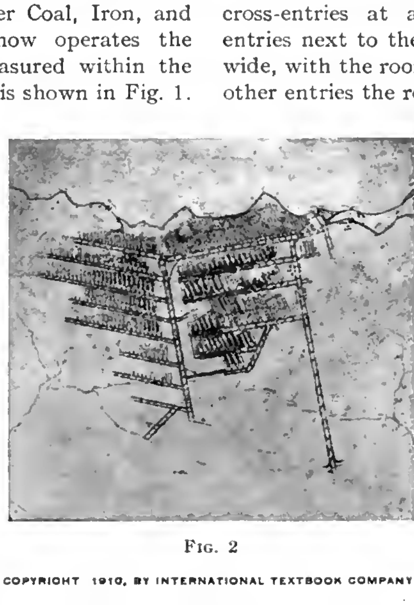

Fig. 2

In all cases, except as noted above, the rooms are driven in 215 feet, leaving 20-foot barrier pillars between the faces of the rooms and the air-course to the next pair of cross-entries beyond. The pillars are at once robbed back to a point within 65 feet of the entry rib. The cross-entries are driven on 40-foot centers, leaving a barrier pillar on the lower side of the air-course. About 75 per cent. of the pillars are cut with machines of the Sullivan

type, one of which is shown in Fig. 3 to be half-way through the pillar on a corner cut, the remainder of the coal being won with hand picks for the sake of safety.

An original modification of mining on a retreating-block system is now being tried. Narrow rooms are driven in pairs on cross-entries on 175-foot centers. When the rooms are driven up, the room pillars are undercut so long as it is safe to do so,

Fig. 3. Making the First Cut

after which the remainder is undercut by hand. The track is advanced after each cut to facilitate loading. The advantage gained lies in the long faces, which are worked quickly and effect a saving of time by concentrating labor, equipment, etc. The roof is carried on timbers until the coal is removed and retreat is made behind a new pillar.

Undermining.—The output is at present about 1,000 tons of coal per day of 9 hours. The coal is all undercut before it is shot, 70 per cent. of the total being mined by Sullivan continuous-cutting electric chain machines, shown in Fig. 5, to be crossing the face of the room under its own power without changing jacks or backing from the face. This machine is the one shown in Fig. 3, disconnected from its starting frame. The remainder of the coal is mined with hand picks and with two chain breast machines. The Sullivan machines are of the low-vein pattern, four cutting to a depth of 6 feet 3 inches, and the fifth, 5 feet 3 inches. They make a cut 5 inches high and are used largely for cutting the long room pillars, where their continuous-cutting principle of operation renders them both rapid and economical. The machines are also employed in mining rooms previous to slicing the pillars and in narrow work in their vicinity. The average rate of cutting is seven to eight 30-foot rooms per shift of 9 hours, each machine furnishing coal for from 20 to 25 loaders. One machine runner recently cut eight rooms 30 feet wide and three narrow places in one shift.

It is found that the best results are obtained by undercutting from 2 to 3 inches above the floor. Owing to its friable nature the coal left at the bottom of the cut is shattered so that it can readily be shoveled up from the floor wherever it has been undercut.

The cost of undercutting the coal with the Sullivan machines is $3\frac{1}{2}$ cents per ton run-of-mine, for room work, with a bonus of 30 cents per place for narrow work. On pillar work and on all cuts 60 feet long and over, the cost per ton is 3 cents, run-of-mine. These costs, of course, include both the machine runner and helper. Twenty-two cents per ton is paid for loading coal over 4 feet in height, with 10 per cent. added when the coal is under 4 feet. This last price includes shooting, loading, and timbering. In blasting in 30-foot rooms, 12 to 14 inches of powder is used in each rib, and in entries about the same amount of powder is required. The average cost for powder per ton of coal is from $\frac{3}{4}$ cent to 1 cent. This low powder cost is due to the fact that undercutting causes the coal to fall readily.

The undercutting is done entirely on the night shift, except the narrow work, which is double-shifted and the coal is loaded out during the day time. This prevents the mining machines being delayed by car blockades or locomotives, when being moved under their own power from place to place, as shown in Fig. 7. It also permits the use of a smaller power plant than would be possible if the undercutting and transportation were carried on at the same time.

Loading Machine.—A coal-loading machine, one of the first built for use at a coal face, is an interesting feature of the underground equipment. This apparatus is practically a dirigible shovel, mounted on a self-propelling truck, which carries also a front and rear endless conveyer. The latter is also dirigible through about 11 feet of arc. The shovel is designed to work in a seam $4\frac{1}{2}$ feet in thickness or higher. It has a capacity of 250 pounds per stroke and makes from 18 to 20 strokes per minute, the machine cleaning up the room from the two tracks, one beside each room pillar. Electricity, gasoline, air, or steam, can be used in this machine for power. Four electric gathering locomotives, one electric train locomotive, two reserve locomotives, and two mine pumps complete the mine equipment.

Haulage.—The method of moving loaded and empty cars is as follows: The cars in the rooms are trammed from the room

Fig. 4. Incline, Wind Rock Mine

neck by the miners and are brought to the mouth of the cross-entry by a gathering locomotive. The tram locomotive coming in switches its empty cars to the gathering motor and picks up the loaded cars. No side tracks are used.

Changing cars is usually accomplished in the following manner: The tram motor, pulling an empty trip in, deposits its empty cars on a cleared cross-entry track, then goes forward

to the next cross-entry and picks up a load. A gathering locomotive distributes the empties left on the first cross-entry and substitutes loaded cars. When a cleared cross-entry is not to be had, the tram locomotives makes a flying switch of its empties to the main entry and switches itself into a loaded butt-entry track. The empties are then delivered to the various rooms, as required, by the gathering motors while the tram motor takes its load to the outside. When the grade permits, the tram motor comes in ahead of its empties, gathers its load as it advances along the entry, and pushes them ahead, distributing the empties as it goes and then returning with the loads.* These methods of course necessitates a large supply of mine cars, some 300 being in use.

Two and one-half per cent. is the steepest grade against the loads on the main entry. The cross-entries are very undulating with a maximum grade of 13½ per cent., which, however, is in favor of the load. On the cross-entries wrecks were frequent formerly, but this trouble has been partly eliminated by replacing the 20-pound rails first used by 35-pound rails, and maintaining a solid roadbed.

On reaching the surface the cars are hauled over the weighing scales to the tipple, where the coal is dumped into monitors, which run by gravity over a standard-gauge inclined plane, to the lower tipple, where the coal is dumped into railroad cars and weighed for shipment. The monitors have a carrying capacity of 10 tons each, and are run double or in tandem, i. e., each trip carries a net load of 20 tons to the lower tipple.

The total length of the incline, a part of which is shown in Fig. 4, is 4,350 feet, and the difference in elevation between the top and bottom is 1,300 feet. The average grade of the incline is 32 per cent., with a maximum grade of 54 per cent. The average time required to run a trip over the incline is 3½ minutes.

The haulage drums are arranged in tandem, the front drum being 8 feet in diameter with four grooves, and the rear drum, 9 feet in diameter with five grooves. The drums are provided with differential groove rings and with 10 inches of brake surface on each side of the grooves, so that the speed of the monitors may be governed with a hand-brake, operated by a man in the tipple. The rope used is 1⅜-inch plow steel, "lang-lay" type so well adapted to inclines where the rope comes in contact with rollers and ties.

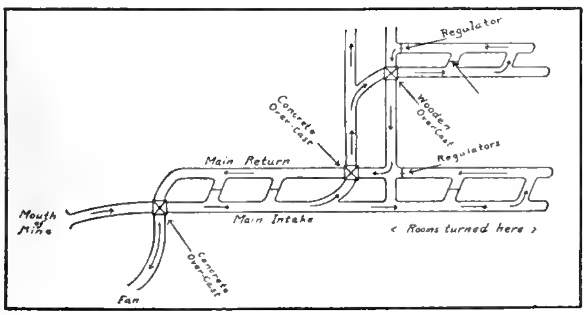

FIG. 6. PLAN OF VENTILATION

Ventilation.—Ventilation is accomplished by means of the split system. The air-current is, so far, split eleven times. Cross-entries, which are driven 1,800 feet as the standard lengtn, off the butt panels, are furnished with wooden overcasts built of 6"×8" framing, boarded on both sides, with clay tamped between the boards. For permanent overcasts, however, quarried sandstone, laid in Portland cement, is used. A plan of the ventilation is shown in Fig. 6.

In the air stops on cross-entries 6"×8" framing is employed, boarded on both sides, with clay filled in between the boards. On all main entries sandstone and Portland cement air stops are used, these being 18 inches thick with a buttress on each side, having a base of 3½ to 4 feet. The buttresses are used for stiffening where the air stops are over 5 feet in height. The regulators are ordinary wood air stops, with a slide-door device that can be locked for any required opening.

FIG. 5. CUTTING ACROSS THE FACE

The fan is of the disk type, belt driven by an electric motor and runs exhausting. It displaces 50,000 cubic feet of air against a ¾-inch water gauge with 310 revolutions per minute.

Surface Plant.—The power house is 250 feet from the pit opening. Direct current at 250 volts is furnishd by two units, one a 150-kilowatt engine generator, direct-connected for the day load; the other a 200-kilowatt engine generator, direct-connected, used for the machine load on the night shift.

A boiler room, equipped with two 150-horsepower high-pressure water-tube boilers adjoins the power house. Coal for the boilers is hoisted from the outside tram road level to the boiler room by means of a small steam hoist.

The water supply is obtained from three small mountain streams which empty into a reservoir constructed in a convenient hollow in the mountain side. The retaining wall is 35 feet in height and has a 15-foot base, channeled 2 feet deep out of solid rock. The wall has a batter of 3½ inches to the foot, giving it a crest nearly 5 feet wide.

The reservoir pumping plant consists of a 5"×8" triplex, electrically driven pump, which raises water through a 2-inch pipe line to a vertical height of 400 feet and discharges it into a 16,000-gallon tank. It is rain and surface water, well suited for boiler use, as it causes little or no corrosion or scale. It is interesting to note that the reservoir has been well stocked with black bass by the government by way of furnishing diversion for the company men during a scarcity of orders.

A well-equipped machine and blacksmith shop, motor barn, fan, oil and tip house, and saw mill, comprise the rest of the surface buildings and equipment.

The writer is indebted to Mr. C. H. Thompson, General Manager of the Wind Rock Coal and Coke Co., for data used in the

*This method of switching is not recommended, as there are too many flying switches and the locomotive should never be behind the trip either going in or coming out.—EDITOR.

preparation of this article and to Messrs. Doyle, Mine Foreman, and Scarborough, Night Foreman, for assistance in securing photographs.

BUREAU OF MINES RESCUE STATIONS

The location of three of the nine new rescue stations recommended for the coal fields of the country by the Secretary of the Interior as a means of reducing the number of deaths in coal mines has been determined upon by George Otis Smith, acting director of the Bureau of Mines.

The first will be at Birmingham, Ala.; the second at Huntington, W. Va., and the third at Wilkes-Barre, Pa. The Alabama station will be accessible to the coal fields of Alabama, Southeast Tennessee, and Northwest Georgia. The Huntington station will cover the coal fields of Southern Ohio, Western West Virginia, and Northeastern Kentucky. The Wilkes-Barre station will cover the entire anthracite fields. Other stations will be established throughout the country as soon as the plans are prepared and the best locations decided upon.

Each station will be in charge of a foreman, a man with practical mine experience, who has been a miner, a fire boss, mine foreman, manager of a mine, or inspector of mines. It will be his duty to train the miners from the coal fields within his district in rescue work.

It is proposed that the miners who work in the nearby mines will, under the guidance of the foreman of the station, form a volunteer rescue corps, ready to respond at once to any emergency call within the district.

The principal equipment at the station will consist of eight so-called oxygen helmets, breathing apparatus, which will permit trained men to enter the most deadly gases in a mine and remain for 2 hours without danger from asphyxiation. An air-tight room will be fitted up and filled with smoke. The miners who are sent to the station will practice with the oxygen helmets in this room until they are perfectly familiar with the apparatus.

It is expected that it will take two weeks to thoroughly train a miner for this work The men will be housed and fed at the station during the training period. When they return to their respective mines it is expected that they will form rescue corps and have properly equipped stations of their own.

At a mine disaster the foreman of the station will have charge of the rescue work A mining engineer will be stationed in the district, whose duty it will be to examine the physical condition of the mines and have general supervision over the training in rescue work

The Bureau also has ordered two portable rescue stations fitted up on specially built railroad cars and ready for immediate response to calls for assistance in the event of mine disasters One car will be stationed at Billings, Mont., to answer calls in Montana and Northern Wyoming. The other car will be for service in the coal fields of Colorado and Eastern Utah. The purpose of these cars will be the same as the rescue stations being established in various parts of the country. They will be fully equipped with apparatus, such as oxygen helmets, and will be sent from one mining camp to another to instruct the miners in their use, as has been done for 2 years at the Pittsburg rescue station.

Fig. 7. All Aboard for the Next Room

One end of each car will be fitted up as an air-tight room to be used in training the men in the use of oxygen helmets. This room will be filled with noxious fumes and the miners wearing the helmets will remain inside for a period of 2 hours in an atmosphere that would kill without the helmets. There will also be sleeping arrangements for 12 men, to accommodate the rescuers at a mine disaster. Each car will contain eight oxygen helmets, a supply of oxygen in tanks, one dozen safety lamps, one dozen electric lamps, one field telephone outfit with 2,000 feet of wire, automatic resuscitating outfits and a limited outfit for use in demonstration and actual practice of equipment in first-aid to the injured in connection with mine accidents.

In addition to the location of branch rescue stations at Birmingham, Ala.; Huntington, W. Va.; and Wilkes-Barre, Pa , mentioned above, the Bureau has decided to have stations at Trinidad, Colo., accessible to the coal fields of New Mexico and Southern and Central Colorado, and at Rock Springs, Wyo.

The erection of the Bristol, England, tower for shot making is credited to William Watts, plumber, in 1769. It was "built" by sawing a square hole in the center of the various floors of his house, and locating the well in the cellar. This tower is still in use, although it has been heightened by the addition of some stories. Watts secured a patent on December 2, 1782, and sold his London rights in 1800 for £10,000 ($48,665).

The lead from which the shot is made is smelted by the present company, and alloyed by their secret process, at their establishment. When molten it is poured into a sieve-like receptacle at the top of the tower and these molten drops, falling into a well, 120 feet below, form the shot, which are then passed through a polishing grader. They are then spilled from a hopper on to an inclined plane; the perfect shot run on to a second plane, while the imperfect drop into the opening between; only the perfect shot reach the last of the four planes.

The tower being only 120 feet in height, a larger size than BBB cannot be manufactured by this process. The larger shot, including shrapnel for the British Government, are prepared in two different ways. For the medium-size shot a wire of the proper material is fed into a machine which, simultaneously, mashes it into a ribbon shape and punches irregular formed shot. The largest shot are made by pouring the molten metal substance into long bullet molds, which, cooling, form irregular shot. The various sizes are then placed each by themselves in gins which are revolved for 6 hours, when the shot come out perfectly smooth spheres.—*United States Consular Report.*

STRIPPING COAL BEDS

Written for Mines and Minerals

Methods in Use in Anthracite Region of Pennsylvania and in Bituminous Coal in Illinois

In a number of places in Northeastern Pennsylvania the coal crops so near the surface it pays to remove the covering and work the deposit by open-cut mining. At Hollywood and Milnesville, 4 miles northwest from Hazleton, open-cut mining has been carried on for at least 35 years. Dr. H. M. Chance described the Hollywood strippings in Volume A. C. of the Second Geological Survey so long ago as 1883. In the vicinity of Hazleton the Carboniferous strata have been folded and subsequently eroded so as to form a number of canoe-shaped basins. In some places the Mammoth bed has been folded, as shown in Fig. 1, so that in the center of the fold there is a mass of rock; in other places the strata have been folded and the rocks eroded so that there is scarcely any cover above the coal, as shown in Fig. 2.

The thicknesses of these deposits vary from 135 to 80 feet, depending on the extent of the folding and erosion they have undergone. The cover above the deposits varies from soil to hard sandstone; however, the coal is in excellent condition, even although at times it is rusty or water stained. The rock walls forming the sides of these basins have steep inclinations

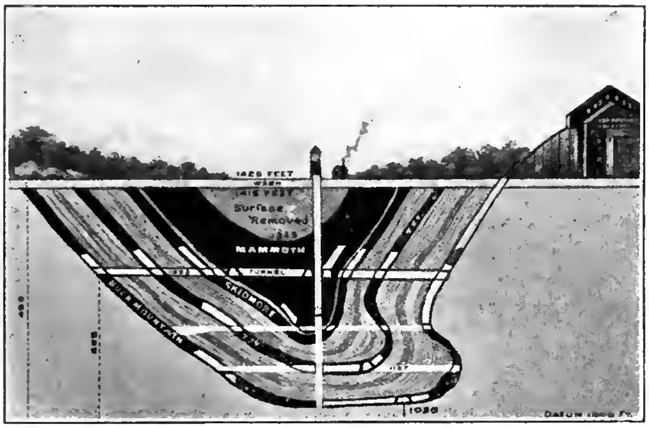

FIG. 1

and this, with other conditions, determines whether the coal is to be mined by the room-and-pillar method, as in Fig. 3, or by the quarrying method, as in Fig. 2.

In case the coal basin is not too long, the breaker is located at one end, and a gangway driven in the bottom of the basin to the other end. In case the basin is long, the breaker is placed at a suitable distance from one end, or possibly on the boundary line between two properties.

In the Hollywood basin the coal was worked from the gangway up each side, by the pillar-and-room system of mining, after stripping off the surface dirt. The rock covering followed the coal into the rooms and was then hoisted out by means of the plane shown in Fig. 3. After the end of the basin was reached the coal pillars were shot down; first, however, removing the rock cover on the coal roof left over part of the excavation. This method of mining was satisfactory and large quantities of coal could have been mined in a short time had there been a market for the product. Mr. Chance, in writing on the cost of mining the Hollywood coal stated: "It will probably pay to remove an average of 2 or 3 cubic yards of debris for every ton of coal." Later the work of stripping was systematized so that it now pays to remove 6 cubic feet of dirt for every cubic foot of coal where room-and-pillar mining is followed. The coal basins, which are practically level at the surface, may carry from 6 feet to an indefinite number of feet of dirt and rock above the coal, but even in the latter case the depth of cover that may be profitably stripped will depend largely on what it is composed of and the facilities at hand for its removal and wasting.

At the Morea colliery, in Schuylkill County, the cover above the coal is soil, and below this rock, which, in some places in the basin, as shown in Fig. 1, reaches a thickness of 80 feet near the center, and will average about 20 feet. In other places in

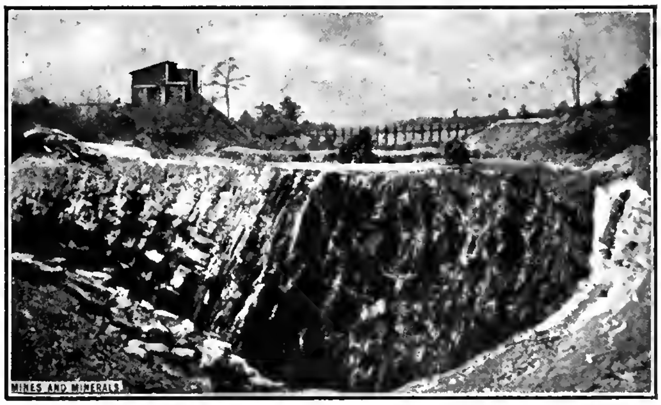

FIG. 2. MAMMOTH VEIN, MOREA COLLIERY

the basin, as shown in Fig. 2, there is only a thin cover, but fortunately where the cover is thinnest the coal is thickest, thus balancing up the differences in the cost of removing the thicker covering. At Morea the soil is removed from the rock by a steam shovel. The rock is then broken with explosives, after which it is loaded into cars by steam shovels and hoisted out of the pit. After the coal has been cleared of rock for a sufficient distance vertical drill holes are put in the coal. As there is a vertical wall of coal a small quantity of powder effectively placed will break down a relatively large quantity of coal, which falls to the coal floor covering the gangway, and from which it is sent down chutes to the mine cars.

There are a number of places in the anthracite fields where flat coal beds outcrop so near the surface that they may be stripped for 100 feet before the cover attains so great thickness as to make the work unprofitable. The Hilldale strippings are

FIG. 3. STRIPPING AT HOLLYWOOD COLLIERY

about 1 mile from the Pennsylvania Coal Co.'s No. 14 breaker and have a section from the surface down about as follows:

Soil, 4.5 feet; coal *A*, 4.5 feet; rock 3 feet; coal *B*, 1 foot; rock, 5 feet; coal *C*, 2 feet; rock, 3 feet; coal *D*, 12 feet.

Coal bed *A* has been exposed so long it is worthless, but it is expected that it will become marketable where it has a rock cover.

Bed *B* is good coal and although somewhat rusty adds to the total tonnage recovered.

Bed *C* is a little short of 2 feet thick and under present mining conditions could not be worked at a profit underground; in the stripping operations, however, it is, like bed *B*, a source of income. Bed *D* is the coal aimed for, and is as good as coal can be, although carrying a slate parting.

The method of stripping followed by Mr. Kinsley, the contractor, is as follows:

First, the top soil and poor coal *A* is removed from the top rock by means of a clam-shell bucket and locomotive crane. The boom on this crane is 42 feet long and can place the top material where it will be out of the way once for all. The dirt is first removed ahead of the crane in the direction it is moving; next from the side of the crane where the mining is to be carried on. The rock and coal are then broken down to the coal bed *D* by blasting. The coal from *B* and *C* is picked out by hand, while the rock is wasted and piled back by the bucket to form the track on which the coal car is shown in Fig. 4. The coal bed *D* is next broken by powder and loaded into the bucket by hand. The bucket is then raised by the crane and the coal dumped in the car as shown in Fig. 4. Anthracite coal is so brittle it breaks in handling, and while it was at first intended to use the bucket to pick up the coal, it was found inadvisable to do so. The method of stripping followed by Mr. Kinsley is equivalent to making a side cut along the crop for the crane track, then excavating below this cut, and filling in. The fill will furnish the road for the next side cut when coming back from the boundary line of the property, as it does for the coal cars in going forward.

Fig. 4. Dumping Coal from Bucket

Near Danville, Ill., there were about 35 acres having a bituminous coal bed 8 feet thick, which was approximately horizontal. The coal bed outcropped on all sides of a flat-topped hill, and had an overburden from 38 to 40 feet thick, composed of coal clay, gravel and about 20 feet of shale. It was decided to strip the coal with a single cut and to take a wide cut so as better to provide for the efficient mining of the coal. The plant decided on was a steam shovel having a dipper of 2 cubic yards capacity, and mounted on a movable platform, provided with a belt conveyer for disposing of the material. The platform, which was 30 feet wide, was mounted on four trucks that were moved as desired on two tracks. The machine, as it appeared in operation, is shown in Fig. 5. After excavating the material above the coal with the bucket, it was swung to a large steel hopper and discharged. From the bottom of the hopper the material was carried on a steel cross-feeder to the lower end of the belt conveyer. The latter was a 40-inch wide belt traveling on a steel arm 105 feet long. The arm was supported by wire ropes from a tower built above the platform to a height of 48 feet. By this arrangement the waste clearance at the outer end of the arm was about 60 feet above the tracks.

The machine is said to have had no difficulty in excavating heavy pieces, stumps, and logs, and depositing them in the space where the coal had been mined. After the overburden had been removed the coal was quarried and loaded into cars on a track laid in the place from which coal had been taken previously.

This is the only reference the writer has to stripping bituminous coal and it has been taken from Volume 28, page 139, Mines and Minerals. As the shovel made a cut, the debris was deposited in the cavity made by removing the coal. The tracks for the machine were laid on top of the coal, which was mined so as to leave a bench for the shovel to come back on.

Fig. 5. Stripping of Consumers Coal Co., Danville, Ill.

It would not be advisable to use steam shovels for scooping up anthracite for two reasons: First, anthracite must be cleaned of slate or adhering rock before it reaches the breaker, and this can be accomplished only by hand. Second, the coal is too brittle and would spall badly.

EVOLUTION OF MINE HAULAGE

Written for Mines and Minerals, by E. B. W.

(Continued from August)

Wire-rope tramways were used 200 years ago, according to Spencer Miller;* cableways, 60 years ago; wire-rope haulage underground about 60 years ago in Scotland; and steam locomotives have been in use nearly as long, at least prior to 1870.

Locomotive Haulage—Steam, Electric and Compressed Air. Calculations

Steam locomotives were first used on return airways. The class of 1883, Columbia College, will doubtless remember receiving a few sparks down their necks and being nearly smothered in No. 1 Drifton, Pa., mine. Outside of a mouthful of sulphur gas, there was no harm, but there have been fatal cases of asphyxiation due to steam locomotives underground.

While steam locomotives are not desirable in gassy mines there seems to be no record which shows they were the direct cause of a mine explosion. Their introduction made it possible to greatly increase the output of drift mines and marked an epoch in the reduction of haulage costs. Where the cost was about 8 cents per ton by mule haulage the locomotive reduced it to 4 cents; at the same time the increased output reduced fixed charges. The first steam locomotives weighed about 6 tons, but as the hauls became longer, necessitating a larger number of mine cars in a trip to maintain or increase tonnage, the locomotives were enlarged. The heaviest underground steam locomotive is that shown in Fig. 52, which was constructed for use at the Pocahontas Mine, in Virginia.

FIG. 52. STEAM MINE LOCOMOTIVE

It is not good practice to fire locomotives underground with soft coal on account of the smoke and gas emitted; therefore, the locomotive shown in the illustration was designed to make a round trip of 7 miles without firing.

To obtain satisfactory work from mine locomotives resistance offered by grades, rolling stock, and tracks must be considered. On grades the resistance due to gravity increases in exact proportion to the steepness of the grade; that is, for a 1-per-cent. grade it is 20 pounds per ton; for a 1½-per-cent. grade it is 30 pounds per ton, etc. The resistance due to friction depends on the physical condition of the track, whether it is wet or dry, clean or dirty, properly gauged, well tamped so as to be solid, or whether the rails are in alinement, and curves made to conform to the locomotive wheel base. The kind and condition of the rolling stock used exerts an influence; for instance, cars in good condition, well made and rigid, may offer a resistance of 8 pounds per ton on a good track, and 20 pounds on a bad track; again, cars in bad order may offer a resistance of 30 pounds per ton on a good track and 60 pounds or more on a bad track. Cars with wheels scraping against the sides may develop 60 to 80 pounds per ton frictional resistance on a good track. Frictional resistance may be determined by noting on what grade a car once started will just keep in motion. If a car will barely keep moving on a 1½-per-cent. grade its frictional resistance is 30 pounds per ton. The tractive force of a locomotive is its pulling strength measured in pounds by a dynamometer. The larger the cylinders of the locomotive are made the greater the tractive force; and the larger the diameter of the driving wheels used on a locomotive the less the tractive force. The first statement is based upon piston area and the steam pressure; the second statement is based upon the crank leverage; for with the connecting-rod close to the axle of the driving wheels there is not so much effective leverage exerted as when it is further from the axle, the cylinder and steam pressure being the same in both cases. The tractive force of a locomotive is the force

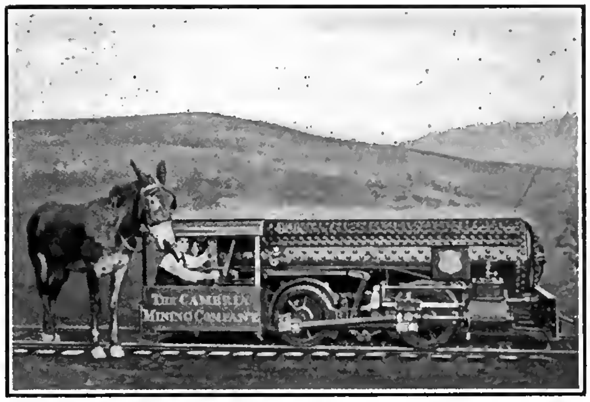

FIG. 53. COMPRESSED-AIR MINE LOCOMOTIVE

necessary to drive the locomotive and to pull the train. It is calculated from the formula:

$$T = \frac{D^2 \times L \times .85\,P}{d}$$

In this formula T = tractive force; D = diameter of each cylinder in inches; L = length of the piston stroke in inches; $.85\,P$ = the effective cylinder pressure which has been found to be 85 per cent. of the boiler pressure in pounds per square inch.*

The hauling capacity of a locomotive is found by dividing the tractive force by the sum of the resistances due to gravity and to friction, and then deducting the weight of the locomotive. This gives the weight in tons of 2,000 pounds which the locomotive can haul.

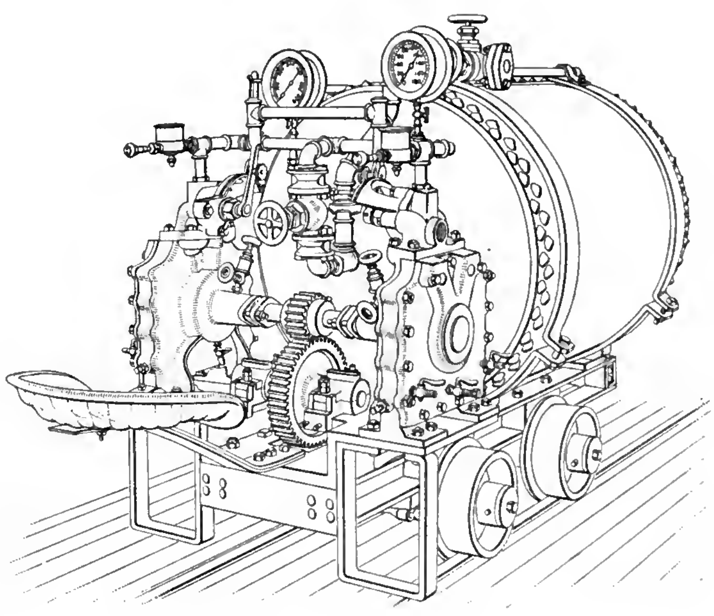

FIG. 54. COMPRESSED AIR LOCOMOTIVE USED IN TUNNEL

*MINES AND MINERALS, Vol. XXIV, page 412.

* H. K. Porter Co.

Example.—What is the hauling capacity of a 20-ton locomotive, 8-inch diameter cylinders; 12-inch stroke, 24-inch diameter driving wheels, working under 150 pounds steam pressure per square inch in boiler; the frictional resistance being 8 pounds per ton, and the grade $1\frac{1}{2}$ per cent.?

Solution.— $\frac{64 \times 12 \times .85 \times 150}{24} = 4{,}080$-lb. tractive force.

$\frac{4{,}080}{8+30} = 107.4$ and $107.4 - 12.2 = 95.2$ tons as the hauling capacity of the locomotive under the above conditions.

(The weight on the driving wheels to produce satisfactory results with mine locomotives must be 6 times the tractive force, hence, $\frac{4{,}080 \times 6}{2{,}000} = 12.2$-ton locomotive.)

It is cheaper to operate a light locomotive wherever the haul exceeds $\frac{1}{4}$ mile than to use mules. However, with steam locomotives, gathering mules must be used to deliver empty cars to the rooms and collect the loaded cars on the partings where the locomotive may reach them. In comparing the cost of mule haulage with locomotive haulage, the tonnage hauled a given distance must be considered. In one instance the anxiety of the buyer of a coal company to purchase something led him to order a locomotive a year before it could be used to advantage. When the cost of hauling 300 tons on the main road to the dump reaches $1,800 per annum, then locomotives can be substituted to advantage. When from any cause the mine is idle the up-keep of the locomotive is practically nothing, while the mules have to be fed and cared for.

In ore mines, where the ventilation is not good, and in coal mines where it would be dangerous to adopt either electricity or steam, compressed-air locomotives are used to advantage. In some respects compressed air as a means of haulage possesses advantages over other kinds of power, but the same can be said of other prime movers under certain conditions. Compressed-air locomotives have been in use for 25 years, and are liked wherever adopted. The great objection to them at first was their length, but this has been partly remedied by using tank tenders to carry a supply of air which would propel them a given distance. To further overcome the difficulty of large tanks an air-pipe storage system was devised, which paralleled the track. This pipe storage is now used almost universally. One feature in connection with air haulage is that small gathering locomotives may be used in place of mules. Fig. 53 shows one of five gathering locomotives adopted to replace mule haulage at the Antelope Mine, Cambria, Wyo. The reader will note that the mule does not seem worried over the change.

It is to be understood that each compressed-air locomotive must be designed to comply with the particular mine road it is to travel, also the air tanks and air-storage system must be designed for the length of haul, and the pressure to be used.

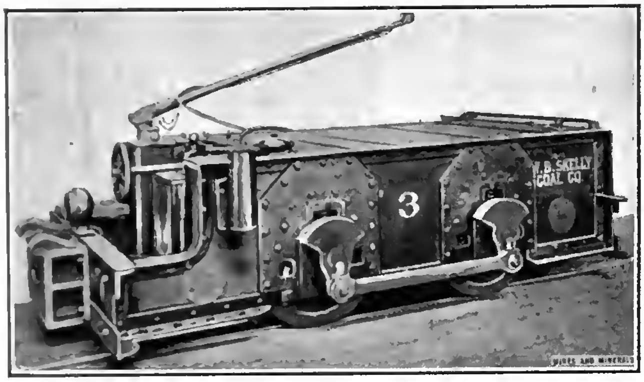

Fig. 55. Baldwin Side-Rod Electric Mine Locomotive

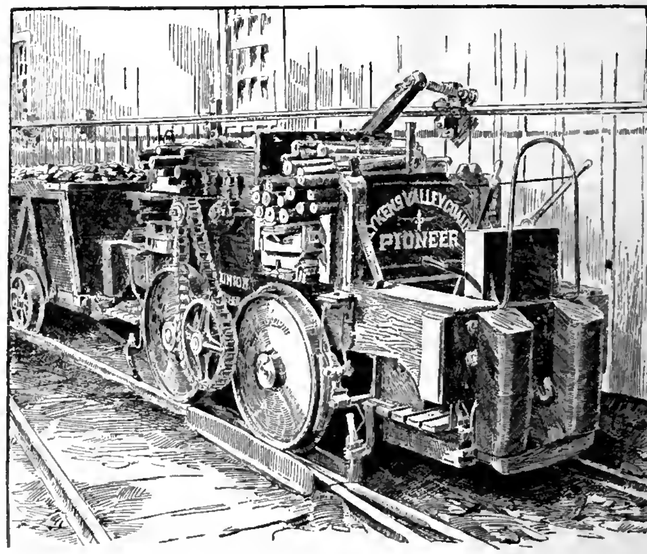

Fig. 56. First Electric Mine Locomotive Used in America, 1887

To install a compressed-air locomotive plant, it is necessary to know the approximate mineral output; design the locomotives of suitable weight and power to overcome the resistances, and then construct the plant to produce and carry compressed air suitable for requirements. The haulage problem includes an air compressor whose capacity can supply the demands of the locomotives for compressed air and furnish a pressure of from 500 to 800 pounds per square inch. Rather than charge direct from the compressor, suitable stations are arranged where the locomotive tanks can be filled with compressed air almost instantly. What is known as the stationary storage system is a pipe line extending from the compressor to the charging station. This system enables the compressor to be run continuously and restore the depleted air pressure after a locomotive has been charged. In order to insure the requisite pressure the relative volume of the locomotive and storage pipes must be compared, as follows:

$$v'(p' - p) = v(p - P)$$

In this equation v = volume of locomotive tanks; P = absolute initial pressure in locomotive tanks; p = absolute final pressure in the

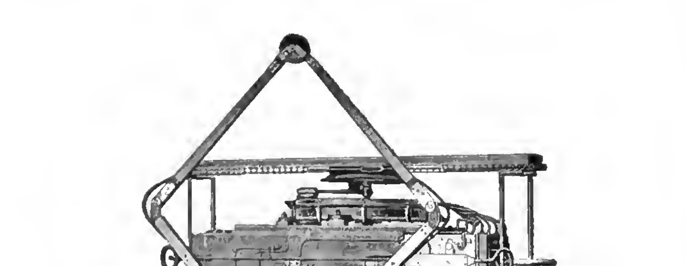

Fig. 57. Electric Locomotive Built 1889, Still in Use

locomotive tanks, usually corresponding to cylinder working pressure; v' = volume of the pipe line; p' = absolute pressure in pipe line to give initial pressure in the locomotive tanks.

To insure the proper pressure, say 800 pounds per square inch, in the locomotive tank, a somewhat higher pressure must be maintained in the pipe line.

To find the volume of the pipe line use equation $v' = \frac{v(p-P)}{p'-p}$, or to find the absolute pressure in the pipe line use $p' = \frac{p(v+v') - vP}{v'}$.

Assume the capacity of the locomotive tank to be 150 cubic feet, with a final pressure of 140 pounds left on the tank at the time of recharging to 800-pounds pressure, and also assume that the pipe line has a pressure of 1,000 pounds above the atmosphere; then, $v' = \frac{150(815-155)}{1{,}015-815} = 495$ cubic feet for volume of the pipe line. Again, $p' = \frac{815(150+495) - 150 \times 155}{495} = 1{,}015$ pounds, absolute pressure, or 1,000 pounds gauge pressure, to give 800 pounds air pressure in the locomotive tank. It is to be expected that various other questions will arise, among them the capacity of the compressor capable of supplying the necessary quantity of air for a haulage system. This is found by calculating the number of cubic feet of free air per minute required to make a given run in a given time. Using the same figures as before and assuming the time occupied in making the run to reduce the tank pressure from 800 to 140 pounds per square inch to be 20 minutes, then at the beginning of the run the volume of free air would be $\frac{(800-140)150}{14.7} = 6{,}734$ cubic feet. Substituting this in the equation $C = \frac{c}{t} = \frac{6{,}734}{20} = 336.7$ cubic feet of free air per minute, as the capacity the compressor must have to fulfil the requirements.*

To ascertain approximately the amount of air needed to perform a given amount of work, tables have been constructed, based on the cylinder working pressure, grades, and resistances. The tractive force of compressed-air locomotives is found from the formula $T = \frac{D^2 \times L \times .98\,P}{d}$, in which .98 is the effective cylinder pressure, there not being so much loss in pressure in air passing from the tank to the cylinders as with steam. For compressed-air locomotives it is always best to install a three-stage air compressor, for with it the final temperature of the air may be kept down to 250° F., provided the plant is not too small. The air locomotive shown in Fig. 54 was used at the Empire Gold Mine, in Grass Valley, Cal., for hauling five 1-ton ore cars on the 2,000-foot level. The distance traveled in a round trip is 5,000 feet. The tank measures about 36 inches in diameter by 48 inches long and carries a pressure of 500 pounds per square inch. The dimensions over all are 5 feet long, 4 feet 4 inches high, and 38 inches wide.

While the locomotive in Fig. 54 resembles a stranded whale, looks do not cut much of a figure in mine locomotives. One of the most picturesque steam locomotives was in business at the Clark Mine, near Allisonia, Va. Its work was done on the surface, although it ran through a small tunnel which also sufficed as its stable. It consisted of a small flat car, carrying an upright boiler, a small horizontal boiler-feed pump, and a small horizontal engine. The latter was geared to one car axle. This locomotive answered every requirement and could whistle with the best of them.

In the anthracite mines of Pennsylvania there were in 1900, 365 steam locomotives, 30 air locomotives, and 38 electric locomotives. In 1906 there were 445 steam locomotives, 108 air locomotives, and 223 electric locomotives. To show the general trend toward air and electric haulage the following statistics are given: In 1900, 84.4 per cent. were steam locomotives, 6.9 per cent. air locomotives, and 8.7 per cent. electric locomotives. In 1906 the percentage of steam locomotives in use was 57.3; air locomotives 14; and electric locomotives 28.7. It is interesting to note that while there was an increase of 158 air

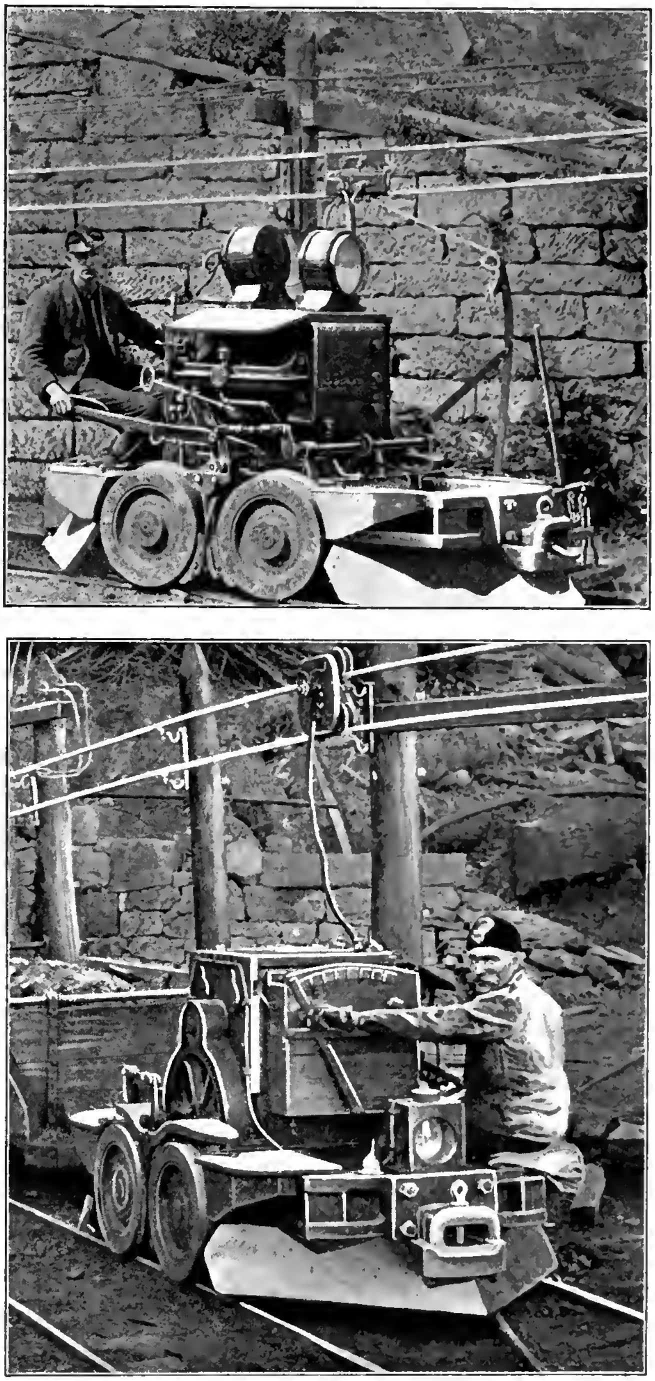

FIG. 58. ELECTRIC LOCOMOTIVES BUILT 1888, STILL IN USE

and steam locomotives, there was also an increase of 185 electric locomotives.

Much can be said from an economical standpoint in favor of steam, air, and electric haulage, but economy cannot always enter into the subject, so that comparative statements given for any one mine are not so absolute as the conditions that govern their use. For this reason it is stated that each kind of locomotive may be better adapted to a certain mine than either of the others.

* See article on "Compressed Haulage," MINES AND MINERALS, Vol. XXI, page 188, November, 1900.

The most critical point in designing a mine locomotive is to make the dimensions a minimum. The haulways in mines are never of more generous dimensions than are necessary, hence the minimum dimensions for mine locomotives are as small as 2-foot wheel base; 8-foot length overall, and 3-foot width. Scarcely two orders carry the same dimensions, and it is necessary for the makers to have a variety of motors suitable for track gauges as narrow as 18 inches, and for wheels 20 inches in diameter. Since the introduction of electric locomotives coal mines are worked to advantage whose beds are 4 feet thick,

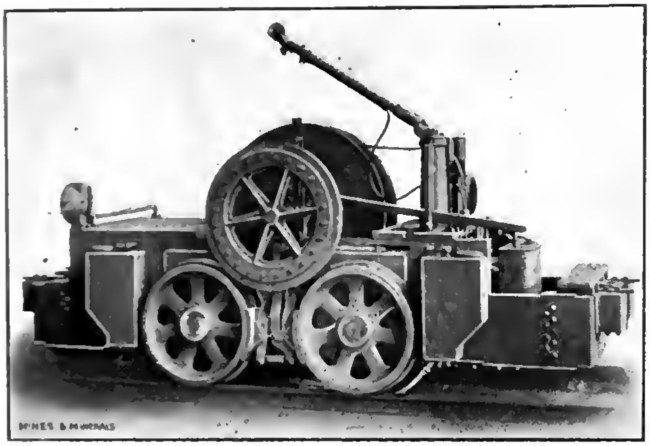

Fig. 59 Wampus Electric Locomotive

and in which mules could not work unless the entries had the roof brushed. Such mines are now competing successfully with mines whose coal beds are 6 and 7 feet thick.

The introduction of electric locomotives has improved the rolling stock, and where formerly it was customary to find as much as 60-pounds per ton car resistance on the level, at present it is found as low as 8 pounds. The several electric locomotive manufacturers have taken advantage of the weak and strong points developed in practice until there are as many styles and constructions as one could desire. The frames have been changed, the motors improved until it would seem as if nothing were left to change, and yet one of the latest improvements, Fig. 55, is to couple the wheels with side rods and use driving axle cranks

The first electric locomotive was built in 1887 for the Lykens Valley colliery of the Pennsylvania Railroad Co. Since that time very rapid progress has been made until the modern locomotive bears little resemblance to the Pioneer shown in Fig. 56.

The locomotive shown in Fig. 57 was built for the Hillside Coal and Iron Co. in 1889, and was still in use in 1910 It does not resemble the earlier one in any respect

The two electric locomotives shown in Fig. 58 were the first built by the Jeffrey Mfg. Co. and were the first ever used in a bituminous coal mine. They were built in 1888, and are still in use at the XX mine near Shawnee, Ohio

For a number of years the manufacturers of electric locomotives have endeavored to eliminate the mule as a car distributor and collector. The first attempts were made with storage-battery locomotives, after which reels carrying wire cables were placed at the rear end of the small locomotives.

The Wampus electric locomotive, shown in Fig. 59, is a gathering locomotive supplied with a reel for a double cable.

Fig. 60. Electric Gathering Locomotive

The reel is turned to wind and unwind the cable by a friction wheel which can be dropped on a drive wheel of the motor.

The Pocahontas Collieries Co., at Pocahontas, Va., has 12 of these machines in use, that seem to be giving general satisfaction. The gathering cable reel is set between the axles with the reel center several inches above the top of the locomotive frame. When it is desired to enter a room, the cable is attached to the trolley wire in the entry and to one rail. The lever shown is then pushed up, which allows the friction wheel to come in contact with the driving wheels and turn the reel at a slightly greater speed than the speed at which the locomotive moves, thus insuring the cable winding on the smallest diameter.

This arrangement can only be used in thick-bedded coal seams, and to work in thin beds the drums are placed on the body of the locomotive, as shown in Fig. 60.

In some cases it is considered better to carry a rope into the room face and by means of a motor mounted on the electric locomotive in the entry pull the cars to the entry. In such cases traction reels are run by a small independent motor connected with them by gearing.

Fig. 61 Jeffrey Storage Battery Locomotive

Fig. 62 shows an electric locomotive on the entry with a man unwinding and hauling a small $\frac{3}{8}$-inch steel rope from a drum into a room in order to attach the rope to the car to be pulled out. The reel, which contains 300 feet of rope, is mounted vertically at the rear end of the locomotive, and can be used for pulling cars to the face of

sloping rooms as well as pulling them out of flat rooms. If there is considerable up grade from the entry, the rope may be run through a pulley at the face and the car hauled up by the locomotive. Fig. 63 shows the traction reel pulling a loaded car from a room.

Where the hauls are not too long and the tracks are approximately level, storage-battery locomotives are sometimes used.

Fig. 62. Taking Hauling Rope Into Room

These locomotives weigh from 2½ to 7 tons and cost from $1,800 to $4,000, depending upon their size.

Fig. 61 shows a 12-horsepower locomotive equipped with series-wound, railway-type motor, and a 42-cell, 16-kilowatt-hour battery, which in service will give an operating range of about 300 ton-miles on a single charge when the tracks are approximately level. The locomotive shown was constructed for hauling material excavated in the extension of the Comstock tunnel.

The economy in actual cost of operation is often secondary to the saving that results in several departments from promptness in handling material, particularly in tunnel driving.

If frictional resistance be neglected the pulling force necessary to draw a load up a grade of given percentage is equal to that same percentage of the weight of the load. That is, a 20,000-pound locomotive has its draw-bar pull decreased 400 pounds on a 2-per-cent. grade. The draw-bar pull for a traction locomotive is taken at from 20 to 25 per cent. of the weight on the drivers, and if there be a deduction of 2 per cent. of the weight of the locomotive from the draw-bar pull in ascending a 2-per-cent. grade, there is a total deduction of from 8 to 10 per cent. of the draw-bar pull. In mine haulage, the train resistance on level roads varies according to the condition of the track, cars, and lubrication, but is generally between 1 and 2 per cent. of the gross weight.

When the increased draw-bar pull required by the train is considered the results are still more serious. Take for example a traction locomotive weighing 30,000 pounds; at 20 per cent. rating its draw-bar pull on a level track is 6,000 pounds. Assuming a train resistance of 2 per cent., this draw-bar pull provides for hauling a train of 300,000 pounds. On a 2-per-cent. grade the locomotive draw-bar pull is reduced to 5,400 pounds, and the total train resistance is increased by 2 per cent. of the weight of the train, becoming 4 per cent. The locomotive now can haul $5,400 \div .04 = 135,000$ pounds, which is a loss of 55 per cent. compared to what it can haul on a level track.

Traction locomotives may be used on short grades of 5 per cent., but above that they are not to be considered. The Goodman rack haulage system is able to haul a certain trip of cars over a given roadway regardless of variations in track or car resistance, conditions that change from day to day to affect traction locomotives.

Fig. 64 shows a Goodman plain rack locomotive climbing a 16-per-cent. grade with 25-ton trips. Since traction locomotive wheels will slip under certain conditions, embracing bad rails, grades, and loaded cars, they are made heavier on this account than they would need to be otherwise. With a rack rail into which driving sprockets mesh for positive pulling, there is no slipping, and hence the locomotive weight can be greatly reduced and retain the same draw-bar pull. The essentials in the Goodman rack-haulage system are: A strong and durable rack rail, supported by the track ties and securely anchored to them. A powerful electric locomotive whose motor drives steel sprocket wheels attached to the axles and which engage the rack rail to produce the forward motion.

The rack rail may be either live or dead. In Fig. 64 the locomotive is working on a live rack rail, which is also the conductor for the power current.

In Fig. 65 is shown a rack rail locomotive which receives its power from a trolley. The Goodman company makes also a combination rack and traction locomotive which is claimed to be preferable in haulage work where there are prevailing or continuous grades, even though they be quite within the practicable or possible limitations of traction locomotives. The combination rack and track locomotive is arranged to run as a rack locomotive on grades, and a traction locomotive on level stretches where no rack rail is needed.

Once the opinion generally prevailed that gasoline locomotives were not suitable for underground work. The Germans thought differently and have been so successful with them that they are being considered in England and the United States. In the August, 1910, issue of Mines and Minerals a general illustrated description of an internal combustion locomotive was given.

There are probably some methods of mine haulage which have been overlooked in this article, because every kind of animal or machine large and tractable enough has been used for the purpose. We might have alluded to horse whims, and water wheels, but these are reserved for another article. The subject of mine haulage has been treated as one of evolution, but in practice the subject includes items which require the skill demanded of mining engineers. For instance, the extent of the haulage, the output of the mine, the grade and direction of the haulage road, the gauge of the track, the construction of the

Fig. 63. Pulling Car Out of Room

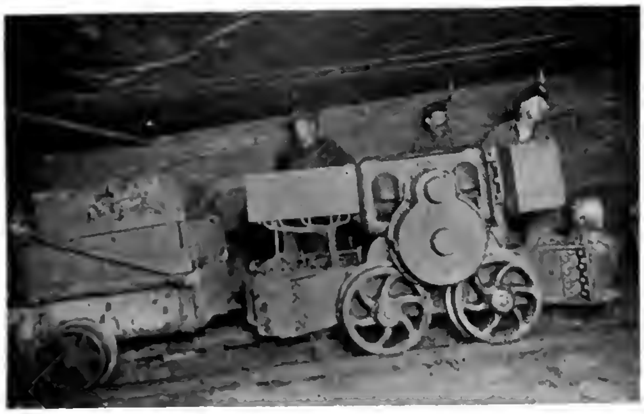

Fig. 64. Plain Rack Locomotive on 16-Per-Cent. Grade

track, with turnouts, curves, switches, etc. Then it embraces the choice of haulage system, whether man, animal, or power or all three, which will of course depend on the mineral, the extent of the mine and its capacity. Each system will require thoughtful consideration and engineering skill, which, if not difficult to the trained man, will at least make him do some calculating to get things right. Take, for instance, an ordinary coal mine. The road is surveyed; the grades and the curves calculated and laid out; the number of ties and the number of tons of rails with fishplates figured. This is not all, the road must be ballasted; the ties centered; the rails gauged, spiked, and joined; the ties tamped and the road lined up. After these preliminaries have been finished the haulage system adopted will soon show weak points that will demand attention. When, however, matters are once working right as far as roadbed is concerned, the rolling stock will require attention, and repairs commence. Mine haulage is a more difficult problem to solve than surface railroad haulage, because the wear is more on the rolling stock, the wrecks more frequent, and darkness enshrouds it all, unless, as at large operations, the haulways are lighted by incandescent lights.

Fig. 65. Goodman Combination Rack and Traction Locomotive

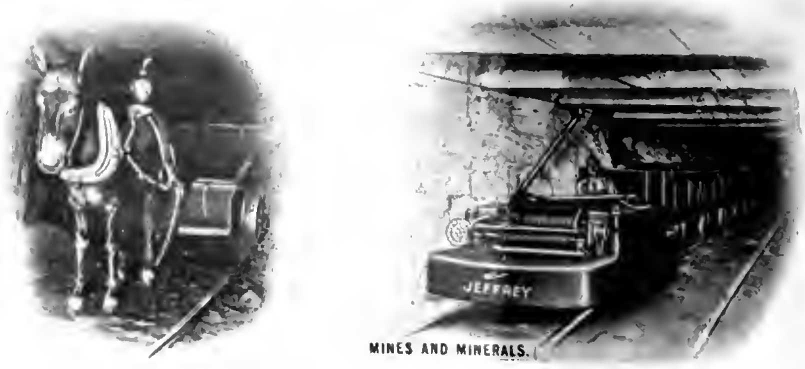
FULMINATING *VS.* WHITE PHOSPHORUS FOR IGNITERS

In *Annales des Mines* Mr. G. Chesneau gives the results of a series of experiments made after the accident at the Lievin colliery to determine the relative safety of fulminating igniters and white phosphorus igniters.

This series of experiments shows conclusively that when lamps, fitted with fulminating-pellet igniters, are introduced in a lighted state into an explosive atmosphere, or are lighted therein, an explosion of the external gases can be caused by particles of the pellet traversing the gauze or deposited on the gauzes and then dislodged by shock. It also indicates the possibility of this phenomenon being reproduced in the course of testing in the mine for firedamp, all the conditions, heated state of the gauze, a stationary explosive mixture, shock caused by the lamp touching the walls of the recess, being present simultaneously. The number of projected particles found after once lighting the lamps shows that even scrupulous care in cleaning the lamps is no guarantee of security, the only effective precaution being to abolish the use of fulminating pellets unless they can be manufactured in such a way as to entirely prevent the projection of unconsumed particles. Further tests point to the danger of firedamp explosions by unconsumed particles of the igniting pellets being greater than the risk of a similar result ensuing from the "Marsaut effect," i. e., the expansion of the flame produced by the explosion of the gaseous mixture in the inner gauze.

There is a fundamental difference between the fulminating and the phosphorus pellet, as the particles from the former are hard and able to pass through a mesh of their own size, while the particles of the latter are viscous and stick to the wire gauze, only the extremely fine ones passing through, and it was only with coarse, unsifted particles that an ignition of gas could be obtained.

These experiments fully confirm the results of previous workers who have tested the phosphorus igniters, and enable the author to recommend the adoption of the latter. This is the more welcome since, without special lighting devices, it would be impossible to retain lamps burning light mineral oil, which lamps—apart from their greater tendency to blow out in a draft—present considerable advantages over colza-oil lamps, both in respect to constancy of illuminating power throughout a whole shift and of their greater sensitiveness in detecting traces of firedamp (1 per cent., as compared with 2½ to 3 per cent. in the case of the oil lamp). The substitution of white phosphorus igniters for those using fulminating caps should not be an expensive operation, at least for the large majority of lamps fitted with vertical igniter boxes and lateral operating mechanism. There is very little difference in the size of the boxes, and it should not be difficult to arrange for the phosphorus igniter boxes to be made of the same size as the others and operated in the same way and thus one of the dangers from igniters would be avoided.



As It Was *And Is*

Fig. 66. Mine Haulage

WORKING A STEEP COAL SEAM

*By Austin Y. Hoy**

The Pacific Coast Co., of Seattle, owns and operates through subsidiary companies (The Pacific Coast Steamship Co., Pacific Coast Railway, and Columbia & Puget Sound Railroad) over 26 steamships in the coastwise trade with Alaska, British Columbia, and California points, and about 165 miles of railroads. This company built the first railroad in the state of Washington, 38 years ago, and is today one of the largest concerns of the Pacific Northwest.

Mines of the Pacific Coast Coal Co., at Coal Creek, Washington

The operation of these steamers and railways requires a large amount of coal. When the Alaska trade is in full swing, over 3,000 tons daily are used to supply the demands of this traffic.

The Pacific Coast Coal Co. (another subsidiary incorporation) owns and operates coal mines at Franklin, Black Diamond, Coal Creek, and Burnett, all less than 30 miles south and east of Seattle. The Coal Creek Mine adjoins the old Newcastle Mine, which was opened some 30 odd years ago, worked to a depth of 2,000 feet, to the boundaries of the property, and is now closed down.

During the last decade, the production of coal has increased so greatly in the United States that the employment of a large percentage of unskilled men as miners has been necessary. Since native-born Americans rarely become coal miners, this labor has been supplied largely by immigration from Italy and the Slav countries, where practically no coal is mined. These circumstances have necessitated the extensive use of machines for doing the work formerly done by skilled miners; namely, "mining" the face of the coal, so as to avoid "shooting off the solid" and the consequent production of great quantities of slack and unmarketable sizes of coal.

Chain machines and compressed-air "punchers" have solved this question under the conditions existing in most of the coal fields of the United States, but in some places the seams pitch so sharply, see Fig. 1, as to render the use of these types out of the question.

Fig. 1. Loading Coal from Chute

This was the situation that confronted the Pacific Coast Coal Co. at the Coal Creek Mine. Skilled miners were almost unobtainable, and as the coal is a non-coking, semibituminous variety, adapted for steam and domestic purposes, shooting off the solid made much unsalable product.

Accordingly, over 2 years ago, experiments were begun to increase as much as possible the percentage of lump (which brings about $2 a ton more in the Seattle market than the smaller sizes).

Compressed-air post mining machines of the radial type were installed, and it was found that after a mining was put in with these machines the coal could be sent down the chutes with only a little pick work, and without any powder, except an occasional light shot at a corner or to shoot out a "nigger head." In fact the powder consumption was reduced over 95 per cent.

Fig. 2. Cutting Coal with a Number of Chisels in Bit

The lump coal was increased in this way from about 25 per cent. to about 60 per cent., and the practical elimination of powder made the mine much safer.

The first machines used developed serious mechanical troubles, due to the unusual stresses imposed by frequent falls of coal. About a year ago the company therefore accorded a thorough test to the Sullivan post puncher, and after several months use an order was placed for 30 machines of this type and make.

Figs. 2 and 3 show a "post puncher" in operation in the No. 4 vein of the Coal Creek Mine, where the coal is 4½ feet high, and pitches at an angle of 38 degrees. As this type of mining machine is practically new in American practice, a brief description may be of interest.

The "post puncher" resembles a rock drill in the fact that it is mounted on a post or column and uses bars or steels of various lengths in doing its work. It resembles the "puncher" or pick machine in its ability to mine across the face, or to shear a room from top to bottom. For this purpose the machine and shell are mounted on a gear segment, controlled by a worm and crank. In mining, the operator swings the bit in an arc back and forth across the face. By loosening one nut, the segment may be set in a vertical plane, and a shearing cut made in a similar manner.

This feature is a very great convenience when the coal will not shoot readily unless both mined and sheared. A valuable feature of the "post puncher" is the fact that the machine does not swing around the post, but around the center formed by the socket, in which it is clamped, about 6 inches from the post. It is, therefore, unnecessary to set the column exactly square with the intended mining, but the machine may be set in a few seconds to mine wherever desired, regardless of careless placing of the post. This is a patented feature, possessed by no other similar machine. Dismounting the machine when swinging from the mining to the shearing position is also unnecessary.

The cylinder and valve motion embody other novelties. The front head is solid with the cylinder, thus eliminating the complication of side rods. When the coal is missed, the piston

* Spokane, Washington. Reprinted from Mine and Quarry.

will overrun the front port and stop, thus obviating damage to the front head. This overrunning occurs very seldom with a skilled operator, but the delay attendant on feeding the machine against the coal, so that it will start again, is nothing to the delay due to breakage that would occur eventually if the piston could strike the front head. The cylinder is made of steel to resist the heavy shocks and strains received from falling coal.

Fig. 3. Post Puncher Using 80-inch Extension Cutter

Felt packing of a very durable character and having an adjustable gland, is employed. A combined shell adjustment and stop, to prevent feeding too far, and a rotation without springs, provided with five round steel pins or pawls, are other interesting features of the "post puncher" design.

The exhaust cap is so arranged as to throw the air in any desired direction to avoid raising dust. The extension rods or length bars range from 20 to 100 inches in length, and are tapered at both ends, one to fit the chuck and the other to receive the bit holder. This bit holder has tapered holes for from three to seven chisels or bit points, as shown in Fig. 2. A solid bit may be used instead, depending on the nature of the cutting.

The mining may be put in at any desired height in the

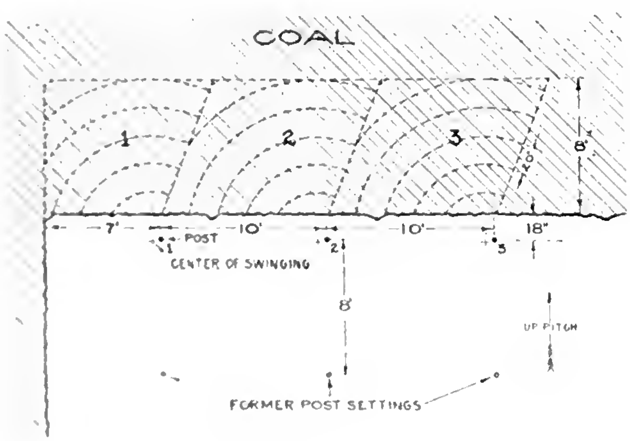


Fig. 4

seam, so as to mine in fireclay, the coal itself, or in a dirt band, by raising or lowering the clamp on the post. In the illustrations the machine is shown mining in a band of bone and clay near the roof, and is accordingly above the segment. In the 6-foot "Muldoon" vein, the impurities are lower in the seam, and the machine is hung below the segment.

Method of Operation.—The rooms are driven 45 to 50 feet wide. The first cut is made from a post set 7 feet from the left rib and about 18 inches from the face, as shown in Fig. 4. A cut 8 feet in depth is put in, using an extension bar 80 inches long. The chuck enters the cut, which accounts for the mining being deeper than the length of the extension. After the 80-inch extension has been swung, a 100-inch bar is used to square up the cut. One man operates the machine, swinging it by means of the worm-crank with one hand, and feeding the cylinder forward two or three turns with the other at each end of the swing.

Although the cuttings fall out of the cut without scraping, due to the pitch, a helper is required to set up, pick down coal, etc. When the operator is completing the left-rib cut, the helper sets up a second post about 10 feet from the first one, or about 17 feet from the left rib, and 18 inches from the face. Upon finishing the rib cut, the machine and swinging attachment are transferred to the second post with only a few minutes delay. While the operator is making the second cut the helper takes the first post down and resets it about 27 feet from the left rib for the third cut, and so on, until the face is crossed. Only a half swing is used, so that the operator is protected by the unmined coal as well as by the machine itself from the coal loosened from the face by the mining.

The machine and posts remain in the room at the face until the room is completed, for there is no shooting of the coal that can injure the machine nor any loading (as in a flat seam) that the machine would interfere with. Hence there is no waste of time due to moving, except from post to post, and little heavy lifting. Two men can set up the machine, see Fig. 5, with ease, as the heaviest parts (the machine and shell) weigh only 225 pounds.

Economic Results.—These machines will average about 300 square feet in an 8-hour shift, or from 45 to 55 tons per machine per shift, according to the height of the coal. While, as stated, the reason for the installation of these machines was solely to increase the proportion of lump coal, even if the cost of mining was increased, the results point strongly toward a material reduction in the cost of mining, after all interest, depreciation, power, pipe line, and maintenance charges have been made against the machines.

In shooting off the solid, the former method, a yardage system of payment was used, the rate being $9.50 for a 50-foot room. Three men worked together, furnishing their own powder. The reason for using a yardage and not a tonnage system was because of the impurities in the seams, and the pitch. The coal and debris go down the chutes together to the slope, there it is loaded in mine cars, Fig. 1, hauled by electric locomotives to the surface and run through a preparing plant of picking tables and washers.

General Mining Features.—The mine where these machines are used is a new one and is worked from a slope 600 feet deep, sunk on the pitch of the seam. Fig. 6 shows the slope bottom of Coal Creek Mine. It adjoins an old mine of the same company, operated through a tunnel. The old mine is nearing exhaustion, but is still furnishing about 600 tons daily.

The new mine is to be worked upon the retreating room-and-pillar system, the entries having nearly reached the boundaries of the property at this writing.

A Sullivan, straight-line, two-stage, steam-driven air compressor with a capacity of 1,843 cubic feet of free air per minute has just been installed at these mines, and a new pipe line laid. The management now plans to put the new mine on one-half capacity (600 tons daily), operating about 12 Sullivan post punchers. Later on, when the old mine is exhausted, the compressor and machine plant will be doubled and the production increased to 1,200 tons.

While the use of Sullivan "post punchers" is particularly adapted to heavily pitching seams, they are also useful in flat seams, where it is desirable to mine in a dirt band above the floor or near the roof. In seams where the cuttings do not fall from the mining by gravity, the helper keeps the cut free by means of a long-handled flat shovel or a scraper.

In some fields these machines have been successfully used for driving entries, and for shearing they can hardly be excelled, especially when both mining and shearing cuts are required, owing to the quickness and ease with which the setting may be altered for either purpose.

From the above article it has been noted that the post puncher was used at Coal Creek with only a half swing, and that the posts were therefore set only 10 feet apart. In stronger coal, or in a flatter seam, where the danger to the operator and machine from falling coal is less serious, the machine is used to cut on both sides of the post, from the same setting, having a maximum capacity of about 18 feet of face from one set-up. To keep the ribs or side walls of an entry or room straight, the bit is swung back and forth across the corner, gradually advancing it with the feed-screw until the angle is square. Or a hole may be drilled at the extreme end of the swing to the full length of the feed-screw, then the bit cranked back and the mining made up to this hole at each swing.

Wedging Down Coal.—The post puncher may also be employed for wedging down coal in mines where the use of explosives is prohibited. After undercutting and shearing, the machine drills a hole about 3 inches in diameter at the top of the seam. An ordinary bit may be used for this purpose. The hole is then scraped out and a compound wedge (plug and feathers) inserted. The machine may be swung around the post if necessary to give access to the hole. When the plug and feathers are placed, the machine is swung back to position opposite the hole and a special hammer inserted in the chuck. The air is gradually turned on, the hammer striking the wedge with increasing force until the coal breaks down.

The writer's thanks for data used in preparing this article are due Mr. J. J. Jones, Superintendent of the Coal Creek Mine, Newcastle, Wash.

THE UNITED STATES BUREAU OF MINES

The act establishing a Bureau of Mines in the Department of the Interior, approved May 16, 1910, became effective July 1. As originally approved, the law contemplated the transfer of the entire Technologic Branch of the United States Geological Survey, the mine accident investigations, fuel investigations, structural materials investigations, the entire personnel, property, and equipment, to the Bureau of Mines, but the Sundry Civil appropriation act, approved June 25, amended the law to such an extent that the structural materials investigations, including the personnel and equipment for these investigations went to the Bureau of Standards, Department of Commerce and Labor.

The Secretary of the Interior has transferred to the Bureau of Mines the investigation of mine accidents and fuels, together with the personnel and equipment of these investigations, and has transferred to the Bureau of Standards the structural materials investigations and the employes of the Technologic Branch of the Survey engaged in these investigations. The Testing Station at Pittsburg also goes to the Bureau of Mines.

The Bureau of Mines therefore includes the mine accidents and fuel investigations for which an appropriation of $410,000 was made. The total appropriations for the Bureau, including salaries, rent, and expenses of removal, amount to $502,002.

The work of the Bureau of Mines for the first year will be a continuation and expansion of the work carried on by the Technologic Branch of the Geological Survey. The law in itself provides for a variety of other problems that properly belong to the Bureau of Mines and which should eventually be undertaken, such as methods of mining and metallurgical processes, but these activities will be deferred for the most part until Congress gives additional authorization in the shape of adequate appropriations. The spirit of the debates in Congress, both on the Bureau of Mines legislation and on the appropriation items, emphasized the desire to regard the mine accident investigations as urgent and this will be the feature of the work.

In all, $310,000 was appropriated for mine accident investigations. Of this sum under the general plans approved by the Secretary of the Interior, $120,000 is to be spent on the rescue stations, $36,000 for housing nine stations; $34,000 for equipping eight new stations; and $10,000 for additional equipment for five existing stations. The allotment for the investigation of explosives is $40,000; for electricity in mining, $14,000; appliances for preventing mine accidents, $8,000; examination and codification of mining laws, $5,000; and other technologic investigations, ore treatment, etc., $10,000. For the analyzing and testing of the coals, lignites, ores, and other mineral fuel substances belonging to or for the use of the United States, $100,000 was appropriated. Of this amount, $35,000 will be spent in the chemical and physical investigation of fuels; $25,000 in the inspection of government fuel purchase; $22,000 in fuel efficiency investigations; $5,000 in lignite and peat investigations; and $4,000 in briquetting investigations.

The publications of the Survey relating to mine and fuel investigations, prepared by the Technologic Branch, will in the future be distributed by the Bureau of Mines and can be obtained by addressing the Director of the Bureau of Mines, Washington, D. C. The publications relating to structural materials will continue to be distributed by the Geological Survey.

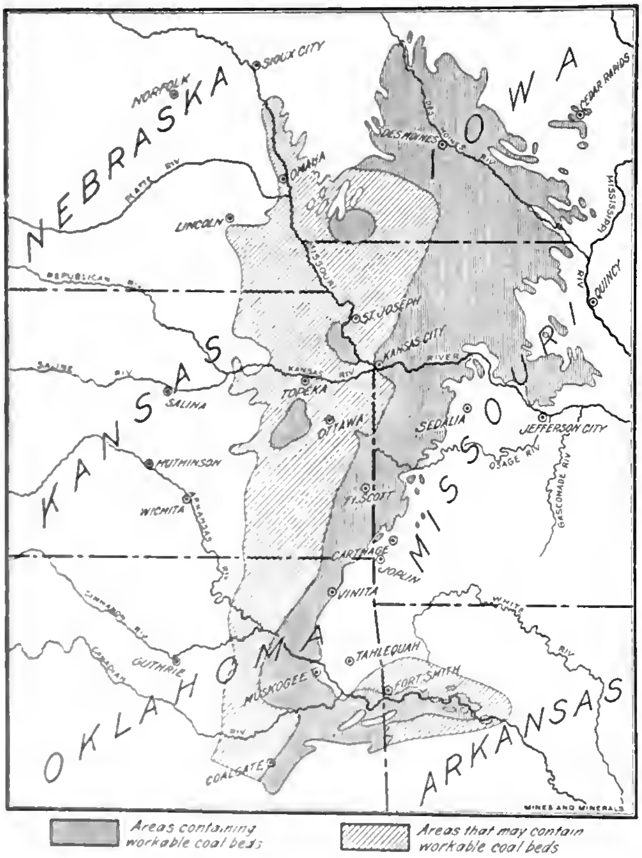
COAL FIELDS OF IOWA AND MISSOURI

By Henry Hinds

Extent of the Beds and Quantity of the Coal. Prospecting. Mining Methods

Extending from northern central Iowa south to central Missouri and thence west of south across southeastern Kansas into Oklahoma is the outcrop of Carboniferous strata that constitutes, one of the most important coal reserves of the United States. Of this region, the coal in Iowa and Missouri is essentially a unit as regards its properties and will be briefly described. Estimated on a most conservative basis Iowa contains 12,560, and Missouri 16,700 square miles of coal-bearing strata, making a total of 29,260 square miles; while a large additional area may contain coal of workable thickness. The possibly productive area in the two states may be 40,000 square miles. Deep drilling west of the present producing fields may increase this estimate, for very little is known concerning the westward extension of the coal horizons.



Map of Iowa and Missouri Coal Fields

Structure.—The structural geology of the region is simple in its general outlines: the strata dip at the rate of from 10 to 20 feet per mile to the southwest in Iowa and to the west in Missouri Small gentle folds and normal faults with maximum throws of 8 feet occur, but are of slight importance. Many of the coal beds, however, rise and fall notably, varying in altitude as much as 40 feet within the limits of a single mine. This feature may not be so much structural in character as the result of irregularities of the floor upon which the coal plants grew. The smaller faults, also, are perhaps due more to unequal shrinkage of the coal-forming peat than to earth movements subsequent to deposition. A feature that is in one sense structural is the presence in the coal of highly inclined clay seams, variously known as "troubles," "wants," "clay slips," or "horses." These seams are in general the result of the filling of fissures in the coal by a squeezing of the underlying clay. In places, however, the fissures were apparently made in the drying peat before it was buried beneath later sediments, and were then filled with material washed in from above.

Stratigraphy.—All of the rocks under discussion are classified on lithologic and economic grounds as consisting of an upper group called the Missouri, and a lower known as the Des Moines. The Des Moines group is divided by Iowa geologists into three divisions known as the Pleasanton above, the Appanoose next below, and the Cherokee at the base.* The subdivisions of the Missouri group need not concern us here. Essentially, the same arrangement of strata is present in both Iowa and Missouri, but in the latter state the Pennsylvanian rocks are often known as the "Upper, Middle, and Lower Coal Measures,"† the "Upper, or Barren Measures" being the equivalent of the Missouri group and the "Middle and Lower Measures" representing the Des Moines group. The maximum thickness of the entire Pennsylvanian series is about 1,400 feet in Iowa and 2,000 feet in Missouri and increases toward the southwest in Kansas to 3,000 feet.

The Missouri group is about 950 feet thick‡ and outcrops in the southwestern corner of Iowa and the northwestern of Missouri. It represents deeper sea conditions than does the Des Moines group, containing as it does an abundance of calcareous and sandy shales and a considerable number of limestones, some sufficiently massive as to form conspicuous topographic features. At times during the deposition of this stage shallow water and land conditions prevailed, permitting the formation of thin coal beds. All of the strata, including the coal beds, are persistent and can be traced over large areas. Two of the coal beds, the Nodaway and the Linquist, have been mined in a small way and the Nodaway is of considerable local importance. It is interesting to note that specially favorable conditions make it possible to profitably mine and ship coal from a bed that is only 14 to 22 inches in thickness.

The Des Moines group, the lower division of the Pennsylvanian series, is from 500 to 650 feet in thickness where it outcrops in a broad band east of the Missouri group. It supplies practically the entire coal output of Iowa and Missouri, its lower portion, the Cherokee shale, being by far the best producer in Iowa and an important one in Missouri. The most striking characteristic of the Cherokee is the extreme variability of its constituents, which are chiefly shale with sandstone and coal and a very few thin beds of limestone. When traced horizontally the coal beds or their associated strata thicken, thin, disappear, and reappear with startling rapidity. Coal merges into carbonaceous shale and carbonaceous shale into light-colored clay shale within surprisingly short distances. Many drill records of prospects taken only a few hundred feet apart have so little in common that it is impossible to correlate them, and sections measured on one side of a narrow valley may show little resemblance to those found opposite. The coal lies in lenticular basins of small extent, for the most part underlying, as a single workable bed, less than 500 acres. In many districts, however, the horizon of one basin is continued by other beds at the same stratigraphic level. The Cherokee shale lies for the most part on a very irregular surface of Mississippian limestone and many of the most productive coal basins of Iowa lie in deep valleys that were eroded in the limestone before Pennsylvanian deposition began. In many places Cherokee strata are thus found surrounded on two or more sides by older rocks. The productive basins of this kind lie well within the main outcrop of the Des Moines, but there are

*Lees, J. H., General section of the Des Moines stage of Iowa: Iowa Geological Survey, Vol. XIX, 1909, page 599.

‡ Smith, G. L., The Carboniferous Section of Southwestern Iowa: Iowa Geological Survey, Vol. XIX, 1909, page 613.

interesting outliers of probable Cherokee age scattered through both states some distance east of the main coal field and completely surrounded by older formations. Coal found in such situations is of poor quality and very limited lateral extent, though surprising thicknesses are reported from Missouri, in one case as much as 75 feet.*

Between the Cherokee shale and the Missouri group is a series of beds that in every way form a transition from the sediments of marginal type prevailing in the former to those of deeper and more quiet waters found in the latter. Limestone is more common than in the Cherokee, but not so thick or abundant as in the Missouri group. Shales, argillaceous, sandy, and calcareous, are still common, but all the strata are more persistent and regular than in the Cherokee. Fairly persistent coal beds are present at several horizons. These are of economic importance and are becoming more so as the more easily accessible basins of the lower formation approach exhaustion. One remarkable bed deserves special mention because of the persistence of special characters and uniform thickness over an area of approximately 1,500 square miles and because it produces nearly 20 per cent. of Iowa's total output and a notable portion of that of Missouri. This is the Mystic, or Mendota, bed. Throughout the wide extent of territory mentioned it varies but a few inches either way from its normal thickness of 32 inches and almost always bears in its middle part a clay band 2 inches in thickness. A thinner clay band near the base of the coal is not quite so persistent but is usually present. The bed indicates a surprising uniformity of conditions over a large area during the time of its deposition. The persistence in position and extent of three thin beds of limestone above the coal shows that the same uniformity continued over the region for a considerable period.

One of the most important questions before the coal geologists of this country at the present time is the western and northern limit of the workable coal beds of the lower Pennsylvanian in this region. Owing to their slight westward dip the formations do not reach a depth too great for profitable mining very far east of central Kansas and Nebraska, but the expense of prospecting deep coal basins as small as those in the Cherokee shale is almost prohibitive. Not one barren drilling in a district, nor even ten, is sufficient to prove that no coal is present. It is possible that no coal may be found in a number of prospect holes that are sunk in the midst of valuable but small coal basins of the lower Pennsylvanian, as is often proved to be the case in prospecting operations along the productive eastern border. Deep mines in Kansas show that the lower Des Moines group is coal bearing as far west as Leavenworth. Deep drilling in Decatur County, Iowa, described recently by the author,† shows the presence of deep coal farther west than it was previously known to occur in the southern part of the state. Certain geologists have advanced theoretical considerations,‡ however, for doubting the continuation of the coal field toward the west, and it is certain that the shaly facies of the Des Moines does thin in that direction. Under present market conditions southwestern Iowa and northwestern Missouri are not legitimate fields for prospecting, but the distant future may witness large mining operations in these districts. The probability that coal may be found much farther north and northwest than it is known at present is not great. The Carboniferous of northwestern Iowa is effectually concealed by a heavy cover of Cretaceous and glacial material. It is probable that the Pennsylvanian, where present, was largely removed by erosion before the Cretaceous was deposited.

Mining Methods.—The occurrence of the lower coal beds in basins of small extent increases greatly the cost of mining, and more especially that of prospecting. In Iowa and northern Missouri a heavy cover of glacial drift from 50 to 400 feet thick adds still another difficulty, as it must be drilled through before the coal horizons are reached and because it effectually conceals all natural outcrops except along the major streams. The irregularity of the beds renders imperative the thorough prospecting of a field before a shaft can be sunk with safety. The preliminary drilling of a large tract commonly results in the abandoning of about one-third of the mineral options held, and when workable coal is finally located its limits can only be determined by drilling at least every 30 acres. This forms a striking contrast to conditions in the neighboring fields of Illinois, where coal beds are, as a rule, quite persistent.

The coal beds of the Cherokee shale, where mined, are in general 3 to 6 feet in thickness. They have a tendency to "thin to the rise" and "thicken in the swamps," as it is expressively termed, increasing locally to as much as 16 feet, as in Marion County, Iowa. Clay-ironstone concretions are plentiful in these abnormally thick portions of a bed, in places partially destroying its value. Coal beds are almost invariably underlain with clay and overlain with at least a few inches of dark shale known as "slate." Now and then a sandstone comes down to form the immediate roof, or fills shallow channels eroded in the coal swamps in Carboniferous time, forming the so-called "rolls in the roof" and the "faults" of mining phraseology. In some few cases an impure concretionary limestone makes a "boulder" or "niggerhead" roof of exceptional stability. Most of the mines in Cherokee beds find it necessary to employ the room-and-pillar system of mining and to carefully timber the roadways. Coal beds in the upper two formations of the Des Moines group and in the Missouri group are somewhat thinner, commonly ranging from 2 to 4 feet. A limestone cap rock generally lies a few feet above these beds and makes it possible to mine longwall, a system that is growing in favor.

Some mining is done in Missouri by stripping, but the greater part of the coal in both states is taken out through shafts, slopes, and drifts. Shafts are never deep; a depth of 300 feet is exceptional. Owing to the small area to be won from a single shaft, not many mine equipments are expensive, and the life of a mine is seldom greater than 10 years. Of late years more systematic prospecting has made it possible to install larger mines with plants that are modern and complete in every respect. Tail-rope haulage, powerful hoisting engines, self-dumping cages, and other improvements are now the rule rather than the exception. It is to be hoped that the wasteful practice of "shooting off the solid" will decrease in favor.

In quality Iowa and Missouri coal is a low-grade bituminous, with a few occurrences of cannel. The bituminous coal shows a range in calorific value in air-dried samples from 10,000 to 12,000 British thermal units, with an average of about 11,000 British thermal units. Sulphur and ash are extremely variable in amount, but are commonly high, the sulphur averaging about 5 per cent. and the ash 13 per cent. Gas-producer tests have been fairly satisfactory; a test on an Iowa coal required 1.73 pounds of dry coal to produce one electrical horsepower, compared with 4.95 pounds under the steam boiler, a gain of 186 per cent. in efficiency in favor of the producer.* Attempts to coke these coals for commercial purposes have not been very successful; the coke made was not of sufficiently good quality to compete with the better grades from fields farther east, while the high content of sulphur precluded its use in iron furnaces. The amount of sulphur present also renders the coal undesirable for making illuminating gas. For steaming purposes the Iowa and Missouri coal gives good results, and for domestic use some of the beds, notably the block coals of the Mystic bed, compare very favorably with those of Illinois.

M. R. Campbell of the United States Geological Survey estimates that original coal supply of Iowa was 29,160,000,000

* Wilder, F. A., Fuel Values of Iowa Coals: Iowa Geological Survey, Vol. XIX, page 411.

short tons and that of Missouri 40,000,000,000.† The total for the two states, 69,160,000,000 tons, was 30 per cent. of that for West Virginia. Of this amount there has already been utilized and wasted at the mines only $\frac{4}{10}$ of 1 per cent. The production of Iowa in 1909 was 7,163,000 short tons; that of Missouri 3,787,000 short tons.‡ The total output, 10,950,000 tons, is 23 per cent. of that of West Virginia. Missouri was the first and Iowa the second state west of the Mississippi River to mine coal, the former being credited with nearly 10,000 tons and the latter with 400 in the United States census for 1840. Iowa's output has steadily increased and kept pace with the wonderful growth of the country which it supplies, and it now ranks second only to Colorado among states west of the Mississippi. Missouri has been less fortunate, as the influx of cheap natural gas and fuel oil from Kansas and Oklahoma has made serious inroads on the demand for coal. The output of the state for 1909 was practically the same as that for 1888. A decrease in the supply of oil from the Mid-Continent oil field will witness a corresponding increase in the coal mined in the states of the southern and central parts of the western interior coal region.

Iowa and Missouri coal has made its influence felt but little in markets outside of the states in which it is mined,§ the product is consumed chiefly in districts immediately adjacent to the mines. Coal that leaves the confines of the fields goes west into Nebraska, Kansas, and South Dakota, and north into Minnesota. Toward the west it enters into competition with the large fields of the Rocky Mountains; toward the north it meets coal that comes by water to Duluth from points in Ohio, Pennsylvania, and West Virginia. Very little is shipped as far east as the Mississippi River, because of the better grades supplied by Illinois and eastern fields. Very little goes south of Missouri, though southern Iowa has sent small quantities as far as Oklahoma. Roughly speaking, 35 per cent. of the product is used by the railroads, 45 per cent. for domestic purposes, and 20 per cent. by manufacturing plants. The future growth of the coal industry will be that of the territory which it supplies, augmented by the inception of manufacturing in territory now purely agricultural.

HOW HE EXPLAINED THE B. T. U.

The increased use of the term "B. T. U." by the buying public has brought out a good story of its introduction in an Indiana town.

It was a Federal institution—and still is. The highbrow in Washington who had drawn up the specification had heard something of B. T. U., and inserted in the specification that each bidder must state the B. T. U. value of the coal proposed to furnish under his bid.

The B. T. U. was a new one on the board of managers of the hospital, whose knowledge was more extensive as to crops, and the best method of keeping the inmates solid for the Congressman who had secured the hospital for that district.

On the day the bids were to be opened the managers gathered about the long table in the board meeting room. The salesmen of 15 bidding concerns were there to see that everything was done according to form, and each determined to bring the contract home for his company.

Each was called upon in turn to tell the merits of his particular coal. Not one failed to discourse learnedly upon the new subject of B. T. U. After it was all over, seemingly, but the actual awarding of the contract, one member of the board waggled his chin whiskers to inquire: "What all this B. T. U. business was about anyhow. I don't know what it means," he admitted, to the relief of the other six members, who were equally ignorant, but not so willing to take the lead in admitting it. "I'd like to have you coal men enlighten me and this board on that subject. You seem to know all about it, but we don't."

The board settled back, relieved of a responsibility and with a hunger for knowledge.

"You, Mr.——," the president said, addressing a salesman at the end of the table. "You tell us what this B. T. U. business is, anyhow."

Not one of the other salesmen in the room envied the honor that had gone to their fellow laborer. He hemmed and hawed and ended by talking all around it, but the rest of the salesmen and the board realized he didn't know what he was talking about. Thus it went down the line. Not one knew the real meaning of B. T. U. until it came the turn of "King Cole"—only that wasn't his real name. He represented a Columbus, Ohio, firm and had a reputation to sustain. His specialty was getting out of embarrassing situations.

He advanced to the center of the group, with a confidence that gave the board assurance that at last a man had been found who would rend the veil.

"Mr. President," he began, "these gentlemen are all wrong. I'll tell you how you can tell the B. T. U. of any car of coal that comes to this institution."

The board was convinced he knew already. The other salesmen were amazed because they were aware that he knew nothing more about it than they did.

"Mr. Secretary, get out your paper and pencil and take down these figures as I give them to you.

"All right, now? When a car comes in here you first look for the serial number. Suppose that is 10,177. Put that down, Mr. Secretary. Then you look on the side of the car for its capacity. That is 60,000 pounds, say. Put that down, Mr. Secretary. Then you multiply those two figures. Have you done that, Mr. Secretary? You got that down?

"Then you go around to the end of the car and look for a number on the brake beam. That's 19,015, say. You divide that into your quotient and that'll give you the B. T. U. of that car of coal. If that doesn't make it any clearer to you I don't know who can."

By that time the room was in an uproar of laughter. The board members realized just at the finish that they were being "jobbed." But it was the psychological moment.

And "King Cole" got the contract!—*E. B. K. in The Coal Trade Journal.*

OBITUARY

WRIGHT S. PRIOR

Wright S. Prior died at Denver, Colo., July 5. He came to Colorado from Worcester, Mass., and had been engaged in the mining business for some years. For the past four years he had been president of the Conqueror Mining Co., at Empire, Colo.

WILLIAM SMURTHWAITE

William Smurthwaite who was engaged in mining for half a century, died in Steubenville, Ohio, on July 12, aged 80 years. Mr. Smurthwaite was born in Philadelphia, Durham County, England, December 19, 1829. At the age of 15 he assisted his father who was deputy foreman. In 1848 he was employed as mine foreman at Quarantine Hill. He emigrated to the United States in 1858, and was employed as mine foreman by the Steubenville Coal and Mining Co. in 1859. A few years later he was appointed superintendent, a position he held for 47 years, retiring at the age of 77. During his entire administration there were but three men killed, and although the mines generate firedamp there was not a miner burned in 40 years. Andrew Roy in his "History of Coal Mining in the United States," pays a tribute to Mr. Smurthwaite's ability as a mine manager.

CORRELLATION THACKER FIELD

Written for Mines and Minerals, by Audley H. Stow

Thacker, Grapevine, Mate Creek, Williamson, and Naugatuck Coal Seams

The "Thacker" seam derives its name from the town of Thacker in the vicinity of which it was first mined. The town in question is located on Tug River, on the Norfolk & Western Railroad, about 14 miles (by rail) east (toward Norfolk, Va.) from Williamson, the county seat of Mingo County, W. Va.

The Thacker seam, as it is originally known, consists of two seams of coal, the interval between which, in the vicinity of Thacker, is so slight that a considerable tonnage has been derived from the mining of the two seams as one.

Fig. 1 shows the Thacker seam, on Thacker and Grapevine creeks, the latter being about ½ mile east of the former. On only a part of the watershed of these two very small streams, however, is it practicable to mine the two seams as one; while going in any direction from the locality mentioned, the interval between the two increases rapidly in thickness, being more usually from 30 to 80 feet.

At Thacker, it is the upper bench, or the upper seam, that gives Thacker coal its high market rating. It is characterized by a middle band of gray splint, and a tough blue slate roof.

On Mate Creek, 4 miles west (toward Columbus) by rail from Thacker, the upper bench of the Thacker seam is mined exclusively (unless perhaps quite recently); on Mate Creek, however, where the holdings of the Red Jacket Consolidated Coal Co. are largely located, the development of the lower bench, is generally fully equal to that of the upper bench, and of equal purity, both being entirely devoid of slate bands or partings. The lower bench is characterized by a sandstone roof.

Owing to the large tonnage now coming from the upper bench of the Thacker seam, as compared with that, if any, from the lower bench, the former is now more generally known as, and will hereinafter be understood to be, the Thacker seam; some years ago, I suggested the Mate Creek seam as an appropriate local name for the lower bench, which has, as far as noticed, been generally accepted.

Fig. 2 illustrates the transition from the sections shown on Thacker Creek, to the two separate seams on Mate Creek. These sections were taken near the mouth of Mate Creek, on the holdings of the Logan Consolidated Coal Co. Farther up Mate Creek, the lower seam becomes clean; the United Thacker Co. having in this territory a large acreage over which the two seams referred to rival each other in thickness and freedom from impurities. Throughout Mingo and Logan counties, W. Va., and that portion of Pike County, Ky., that is drained by the waters of Tug River, the Thacker seam (upper bench or seam), may be said to be the lower limit of the splint coals; that is, the proportion of splint in the Thacker seam, and those overlying it, is much greater than in those underlying the Thacker seam. The seams above are not infrequently solid splint, while much the larger portion of the coal in the lower seams has a bright glassy luster and conchoidal fracture.

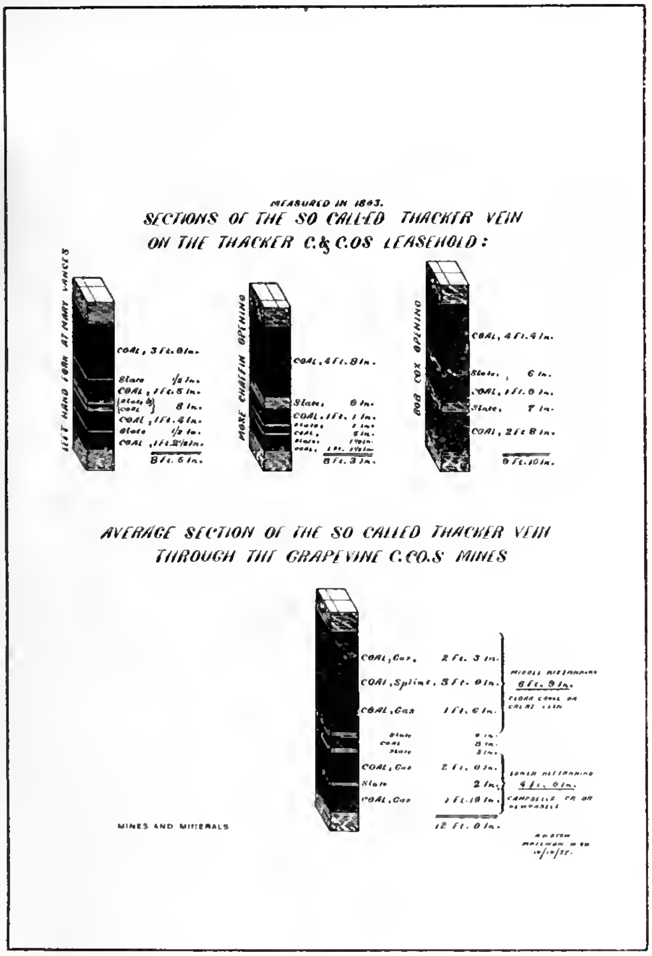

FIG. 1

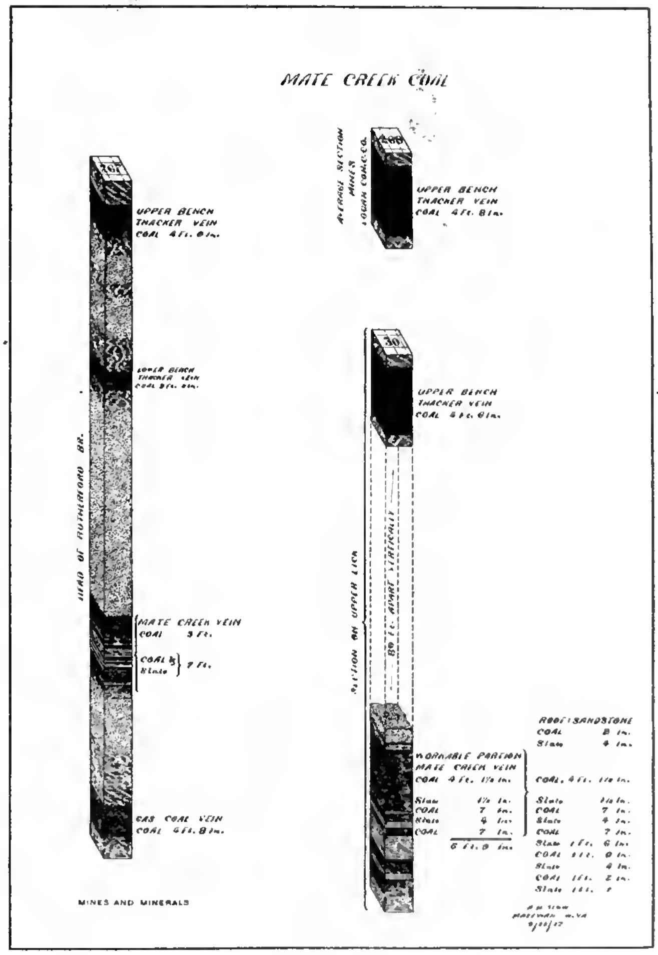

FIG. 2

At an interval of usually 90 feet above the Thacker seam, is one that is of interest, owing to its great persistence and comparatively regular thickness, the roof also being a blue slate. The tonnage in this seam must closely approximate the Thacker seam, and has not as yet been noticed to contain any slate bands or partings whatever. As it is only 3 feet in thickness, it is not,

in comparison with the Thacker seam below, now considered workable. As only too often happens, it is most unfortunate that the relative positions were not reversed, at least in so far as the conservation of natural resources is concerned.

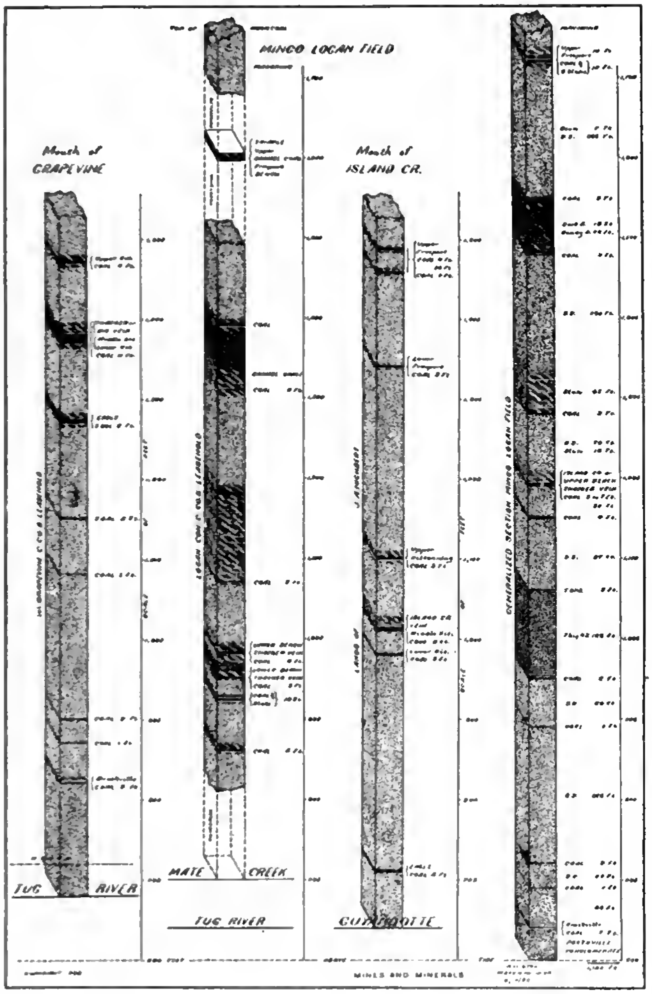

Fig. 3

At the mouth of Grapevine Creek, the Thacker seam is 700 feet vertically above the railroad, whereas at the mouth of Mate Creek, about 5½ miles west by rail, it is only 450 feet, the strata thus dropping, in the distance stated, 250 feet faster than Tug River.

Two miles west of the mouth of Mate Creek, an effort was made, some years ago, to locate the Thacker seam. As the dip of the strata had been determined beyond question, and as the seams above and below were well understood, the problem was easy. The "bench" on which the Thacker seam was due to be found, at an elevation of 350 feet above the railroad, shows only a dirty seam having a band of cannel shale, thus illustrating the relation between splint and cannel coal.

At Williamson, 250 feet above the railroad, the Thacker seam, locally called the Garner seam, shows a total section of 4 feet 3 inches, 6 inches of which is slate, in three separate bands or partings; the roof still being a tough blue slate, while the splint is also still somewhat in evidence. At Nolan, 9 miles west of Williamson by rail, the Thacker seam, at an elevation of 140 feet above the railroad, shows a total section 4 feet 10 inches, 2 inches of which are slate, as before, in three bands.

At Naugatuck, the mouth of Pigeon Creek, 18 miles west by rail of Williamson, is found, at an elevation of 300 feet above the railroad, the upper Freeport or Stockton seam, which has been mistaken for the Thacker seam. The following, although not a detail section, will give an idea of this seam, at the point under consideration:

Roof, Sandstone			
Coal	1′ 10″		
Slate		4″	
Coal	1′		
Slate		1″	
Coal	1′ 7″		
Slate		1′ 10″	
Coal	1′ 6″		
	5′ 11″ +	2′ 3″	= 8′ 2″

The bottom bench, given as 18 inches, more usually appears as 4 to 5 feet total section, somewhat cut up, however, with slate, the total section being more usually 10 to 12 feet. This seam is easily recognized over a considerable extent of country, and is a most convenient horizon for correlation. One of its characteristic features is a considerable band of extremely fine black slates interleaved with thin laminæ of coal which break up into minute flat square blocks, somewhat resembling splint, on fractures at right angles to the seam.

The Freeport, as it is often called even locally, in the vicinity of Dingess, on the Norfolk & Western, at which point the tunnel to the head of Twelve Pole, is located, was measured as follows:

Roof, Sandstone			
Coal, gas, good	1′ 1″		
Slate, tough		4″	3′ 5″
Slate, shelly		5″	
Coal, splinty, good	1′ 7″		
Splint, slaty	1		
Splint, and slates		8″	1′ 8″
Coal, splinty, good	2:		
Slate, shelly		7″	
Blast and splint or bone		4″	5′ 8″
Coal, gas, 3 small bones	2	9″	
	7′ 8″	3′ 1′	10′ 9″

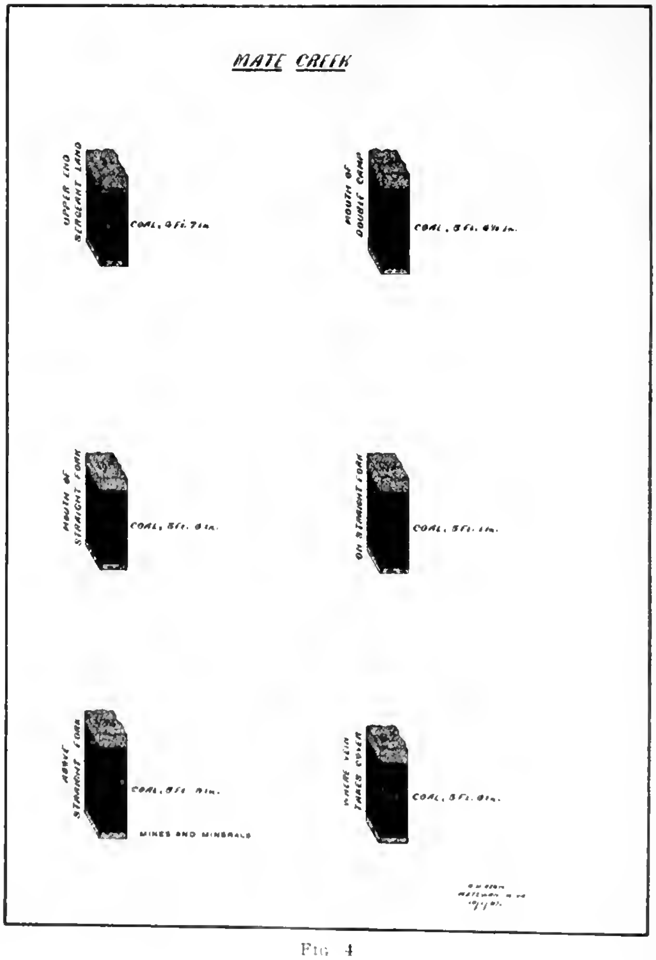

Fig. 4

As will be evident, this seam consists of two main benches, each of which in turn also consists of two benches, making four in all. The 10-foot 9-inch section just given may be said to be a fairly representative section of the seam under consideration.

The interval between Nolan and Naugatuck has not as yet been prospected by myself, so the above chain of evidence may appear defective. As the Warfield anticline is being approached, it might be argued that the Thacker seam rises from an elevation at the former point, of 140 feet above the railroad, to 300 feet at Naugatuck. Yet that such is not the case would appear from a partial exposure, 4 miles west of Williamson, at an elevation of between 600 and 700 feet above the railroad, of what was fairly clearly the Naugatuck, or Upper Freeport, seam given above.

The accompanying generalized sections, Fig. 3, were made in 1897, from aneroid measurements, the exposures being seldom vertically one above the other, the dip of the strata being, however, allowed for. The intervals between the seams are probably not sandstones and shales, exactly as shown, but were so, as nearly as at the time could be determined from natural exposures in the immediate vicinity. The interesting area of Winifrede coal west of Williamson had not at that time been prospected, although the Winifrede and Coalburg seams at the latter point are probably the two seams below that designated as the Upper Freeport, in the generalized section of the Mingo-Logan field. The section on the lands of J. A. Neghtert, is on what is now the holdings of the United States Coal and Oil Co., at Holden, W. Va. The two remaining sections were taken in the holdings of the Red Jacket Consolidated Coal Co.

The intervals shown apply to the territory east of Williamson, to Grapevine Creek of Tug River, and across to Logan, the county seat of Logan County, on the Guyandotte River. From a point 9 miles west of Williamson, going toward the Ohio River, it appears probable that there is a rapid thinning of the measures, the intervals at Naugatuck being probably much less than shown. At the time these sections were made, it appeared preferable to refer them to the Pennsylvania series.

AUTOMATIC COAL SAMPLER

Quite a number of letters have been received by Mines and Minerals, requesting information on automatic coal samplers. After diligent search the one illustrated in Figs. 1 and 2 was furnished by Mr. H. G. Statt, superintendent of motive power, Interborough Rapid Transit Co.

It consists of a spout *a*, attached to the sloping side of a scale hopper *b*. In the spout are two sliding plates *c* and *d* actuated by the levers *e, f, g, h, i* in such a manner as to move one in as the other is moved out, thus cutting out a sample of coal in the spout *a*. There is a reach rod *j* connected with lever *e* and a hand wheel *k*, for the purpose of causing the sliding doors to reciprocate as the wheel revolves.

The metallurgist will see at a glance that the principle on which the sampler is constructed is wrong, and that even a fair average sample of run-of-mine coal could not be taken with it, let alone prepared sizes. If coal is purchased on analysis from this kind of a sampler, it is certainly proof positive that the producer is furnishing an excellently prepared coal. As previously stated, nothing is to be gained by purchasing coal on analysis. Coal producers prepare their coal for market to the best of their ability whatever way it is sold, and in addition have coal inspectors on each car looking for impurities as the car is loaded. Market conditions are such that if the producer does not ship good clean coal he will lose his customers once and for all, because consumers do not care to change coal dealers if it can be avoided.

It may be added that experience has shown that inter-

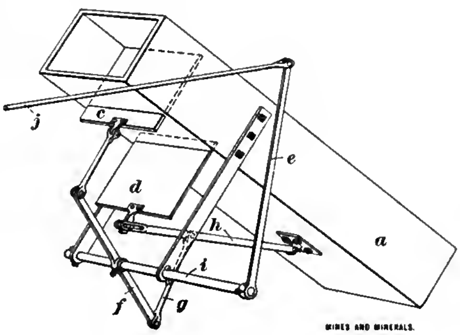

Fig. 1

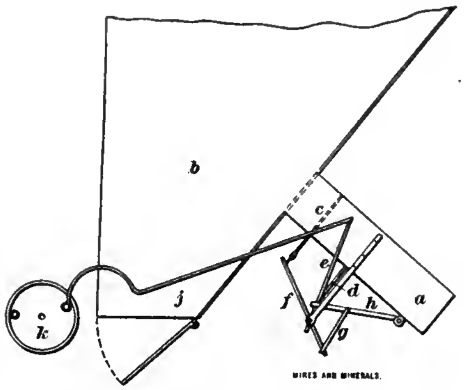

Fig. 2

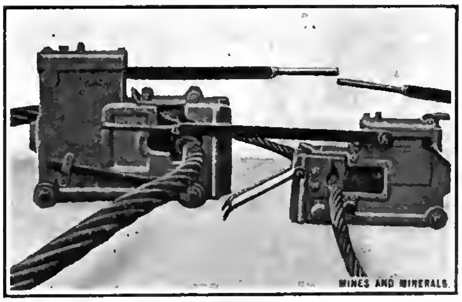
mittent samplers are failures in furnishing fair average samples and since the sampler illustrated is in this class it too must prove a failure.

Most consumers think miners work by the day and are under the eye of a foreman who can inspect their work. For their benefit it is stated that coal miners are contractors who mine by the ton, and while most of them undoubtedly try to clean the coal, some in the hope of its passing inspection are not so particular. The value of a first class coal sampler under these conditions becomes apparent, because if the consumer notices impurities in a single case he is likely to think they extend through the whole shipment. With a good sampler he would know.

A WIRE ROPE CUTTING MACHINE

Written for Mines and Minerals, by Frank C. Perkins

The accompanying illustration shows the construction and method of operation of a novel English mining wire rope cutting machine of the Selby type designed in London for use in collieries and other mines. It is a simple portable device and rapid in its operation, requiring only one man to actuate it in cutting wire ropes up to 9 inches in circumference.



Wire-Rope Cutter

In charging the cutter the ram is moved back and the reservoir filled with clean water with a small quantity of glycerine added, the air screw in the device being opened and the relief valve screwed up when ready to cut the rope. The cover is opened and the rope inserted when the former is replaced and locked. The pump is then operated by means of the lever until the rope is cut by the shears. The relief valve then has its screw slackened in order to return the shears by sliding the lever on to the hexagon spindle and pressing back the same steadily. The operation of the shear by the ram in cutting the wire rope is clearly indicated by the accompanying illustration.

POWER USED IN MINING*

By Edward O'Toole†

When mining first began human beings furnished the power. They broke the coal and loosened it with rude tools fashioned by hand from wood, stone, or iron, often carrying it on their backs, in baskets made from willows or bark from trees, to places where it was used, sometimes it being necessary to carry it up ladders for considerable distances.

Men, Live Stock, Mechanical Power, and Explosives. Payments in Case of Accident

When there became what was considered in those early days a scarcity of labor, animals, such as horses, donkeys, oxen, etc., were brought into use for the purpose of raising and transporting the material mined.

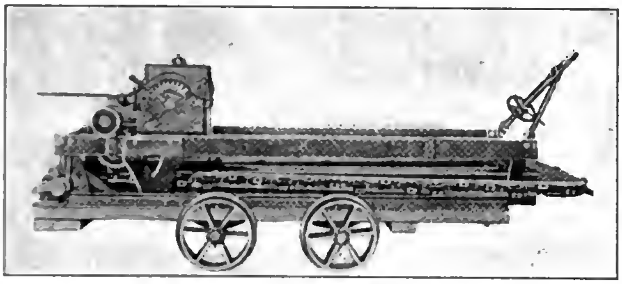
Afterwards explosives were introduced to help break down the materials, hydraulic, steam and electric machinery coming later for various purposes.

This gave six sources of power; namely, labor, animal, explosive, hydraulic, steam, and electricity, the five latter being introduced by the miner to lighten his labor.

This will bring us to the present, when the percentages of power cost, as used by the United States Coal and Coke Co., and the percentages of energy produced, are as follows:

	Cost Per Cent.	Energy Per Cent.
Labor cost per ton	87.6	38
Total live stock expense	4.0	12
Mechanical power	4.7	35
Explosives	3.7	15
	100.0	100

The above shows that while our mines are well equipped with machinery, we are still large employers of labor. This labor is divided into executive, engineering, supervising, laborers, and clerical. The engineers directing what is to be done and how to do it, the supervising department carrying out the ideas of the engineers by directing the laborers and guiding them in the most practical way to perform their task, the laborers performing the task, and the clerk in the accounting department keeping the accounts and distributing the allotted compensations.



Morgan-Gardner Coal-Cutter, Mounted on Truck

Of the various departments, the supervising is the most important, for the reason that the labor is the most expensive item, and therefore, the most important; and a good executive is considered of more importance than a good engineer. As the mechanical appliances around a mine increase, the engineer becomes of more value, particularly is this the case where the property being developed is large and the machinery diversified. When the engineer is thoroughly competent, does the advance thinking, and gives his property the attention it should have, his value is second to none. We appreciate the value of the engineer and employ him possibly more than he is employed by the mining industry generally.

Our supervising department follows the plans and the instructions given by our engineers, but they are encouraged in reporting what, in their minds, will be desirable changes; and they are often able to assist the engineering department with suggestions, otherwise they simply supervise and direct.

The general labor around coal mines is diversified. Our laborers represent 12 nationalities, and as the Americans are divided between whites and negroes, they actually represent 13, which are as follows:

Nationality	Per Cent.
American	17.80
Hungarian	22.20
Slavs	5.80
Russians	3.00
Poles	4.50
German	.50
Italian	13.80
Roumanian	5.50
French	.01
Greek	.06
Spanish	.01
Swede	.02
Negroes	26.80
	100.00

You will notice the absence of the English, Scotch, and Irish, which nationalities in former years were numerous among the rank and file of mine laborers. Where mining has been carried on for a number of years, they or their children are still largely employed, but with us they are only represented in the official classes. Some of the above nationalities are also represented among the officials, particularly the German, Italian, and Hungarian. These people all make very good mine employes, and, if properly instructed, soon recognize the necessity of care and readily adapt themselves to any safety measures introduced for their benefit. Some of the negroes are reckless and are prone to take chances, but this applies to some of the younger ones only, and usually the matured men are ideal miners, capable and trustworthy. They mostly follow the transportation and mechanical departments, run mining machines, motors, etc., and where premiums are offered for the care of the machinery they are often successful in earning them.

Our miners and other laborers around the mines are required to obey the mining law and the rules of the company, which they do fairly well; and while some 2 or 3 years ago, when breaking up the blasting from the solid, it was necessary to have some of them prosecuted, I have heard of no breach of the law or rules since that time. These people are also law abiding and peaceful at their homes or on the streets, and with a population of 10,000 to 12,000 in this mountainous district, we have very little trouble. We employ no police officers except the regularly elected constables and justices of the peace, and they do not have sufficient business to make a living at their office. This, I believe, will compare favorably with any community where any class of people are employed in the same numbers.

The other, or accounting department, needs no comment, it being the same as the clerical department of any mining company.

Source of Power.—The introduction of explosives in coal mining was very unfortunate, as there is hardly a mining community that has not suffered from a disaster which is directly traceable to them, and of late years, as their use has increased, the disasters have become more frequent; and in communities where their use has been unrestricted, it being left to the judgment of the individual miner, the results have been appalling. Fortunately for those engaged in coal mining, the government is now testing explosives and giving their approval to those that will justify it, after a public demonstration. The powder they approve they term a "permitted explosive," and if the people will use this permitted explosive in limited quantities at each blast we will surely have fewer disasters, and the fatalities and injuries to employes will be greatly reduced. All of the mining countries in Europe have what is known as a charge limit, and in Belgium the use of explosives is not permitted in gaseous mines under any circumstances or for any purpose.

*Paper prepared for Summer Meeting of West Virginia Coal Mining Institute.

†General Superintendent United States Coal and Coke Co., Gary, W. Va.

Explosives are undoubtedly of great service to the miner and assist him materially in getting his coal, but their use would better be stopped entirely than to go on at its present cost to human life.

We use only permitted explosives in our mines, or powder that has passed the government testing station. The miners seem to prefer those listed under the name of Colliers or Monobel, which are recommended and sold to us as a powder that will not deteriorate and can be bought in carload lots, which is quite an item to us, situated as we are, so far from the source of supply. The only requirements we make of the powder people is that the powder will sell to the miner at 5 cents per stick. Our charge limit for these powders is 1½ pounds.

Baldwin-Westinghouse Electric Gathering Locomotive With Electric Cable Reel

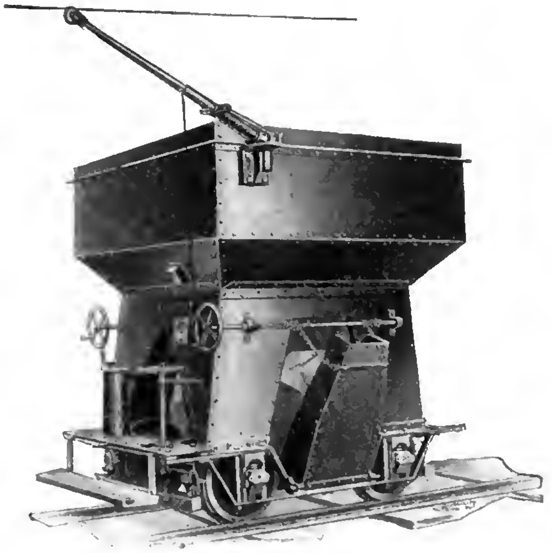
Animal power is also largely used in our mines, equaling 4 per cent. of the total power cost, while the energy produced is about 12 per cent. We have made some efforts to introduce mechanical power to displace the mule, but so far, for certain services, he has proved indispensable. The mule is the principal animal power, but horses are used in some of our mines.

Mechanical power will undoubtedly be the power of the future; and while the cost of the mechanical power used only represents 4.7 per cent. of the total cost of mining coal, we supply mechanically more than 35 per cent. of the total energy required. This would certainly justify us in endeavoring to increase the use of mechanical power at the expense of power of any other kind. The introduction of machinery into coal mining has come by numerous ways. It was first used to raise material out of shaft workings, then water, then as a transportation and ventilating power, and last, to undermine the coal. The machines used for the different purposes have been subjected to a series of modifications; and while some have been simplified, some have been made more complicated as their uses have been extended, until at present, we have the self-propelling under- and over-cutting mining machine, the electric and compressed-air haulage motors, which operate with equal facility both on the surface and in the mine, rotary pumps, and electric-driven, self-starting, ventilating fans. We also have extended systems of underground railroads or haulageways, in some instances laid with rails which weigh 90 pounds to the yard; vast numbers of mine cars, and other equipment too numerous to mention, which cost money to install and operate; but the cost is insignificant when compared with the cost of labor, and it would be utterly impossible to find labor to produce half our present tonnage should we dispense with the use of mining machines for undercutting the coal and the explosives for blasting it down. In fact, with all our machinery, there never was a time in the history of mining when labor was as scarce as it is today. This being the case, it behooves us who wish to stay in the mining business to find more ways and means of using machinery. We must also find ways of improving the machinery we now have to make it more effective. We must find more direct methods of applying our power. We must eliminate all useless operations and roundabout ways; go to the portions of the mining operations which now require the manual labor and apply mechanical power to the same in our efforts to reduce the cost of labor per ton.

At the present time we are developing, and have partly developed, a system of mining and handling coal, which we think will eliminate a large portion of labor now used, particularly where the coal mined is to be used for the manufacturing of coke or the raising of steam, where the firing can be done by means of mechanical stokers. We have accomplished this by the use of a machine which cuts out the total thickness of the seam, removing the coal as it is cut by the machine to the outside by means of currents of air at high velocities, on the order of the pneumatic carpet cleaner. We have termed this method of handling coal "The Pneumatic Transportation." We have had an experimental plant in operation at our No. 9 mine for a period of about 6 months, and are now through with our experiments, having gathered all the data we consider it necessary to have for the establishing of a commercial operation. We will operate this plant for the benefit of the Mining Institute, and after said operation the experimental plant will be partly dismantled.

In the changing of mining from hand power to mechanical power, both for mining and transportation purposes, we have largely increased the number of accidents, not only per 1,000 men employed, but per 1,000 tons of coal mined as well. This shows clearly that the introduction of machinery so far has not paid when calculated on the basis of accidents. This increase of accidents applies to the mines in which no machinery is used, as well as to the machine mines, and it is undoubtedly caused by the changes in the occupation of the men in the machine mine, and to the increased amount of coal they endeavor to get in the hand mines to compete with the machine mines.

This increase of accidents cannot go on, as it is now much higher in this country than in Europe, I will not use the general term, "Where the mining is more hazardous," but say instead, where the conditions of labor are more severe and exacting; neither will I attribute it to our less skilled labor, but rather blame our less rigid discipline, freedom, and variable methods of operation. There is an awakening; the public is being aroused to a sense of responsibility in the matter of industrial accidents, and to the amount of property and distress occasioned by them, not only in coal mines, but in every other industry, and will gladly pay the few additional cents per ton necessary to permit the business to be conducted in a more safe and humane manner, and whatever additional cost is necessary to alleviate the suffering and distress caused by unavoidable accidents. I wish to assure you and the public at large that



Scottdale Electric Coke-Oven Charging Larry

there is no coal operation but what will gladly sacrifice its dividends, if by so doing it can reduce the number of accidents in and around the mine.

To reduce these accidents it will be necessary for the miners to become more thoroughly familiar with the machinery and with the conditions created by its use, and to protect the machines with guards of different kinds so that accidents from the same will be impossible. Where coal is still mined by hand, it will be necessary to revert to the old method of mining; namely, the undercutting of coal must be done as formerly, so that large charges of powder will be unnecessary. In both cases the supervision will have to be more thorough and vigilant than it has been heretofore.

H. K. Porter Co. Compressed-Air Mine Locomotive

I would suggest increasing the number of district mine foremen, so that the working places can be visited three to four times each day, and that some means be adopted to insure his attention to business, particularly in regard to accidents. In addition, I would suggest each company putting accidents on a financial basis, which would take the nature of an insurance or assurance to the victim, and that in case of accidents, whether fatal, serious, or minor, for that matter, a stipulated amount will be received by him, sufficient at least to furnish the necessaries of life during the disablement period, and in cases of permanent or fatal accidents a stipulated sum.

The following is the basis on which the United States Coal and Coke Co., as well as all other constituent companies of the steel corporation, award payments in case of accidents:

TEMPORARY DISABLEMENT

Single Men.—Single men who have been 5 years or less in the service of the company shall receive 35 per cent. of the daily wages they were receiving at the time of the accident. Single men of more than 5 years service shall receive an additional 2 per cent. for each year of service over 5 years. But in no case shall single men receive more than $1.50 per day.

Married Men.—Married men living with their families, who have been in the service of the company 5 years or less, shall receive 50 per cent. of the daily wages they are receiving at the time of the accident. For each additional year of service above 5 years 2 per cent. shall be added to the relief. For each child under 16 years 5 per cent. shall be added to the relief. But in no case shall this relief exceed $2 per day for married men.

PERMANENT DISABLEMENT

For the loss of a hand, 12 months wages.
For the loss of an arm, 18 months wages.
For the loss of a foot 9 months wages.
For the loss of a leg, 12 months wages.
For the loss of one eye, 6 months wages.

FATAL ACCIDENTS

In the case of married men living with their families, who have been in the service of the company 5 years or less, and leave widows, or children under 16 years of age, the company will pay relief to the amount equal to 18 months wages of the deceased employe. For each additional year of service above 5 years, 3 per cent. shall be added to this relief. For each child under 16 years, 10 per cent. shall be added to this relief.

In addition to the above, we have adopted a system of paying premiums for the elimination of accidents.

The ratio of accidents for the first 4 months of the year 1910, in our mines, is as follows:

Fatal

	Per Cent.
Falls of slate and coal	83.3
Mine cars and motors	16.7
	100.0

Injuries

	Per Cent.
Falls of slate and coal	47.2
Mine cars and motors	38.9
Blasting coal	2.8
Mining machines	2.8
Miscellaneous	8.3
	100.0

This shows very plainly, under our present method of mining, that the large percentage of accidents come immediately under the supervision of the minor officials of the mine, and can be materially reduced if these officials give slate and loose coal their personal attention; and I am glad to inform you that I believe we are now on the right road to eliminate a large number of the accidents at our mine. Our officials are beginning to understand that there is something expected of them besides getting cheap coal.

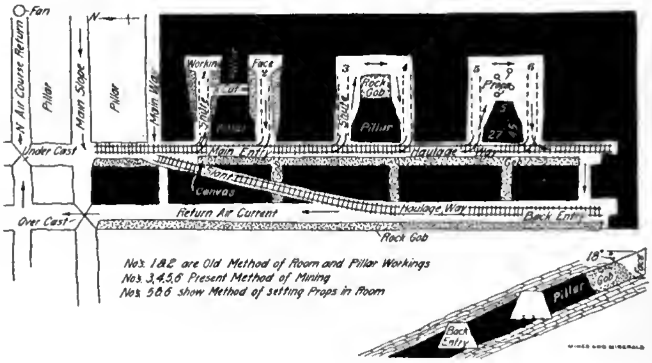
I thank you, gentlemen, for your kind attention, and I hope that something I have said may assist you in not only producing your coal more cheaply in dollars and cents, but that you will use your best efforts to bring the mining accident record of West Virginia, not only up to the record of any state in the Union, but the equal of any in the world. So be it.

A ROOM-AND-PILLAR METHOD

Written for Mines and Minerals, by A. E. Robinson

The No. 4 mine of the Kemmerer Coal Co. has three openings, and is ventilated by a small exhaust fan capable of 33,000 cubic feet of intake per minute. The mine has 5 feet 6 inches of coal on an 18-inch pitch, with a soapstone covering averaging 15 inches thick, which at present has to be taken down and gobbed.

The roof above this covering is good, and the system of working the mine is by room-and-pillar method. At first, as indicated by sketch, it was worked by single rooms with 55-foot centers, with chutes placed in the centers of rooms, and the rock covering gobbed on both sides of the chutes. At present it is being worked with much better success by a double-room system, the two rooms being broken away from the entry by two openings at a distance of 45 feet from the outby rib to the inby rib At a distance of 45 feet up the rooms, the two rooms are joined together, making a 45-foot working face with two chutes, and the rock is gobbed in the center of the double room, tight up to the roof, thus forming an air-course or a "wind pack," so that fresh air sweeps the working face of each set of rooms. No crosscuts are needed as each set of rooms has its own circuit of air, which is obtained by throwing a brattice cloth across the entry at each three sets of rooms, affording ample ventilation for the miners.



Room-and-Pillar Method

The entries are worked on the butt-entry system, driven 9 feet wide; the rock taken down over the coal is gobbed in the lower side of the entry after a butt shot has been taken out to make place for the rock.

COAL AND COKE SAMPLING

*By E. G. Bailey**

Much money is wasted by having non-representative samples of coal analyzed; unwarranted complaints are often based upon analyses made from such samples; and sometimes unjust premiums are paid or penalties exacted, due to the samples not truly representing the coal from which they were taken.

Taking the Sample. Quantity and Method of Reduction. Sampling Mine and Railroad Cars

Properly taken samples of coal are of great value, for the correct analyses of them assist the coal operator to intelligently direct the working of his mines and the preparation of coal or coke being produced; they aid the sales department in placing coal where it will give best satisfaction; and they make it possible for the consumer of coal to buy intelligently and secure the fuel best adapted to his needs, but non-representative samples are worse than valueless under all circumstances.

The variety of conditions under which coal and coke must be sampled makes it quite impossible to follow any one method without some deviation; however, there are a few general principles, which, if understood and practiced, will greatly increase the value of samples taken.

Coal should be sampled:

1. By taking equal increments from a great many equal parts of the original quantity.
2. By taking increments of such size that the largest lumps may be included.
3. In such a manner that a true proportion of all sizes will be secured.
4. Blindly, so far as slate and impurities are concerned.
5. By taking such a quantity that the largest pieces of slate or impurities will be insignificant in proportion to it.

The original sample should be reduced in such a manner that:

1. The part discarded is exactly like that retained.
2. There will be no loss or gain in moisture.
3. No dust or other material will be blown away or lost through cracks in the floor.
4. No foreign matter will get into it.

The above fundamental principles should be followed whether the coal is sampled in the mine, as it is being burned, or during any intermediate stage of its transportation, but the detailed method of applying them will naturally vary with conditions. Some of the principles are self-evidently essential, while others may at first appear to be unnecessary precautions.

Taking Original Sample.—There may be a great difference in the quality of coal in different parts of a car, cargo, or pile, therefore if a sample is to represent any of these quantities of coal it should be accumulated from enough different parts that it will represent the average, rather than merely the coal which happens to be most available. In many cases it is impossible to comply with this condition, except where the coal is being loaded, discharged, or rehandled. Coal becomes better mixed each time it is rehandled, thus reducing errors arising from failure to fully comply with this stipulation.

A small shovel or scoop of 2 or 3 pounds capacity is well enough for accumulating samples of slack or small sizes of anthracite, but it would evidently be wrong to take such small increments from run-of-mine or prepared sizes where large lumps are present. When coal is extremely lumpy it is best to break a proportional amount of the lumps before taking the various portions of the sample. As a rule, 10- to 12-pound increments are satisfactory for the ordinary sizes of coal.

There is a natural tendency for a person to take a larger amount of fine coal than is proportional to the total, when taking a sample by shovel. In other cases the coarser coal may be more available, and with a mechanical sampler it is possible for a constant error to exist in obtaining an undue proportion of either the fine or coarse coal. Such conditions should be carefully avoided to prevent serious errors. In some coal the fine material is much higher in ash and sulphur, while in others the reverse is true.

A mechanical sampler cannot discriminate for or against slate and other impurities, and if the sample is taken by shovel, the person doing so should be as blind to such impurities as is the machine. There is no one who can possibly be capable of judging whether any certain impurities should be included or rejected, as he cannot view the entire quantity of coal as carefully as he can the sample; but even if he could, it would be useless for him to attempt to accurately estimate the proportional amount of impurities. The only safe way is to accumulate portions of the sample from equal parts of the whole, and leave the amount of impurities entirely to the law of chance.

Quantity of Original Sample.—The total weight of the original sample accumulated is of the greatest importance. For illustration, take the problem of sampling 100 tons of coal containing 200 pieces of slate which weigh 1 pound each. This corresponds to a 1-pound piece of slate to each 1,000 pounds of coal, or only .1 per cent. ash over and above the other ash contained in the coal, which, we will say, is 6 per cent., making the total correct ash 6.1 per cent. If a person took a 10-pound sample, which is as large as many people do take, it is possible for one of these 200 pieces of slate to be contained in it, which would amount to 10 per cent. in addition to the 6 per cent. intrinsic ash, making 16 per cent. total ash in the sample. Even a 100-pound sample containing one piece of this slate would show 7 per cent. ash, instead of the true 6.1 per cent., and unless a person has actually counted the pieces of slate in the entire 100 tons he does not know whether or not he should have one or more such pieces of slate to every 100 pounds he might happen to take as a sample; but if a 1,000-pound original sample were taken, and it had even two or three pieces of slate more or less

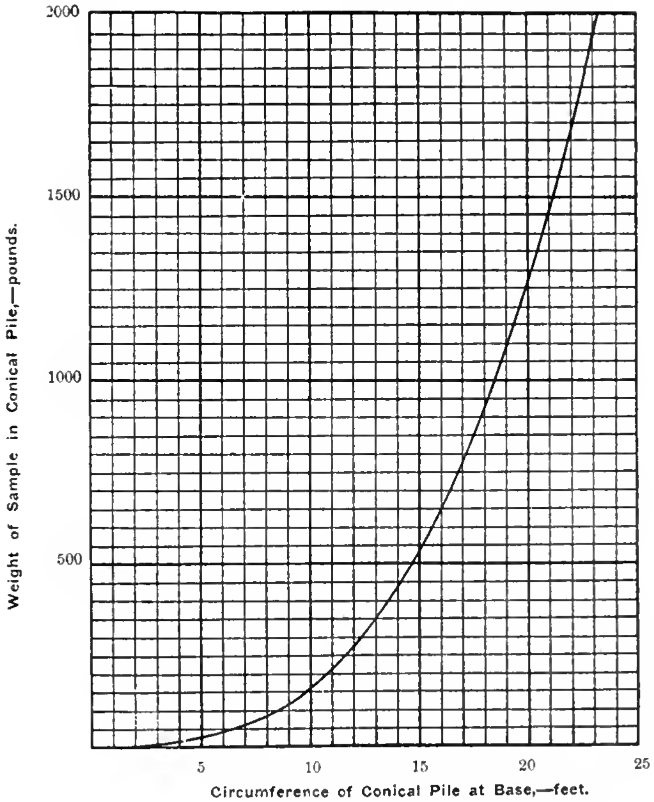


FIG. 1. CURVE SHOWING APPROXIMATE WEIGHT OF SAMPLE WHEN FORMED INTO A CONICAL PILE

*Mechanical Engineer, 220 Devonshire Street, Boston, Mass.

than the true proportion, it would cause an error of only a few tenths of a per cent. ash, which is allowable.

If this 100 tons of coal contained 2,000 pieces of slate, weighing 1 pound each, the true ash would be 7 per cent., and while there is one piece for each 100 pounds of coal, a sample of this weight might happen to contain several, and each one would cause an error of 1 per cent. Even a 1,000-pound sample, which should contain 10 such pieces of slate, might happen to contain only five, or as many as 15, which would correspond to a possible error of .5 per cent. below or above the average, as compared with less than half this possible error with the smaller amount of free slate.

In order to secure an accurate sample of coal it is absolutely necessary to take such a large original sample that several of the largest pieces of slate or impurities more or less will cause no material error. The larger the size of the pieces of impurities, the larger should be the original sample to prevent excessive error, and the same is true with respect to the quantity of impurities. In a similar manner the quantity of impurities and the size of sample to be divided should govern the fineness of crushing the sample throughout the various stages of dividing and quartering, from the original sample to that which is pulverized in the laboratory for analysis. The total percentage of ash or impurities does not indicate the size of sample which should be taken, but it is the impurities existing as slate, bone, and extraneous matter which should be considered, regardless of the amount of impurities distributed uniformly through the coal itself

On account of the variation in the size and amount of the impurities in different coals, it is impossible to state how large a sample should be taken in each case. Many coals contain between 1 and 2 per cent. of ash in the form of slate and free impurities, and when the larger pieces of slate do not weigh more than 1 pound, a 2,000-pound original sample would be sufficient for reasonable accuracy. If there is any doubt about the quantity of sample that should be taken, it is best to pick out all slate and bone larger than ½ inch from the sample as it is being taken and weigh it, and from the weight of sample from which it was taken then determine approximate percentage of ash existing in this form. With these data and the size of the largest piece of slate, one can determine the quantity of sample which should be taken by referring to Table 1. All of this slate and bone should then be broken and thoroughly mixed with the coal before quartering it.

Table 1. Weight of Original Sample to Be Taken

Largest Size of Slate Existing in Coal	½ Per Cent. Ash in Free Impurities	¾ Per Cent. Ash in Free Impurities
2-inch screen	2,000 pounds	4,000 pounds
1½-inch screen	1,000 pounds	2,000 pounds
1¼-inch screen	600 pounds	1,200 pounds
1-inch screen	300 pounds	600 pounds
¾-inch screen	120 pounds	250 pounds
½-inch screen	50 pounds	100 pounds

Samples of the above size will also insure sufficient accuracy in the sulphur determination unless there is a large percentage of sulphur balls present, in which case the sulphur would be much higher than exists in coal used in iron, steel, and gas industries, and extreme accuracy would not then be required.

The most satisfactory method of determining the approximate weight of samples accumulated is to measure the conical pile. The circumference at the base and the slant height are the dimensions most readily determined. The slant height is very nearly one-fifth of the circumference, and whatever variation there may be from this figure causes only a slight error, so the weight of coal in a sample can be expressed in terms of the circumference of the base of the conical pile. This can easily be measured by means of a 25-foot tape measure, and from the curve in Fig. 1 the weight of coal can be determined accurately enough for all practical purposes.

The size and percentage of the impurities have more influence on the amount of original sample to be taken than has the quantity of coal to be sampled. It has often been stated that a certain percentage, say .1 per cent., of the original quantity of coal should be taken as a sample, which would mean about 15,000 pounds from a 7,000-ton cargo, and 50 to 100 pounds from a railroad car. As a matter of fact, the same size sample should be taken from each, if they contain the same kind of coal and the same accuracy is desired in each case.

Reduction of Sample.—The original sample is larger than can be conveniently sent to the laboratory, and the manner by which it is reduced to a smaller quantity is equal in importance to the method of accumulating the original sample. It is usually broken, mixed, and divided repeatedly until any desired quantity remains. In doing this it is essential that the part discarded be exactly like that retained, and so long as this is true the final sample represents the original. In order to meet these conditions it is necessary to break all lumps of coal, slate, and impurities very fine, as compared with the quantity of sample before every division, in order that the slate and impurities may be equally distributed throughout the whole by thorough mixing. Table 2 will be found of assistance in determining how fine the sample should be crushed before mixing and dividing.

Table 2

Weight of Sample to Be Divided	Size to Which Slate and Impurities Should be Broken
4,000 pounds	1½ inch
1,200 pounds	1 inch
500 pounds	¾ inch
200 pounds	½ inch
50 pounds	2 mesh
5 pounds	4 mesh

It is not necessary for the lumps of coal to be broken as fine as should be the slate and impurities.

When taking large samples of coal a person should have a smooth solid floor upon which the sample can be broken and mixed, also an easy rapid method of crushing the coal. Where a great deal of sampling is to be done at one place the necessary arrangements can be made and a hand or power crusher installed, but when samples are to be taken from miscellaneous places a light portable outfit is necessary. In the absence of any crusher, an iron tamping bar is the easiest and most rapid method of crushing the sample, but for portable work a flat-sided hammer is about the best tool that can be used. Meat choppers work fairly well for the finer crushing, but are rather slow and difficult to feed.

Whenever the different shovelfuls or increments of samples are taken throughout some considerable period of time, each shovelful should be crushed as soon as taken, and the impurities can often be broken sufficiently small to permit the total accumulated sample to be quartered three or four times before further crushing is necessary.

In the absence of a smooth tight floor it is necessary to use a heavy canvas sampling cloth. The coal can be broken on a solid piece of iron or block by means of a hammer, and after the sample has been accumulated and broken it can be mixed by raising first one end of the canvas, then the other, rolling the sample back and forth. A sample of 300 or 400 pounds on a canvas 6 ft. × 8 ft. is about all one man can handle, and in cases where a larger sample is necessary it can be taken by instalments, each 300 or 400 pounds being broken and quartered three or four times and then reserved till the entire sample required has been so reduced, then they can be mixed and worked down as one sample.

After a sample has been broken to the size corresponding to its quantity, as given in Table 2, it should be thoroughly mixed by shoveling it over and over several times, or by rolling back and forth on a canvas, before it is divided.

Original samples larger than 300 pounds can best be divided

by discarding alternate shovelfuls, while samples of about this size or smaller can be formed into a conical pile and divided through the center into four equal parts and the two opposite quarters discarded. The part of the sample remaining should be crushed smaller, again mixed and divided, or quartered, until it is finally reduced to not less than 25 pounds, all of which will pass through a 2-mesh sieve; or 3 pounds, finer than 4 mesh; which may then be sent to the laboratory.

A man can take and properly work down a sample of 1,500 pounds of soft semibituminous coal in a day, doing all crushing by hammer. A correspondingly less amount of the harder gas and anthracite coal can be taken and reduced, much depending upon the average size of the original coal.

Special Moisture Sample.—The percentage of moisture contained in the coal sampled should be determined as accurately as is the ash or any other constituent, but this is impossible if it is taken in the manner just described, even though it is sent to the laboratory in hermetically sealed jars or cans. In other words, it is impossible to obtain a sample which will correctly represent the ash and sulphur and still retain the original moisture, if it is worked up in the open air. The necessary crushing, mixing, and dividing cause a loss of 2 to 3 per cent. of moisture under average weather conditions. The only method by which the true moisture can be determined under normal conditions is by taking a separate special moisture sample. This is accumulated by placing small quantities from the freshly taken portions of the original sample into a hermetically sealed receptacle, which is not again opened until it reaches the laboratory. This special moisture sample is used for no other purpose than to obtain the total moisture in the coal sampled. The analysis of the other sample, which is practically air dried by the time it reaches the laboratory, should be calculated to the total moisture, as determined from the special moisture sample, in order to obtain the true analysis of the coal sampled.

Loss of Sample.—It might seem unnecessary to caution against losing any dust by the wind, or fine coal sifting through cracks in the floor, but errors due to failure to realize the importance of such precautions are often encountered. Another error is sometimes caused by hard pieces of bone or slate flying out of the sample when struck a glancing blow with a hammer.

SAMPLING AT COAL MINES

Samples From Seam of Coal.—Samples of coal cut from the working face in a mine are of little value for determining the quality of coal shipped to market, due to failure on the part of the miner to eliminate all roof, floor, and parting slate, and impurities in the coal loaded, as is usually done in taking section samples. However, mine samples are of value in determining the character and approximate quality of coal from a new or idle property. They are also of value when taken from strata of the seam separately, in locating the part of the seam which contains the higher or lower percentages of ash, sulphur, phosphorus, or clinker-forming impurities. If consistent with economical mining, parts of the seam may be left in, or gobbed, in order to produce a coal of desired purity to meet certain market demands.

Mine samples should be taken as a standard in representing the best coal that could possibly be produced with perfect preparation, and the quality of coal being shipped should be made to approach this standard as closely as is practicable.

In some mining districts the sulphur varies widely in different parts of a mine, and often certain headings will be found to produce coal low enough in sulphur to meet certain specifications while the average of the mine would be prohibited.

Very few coal operators open up a new property without first diamond drilling it to learn the dip and uniformity of the seam. After expending so much money to obtain these cores, they should be analyzed and the quality of coal from different parts of the field determined. It even pays to make a separate sample from each 6 to 12 inches of the core, whether divided according to natural partings or not.

The method of taking mine samples is to select or make a freshly exposed full section of the seam and spread a canvas (4 ft. × 6 ft.) on the floor beneath it, then cut a channel about 4 inches wide and 4 inches deep from the bottom to the top of the seam, leaving any partings or streak of impurities which are to be discarded in mining. Care should be taken to see that all coal cut from the upper part of the seam falls on to the canvas, as it has a tendency to spread when it falls. It is also essential that the groove be uniform in size from top to bottom and not smaller where the coal is hardest and larger where it is softest. When the coal has well-defined butts and faces it is easier to cut a uniform groove from the butts. After the sample has been dug from the seam it should be broken and reduced in accordance with the method already described and placed in a hermetically sealed jar or can, if the actual moisture is desired, otherwise a coin sack will be more convenient. It is unnecessary to take a special moisture sample before crushing and mixing mine samples, provided the work is done immediately and before the sample is taken out of the damp atmosphere of the mine.

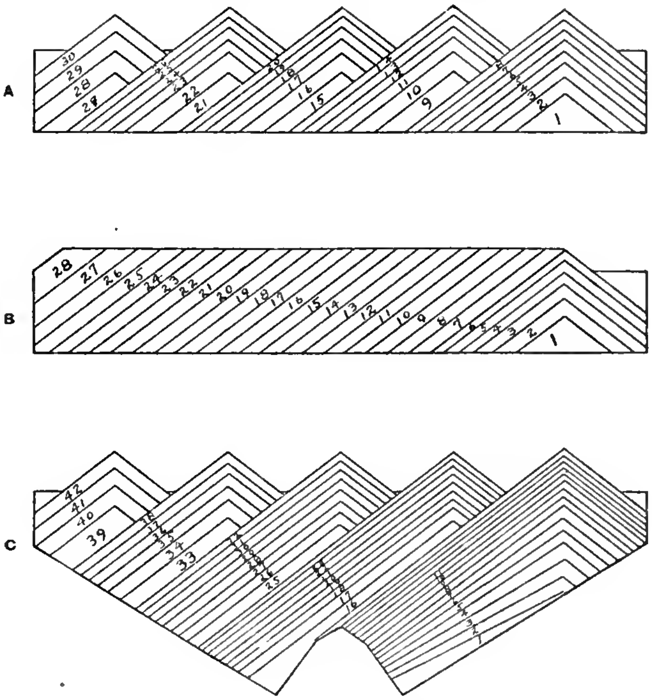

FIG. 2. DIAGRAMS REPRESENTING THE DISTRIBUTION OF COAL AS DUMPED FROM MINE CARS INTO RAILROAD CARS
A—Section representing car moved to five positions as loaded at the mines
B—Section representing car moved a short distance as each mine car of coal was dumped. C—Section representing steel-hopper car moved to five positions as loaded at the mine

If detailed information of the quality of coal in different parts of a mine is desired, and the cost of having a large number of samples analyzed is not too great, such samples should be taken from every three or four working places. Where only a few samples can be analyzed it is not best to depend upon single sections for each sample, but three or more such grooves should be cut and the coal from them mixed as one sample to represent the heading or part of the mine from which they were taken.

It is frequently desired to know the quality of coal coming from different benches or strata of a seam, in which case the groove should be cut across such parts of the seam separately.

Samples From Mine Cars, Tipples, and Loading Railroad Cars.—The comparison of the analyses of samples taken from mine cars with those taken from sections in the working places indicates the care used by the miners in cleaning the coal. A

similar comparison between the results of mine-car and railroad-car samples shows the efficiency of the tipplemen and car trimmers with respect to preparation. Railroad car samples represent the quality of coal shipped to market, as well as a comparison of the different grades, where the coal is screened or washed.

Mine-car samples should not be taken from the tops of loaded cars, as they are likely to be trimmed with lumps, thus preventing the sampler from securing a true proportion of the lumps and fine. There is also a chance of pieces of roof or draw slate having fallen on to the car, which might cause considerable error in a sample taken from the tops of the cars. It is better to take mine-car samples from the open end of the car as it is being dumped, or from a chute as the coal passes. A large shovelful (15 or 20 pounds) should be so taken from each mine car at the smaller mines up to every tenth or more cars at the larger producers, and the sample accumulated throughout at least one entire day's loading. It is often desired to know the quality of coal being loaded from different headings separately, which can readily be done by throwing the shovelfuls taken from cars coming from different parts of the mine into different piles. Each individual sample should be about as large as if

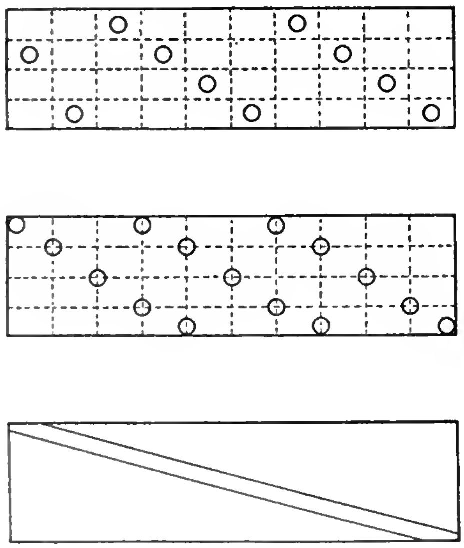

Fig. 3. Diagrams Showing Different Methods of Locating Holes and Trench on the Surface of Railroad Cars from Which Samples are to be Taken

one large sample were taken from all mine cars as a whole. The total weight of sample taken in either case should be governed by the size and amount of impurities contained in the coal. Size of sample and method of reducing it should be as previously described.

If there is any attempt made to throw out impurities as the car is being loaded, the samples representing the coal shipped should be taken from the railroad cars throughout their loading. Shovelfuls should be taken from the slanting surface just before a new mine car or basketful is dumped, and after the slate pickers have finished cleaning the one previously dumped. There is a tendency for the lumps and heavier impurities to go to the bottom of the slanting surface, hence shovelfuls should be taken systematically from various parts of this surface. The shovel should be pushed well into the coal in order to avoid getting only that on the surface from which the impurities have been picked. Occasionally it is desired to take such a sample from a single car, in which case it would be necessary to take several shovelfuls from each mine car dumped, but if a whole day's loading is to be represented, a shovelful need be taken from only every fifth, tenth, or whatever number of mine cars is necessary to secure the required total sample.

An operator often investigates the quality of coal actually being shipped to the market for the purpose of seeing whether or not the coal can meet certain specifications for ash, sulphur, or British thermal units, and if not, how much better preparation would be required to meet such specifications. Very valuable information is gained by taking duplicate samples from the cars and picking out all slate and sulphur from one and comparing the result with the regular representative sample. This will indicate what reduction can be made in the different impurities, and by weighing or measuring the sample, and weighing and noting the size of impurities picked out, one can determine if this better preparation could best be accomplished through inside or tipple inspection, or whether a picker belt would be required. If a washery is being considered, laboratory washing tests can be made to determine the quality of washed coal and the loss resulting from washing to any desired quality.

Sampling Railroad Cars—Loaded or Unloading.—There is great difficulty in obtaining a representative sample of coal from a railroad car that was loaded from individual mine cars, unless the coal can be sampled while it is being unloaded. The usual method of loading cars at the mines makes it almost impossible to obtain a sample from a loaded car which will contain a true proportion of whatever slate and impurities remained in the car. The slate and impurities are usually picked from the surface of a car as it is loading. Fig. 2 represents some of the conditions frequently encountered; the areas containing numbers representing the quantity of coal from each mine car and the numbers give the order in which quantities were dumped. "A" represents a car that was moved to five different positions while it was being loaded. It is evident that any scheme of laying out points from which to take shovelfuls for a sample, or digging trenches, will not include any coal from several mine cars which lie near the bottom and will include an undue proportion of coal from the mine cars emptied on top. "B" illustrates a flat-bottom car which was moved a short distance each time a mine car was dumped. When coal is loaded in this manner, the digging of a trench or holes should secure almost an equal proportion of sample from each mine car, but there is another error of even more importance that is likely to be greater from cars loaded in this manner than those like "A." This error is due to the tendency of the bone, slate, and heavier impurities, as well as the lumps of coal, to roll toward the bottom of the car while it is being loaded. Some authorities who have taken separate samples from the top and bottom of a car upon its arrival at destination, have claimed that the higher percentages of ash and sulphur found in the samples taken from the bottom of the car are due to the heavier impurities settling to the bottom during transit. While these impurities may tend to settle some in transit, the most plausible explanation of their being at the bottom of a car is found in the manner of loading the cars at the mines. Car "C," representing a steel hopper, illustrates the tendency for slate to slide to the bottom while being loaded, and the increased difficulty of obtaining a representative sample at destination without unloading the car.

If there is no alternative but to sample a loaded railroad car, points should be located systematically on the surface and 10 to 15 holes dug at least 2 or 3 feet deep. The upright braces on the side of the car can conveniently be used as guides in locating the position of the holes according to some fixed system, similar to those illustrated in Fig. 3. Directions regarding the amount of sample to be taken and the method of its reduction, as already given, should be followed.

If a sample is to be taken from a car being unloaded by hand, it is best for the sampler to have one shovelful out of every so many placed into the sample. As usually shoveled, there are about 125 to 150 shovelfuls per ton, and from the amount of coal in the car and the size of sample required, one can quickly estimate about how frequently a shovelful should be thrown into the sample.

If the car is unloaded through hopper bottoms to a pile,

the sample should be taken as the coal is dropping out of the car, and if one car is to be sampled as an individual it may be necessary to retard the dumping in order to have enough time to accumulate a sample of sufficient size from all parts of the car. Coal should never be sampled from the pile if it is possible to do it otherwise.

If a car of coal is unloaded into a mechanical conveyer, either by hand or drop bottom, the sample should be taken from the conveyer. If a clamshell or grab bucket is used to take the coal from a car, the sample may be taken from the bucket itself or from the newly exposed surface in the car throughout the unloading, unless it is discharged into a mechanical conveyer or industrial railway from which the sample could be more easily taken.

A composite sample is often desired from several cars of coal loaded into or from a single vessel or else where shipped as a special consignment, in which case a proportional amount of the required sample should be taken from each car. In the case of coal shipped all rail to the consumer it is best to sample a car individually, even if only a part of the total number of cars received can be tested. It is then possible to supply definite information regarding that particular shipment, while if a composite sample were made from two or more cars there could be no definite knowledge gained in case they were loaded at different mines.

COAL MINING NEWS

A German mining engineer and mine director advises an American consular officer that he has made a special study of the possibilities for the profitable importation of American coal into Germany and various parts of Europe, and that he is convinced a successful business could be developed providing the coal could be sent over in shipments of 8,000 to 10,000 tons. He therefore desires to enter into correspondence with parties in the United States who might be interested in exporting to Europe coal, anthracite and steam coal of all kinds and sizes, as well as coke, with Hamburg, Amsterdam, and Genoa as European ports of arrival.

One of the largest single sales of transformers made by Allis-Chalmers Co. during the month was to the Delaware, Lackawanna & Western Railroad Co. The order includes six 200-kilowatt three-phase; three 200-kilowatt single-phase; two 150-kilowatt three-phase, and one 100-kilowatt single-phase, oil-filled, self-cooled transformers. These will be installed in collieries and washeries of the company at Scranton, Nanticoke, and Taylor, Pa.

A good gas coal will furnish 5 cubic feet of gas per pound of coal, or about 11,200 cubic feet of gas per ton of 2,240 pounds.

The imports of American coal into Brazil in 1909 were larger than ever before, owing to a threatened strike among the coal miners of Wales. Consul-General Anderson says: The imports of coal into Brazil were valued at $8,689,482, of which the United States furnished $238,645. In the previous year the value of the coal imported was $9,719,334, and the share of the United States was $19,015. The registration and port dues taxes amount to 4 per cent. of the gold value of coal, or about 95 cents United States money. Coal imported by steamship companies for their own use pays a tax of 40 cents per ton. The contract price for Welsh fuel is at Rio de Janerio 32 shillings, or $8 per ton. The coal trade of Brazil has been and is practically controlled by British interests, which first developed it. Railways first constructed in Brazil were generally built by British capital and have preferred British coal; steamships touching at Brazilian ports have been preponderatingly British, with British engineers who prefer British coal, and the firms handling British coal have been British themselves. The concern now handling most of the coal sold along the east coast of South America is not only British, but is directly interested in the mines in Wales from which most of the coal comes.

The value of a coal mine decreases with every ton of coal removed; the cost of mining increases as the excavation expands; the machinery deteriorates at coal mines so that if 10 per cent. is knocked off yearly for depreciation it will not always cover the loss; the equipment deteriorates at a much greater rate, in fact timbers, ties, cars, tools, etc., sometimes have to be replaced in a year's time. The money for the renewal of equipment and machinery must come from the mine which is gradually becoming bankrupt.

To overcome the fixed charges due to the expansion of a mine, it is necessary to mine a certain number of tons of coal on which there is no profit. This number will depend on the size of the operation and the selling price of the product. There are instances where it is necessary to drive 1 mile of entry in order to obtain sufficient coal from rooms to pay fixed charges. Bearing in mind that the cost of mining increases with development, and that machinery and tools deteriorate and must be paid for in coal, it becomes evident that in due time the mine will become bankrupt unless the selling price of coal is increased to insure a profit.

It is one of the laws of trade that if one man has a thing to sell which another man wants to buy, a sale can be brought about; nevertheless there have been rumors that competition has been so severe in bituminous coal that operators have not made money, and have actually sold coal to railroads below the cost of production, with the hope of obtaining a price from legitimate customers that would make up the deficit.

In 1905 the Chesapeake & Ohio Railway officials informed Abram S. Hewitt that he would have to give them his product from the Gauley mines for considerably less than formerly. Mr. Hewitt said he would not and would hold them to the former price. The officials stated they would not take the coal, and wanted to know what he was going to do about it. Mr. Hewitt replied, "Shut down the mines." "What? Shut down your mines and force us to lose all that coal freight and involve us in contracts we have made?" "Yes, sir; we are not running our coal mines to lose money." Mr. Hewitt was not cut in prices, although other Chesapeake & Ohio operators were.

Recently the coal operators in the Eighth Ohio District determined to stand together for a price that would yield them a profit. It appears that they had been maintaining coaling stations to supply railroad locomotives and selling the coal below the actual cost of production, and had not been making any money. They boosted the price to the railroads 10 cents, whereupon the railway purchasing agents declared they never would pay it, as they could buy coal cheaper elsewhere. To use a Congressional expression the operators were "stand patters" and said, do so. The railroad officials interviewed the operators, and were told pertinent facts concerning the coal business, also that the railroads would have to haul coal to their coaling stations, also store it, employ men to handle and watch it day and night, and dump it into the tenders. The railroads opened negotiations for a compromise, but the "stand patters" would have none of it, and won.

Satisfactory progress is being made at the new operations of the Four States Coal and Coke Co. (Jones interests) in northern West Virginia. The town of Annabelle is being built in connection with the development work, and work upon the openings is also being pushed. When the plan is fully developed it will form one of the largest mining operations in the country, rivaling in size the new operations of the same interests in Southwestern Pennsylvania.

Some people are getting apprehensive in regard to the future value of Rhode Island coal stock, and a Boston publication comments upon a drop to $6 per share for the stock in the curb market. President Whitney is still optimistic and states that developments have been very favorable and all experiments have proven very satisfactory. Between 35 and 40 tons a day are now being produced, and a large increase is expected in August, when the permanent breaker will be in operation.

It is maintained that the coal can be sold for $6.50 a ton, which, with $1.50 for delivery expenses and $2 for mining, assures a profit, according to the calculations of the head of the enterprise, amounting to $3 per ton.

The proved coal fields in Mexico are all in the Sabinas coal field, state of Coahuila, although coal should be found to the west as well as oil. The known coal covers 300,000 acres, from which the minimum average production is fixed at 3,000 tons per acre. The operators in Mexico have invested $20,000,000, and believe they are entitled to some protection, as they are unable to ship into the United States owing to the tariff wall, while on the other hand they are obliged to compete with coal and coke that is sold as a surplus from the mines of the United States and shipped as ballast to Mexican seaports. It would not be advantageous for Mexico to impose any duty on coal or coke, as it would seriously cripple consumers who operate plants on the west coast as well as other points in Mexico impossible to be reached by the native products, but the railroads should protect the territory in the immediate vicinity of Mexican mines from foreign coal and coke by making the rates at least as high per kilometer as is charged from native mines to such points. The railroads claim that it is impossible to make any reduction on the rates on coal and coke from the mines to the different points of consumption in Mexico, and that the rates on foreign coal and coke from Vera Cruz and Tampico to interior points were originally too low. It is therefore asked by the Mexican mine owners that the rates on the foreign products be increased.

The *Black Diamond* has this to say about convict labor in mines: Should the measure pending in Congress ever become a law and operative, whereby convict-mined coal could not be shipped outside of a state, the state coal mining business of Tennessee would be doomed. The coal operators of Tennessee and Kentucky are laboring on their part to obtain legislation whereby the state will cease coal mining altogether.

Appropos, Alabama is a peach. The law in Alabama says the miner shall be paid $1 per ton for coal. The convicts are let out to contractors who feed and work them in the mines of the large operations. Greenhorns from the farms are put in gassy mines to work, and if they do not produce the required amount of coal are flogged. No person talked to in Alabama likes the system, which is graft from top to bottom, and it is not believed the Steel Corporation will perpetuate the present disgrace. It would be a very easy matter to trump up a charge to keep men indefinitely or send new men into the mines of Alabama.

A widespread interest is being taken in opening the Mullaghmore colliery, in Queens County, Ireland. It is thought that if the operation of this mine is successful, others will again be put in operation in different parts of Ireland. Coal it is said was extensively mined in this county some 30 years ago, but the product is not suitable for all purposes, and the mines were abandoned. For certain purposes it can be used to good advantage and will prove vastly more economical than imported coal.—*United States Consular Report.*

According to the *Iron and Coal Trade Review*, of London, England, Welsh coal operators are having a serious time through the loss of foreign contracts. The most important cause leading up to this crisis are the numerous isolated strikes which close the mines for a few days. This sort of thing has created abroad an uncertainty and fear among large consumers in regard to contracts being carried out. After the great strike of 1898 the miners worked with their utmost energy, and the supply of coal could be relied on; now, however, they throw down their tools and leave the mine in consequence of some trivial dispute. The falling off in the demand for coal is making itself felt among the miners, as work is not continuous, and distress is being felt, more especially in Monmouthshire, where children are being fed by the public. Another cause for the lessened demand for Welsh coal is the difference in price between it and the North of England coal. The superiority of the South Wales coal naturally gives it a higher market price, but there is a limit to this difference and the best North of England coal is selling from 75 cents to $1 below the Welsh coal. Coal operators in Wales realize the effect this difference in price has upon their trade, but they declare that since the passing of the Eight-Hours Act the cost of working the mines has so increased they cannot decrease the price of coal except by a reduction of miners' wages and the introduction of such measures as will increase the output. All the great foot-ball matches are played on Saturdays and the younger miners desire to leave work early to attend them or other amusements. They have no objection to commencing work at an earlier hour, but there is an Act which determines the interval that must elapse between one shift and the next at coal mines. The miners thought that their Federation would support them in regard to this matter of overlapping shift, but as this was not done, the men are not supporting the labor union. It is said that many miners have never paid one penny to the Federation since the agreement was signed, and this, with the secession of special mine laborers, is a serious blow to the association.

In 1909 the number of men employed in the Yorkshire and Lincolnshire districts, in 399 mines, was 141,102. Of this number 111,404 worked below ground, and 29,698 above ground. There were 35,894,776 tons of coal mined, and the output of mineral per person below ground was 327 tons, and for those above and below ground 258 tons. In this district there were 155 fatal accidents inside and 27 outside the mines. The death rate in 1909 was 1.29 per thousand persons employed; 63.2 per cent. of the fatalities came from roof falls; 6.4 per cent. from accidents in shafts; 1.9 per cent. from explosions of gas; and 28.5 per cent. from miscellaneous causes. There were 22,002 non-fatal accidents which disabled the injured more than 7 days. Legal action was taken against one coal operator, and 249 workmen. Coal operators show a disposition to abandon the system of fining in favor of prosecutions. In the 249 charges preferred against workmen, 244 convictions were obtained, and fines and costs inflicted; in three cases costs only were imposed; and two cases were dismissed.

During the fiscal year that ended June 30, 1910, the value of the bituminous coal exported from the United States amounted to $26,000,000. Both anthracite and bituminous coal exports had greater value than in any earlier year.

The Pocahontas semibituminous coal is the best all-around coal in the country. The mines for the most part are worked by lessees who pay royalty to the land owners. For years the operators have been working on a very narrow margin of profit and selling their product in competition with poorer coal. Apparently they have awakened to the fact that their coal is in a class by itself and as such can command a price which will return a reasonable profit. The operators last year received $1 per ton for run-of-mine coal on board cars at the tipple, while in Alabama the miners are paid $1 per ton for mining. This year the operators split up into several selling agencies, although previously, with the few exceptions of independent operators, they had been selling through one agency. In April of this year the price of Pocahontas coal was advanced to $1.10 at the tipple, and consumers who had been paying $1 refused without good reason to pay the 10 cents increase. In taking this stand the consumers are the losers, for the intrinsic value of Pocahontas smokeless coal is more than most other coals. While perhaps it was policy to at first sell smokeless coal cheap in order to educate consumers to its value, that time passed long ago, and had selling conditions been different the price of this coal would have stiffened and operators would not have been working on a hand-to-mouth basis.

In the past large corporations told the Pocahontas operators at what price they would allow them to mine and ship coal. Because the operators refuse to be dominated, the large corporations have gone on a strike.

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

(Continued from August)

Mine Inspectors' Examination Held at Scranton, Pa., May 2-5, 1910

QUES. 16.—What determines the size of a barrier pillar in the anthracite field?

ANS.—The rule adopted by the leading coal companies, and the mine inspectors of the anthracite district for determining the necessary width of barrier to be left between adjoining workings is as follows: *Add 5 feet to 1 per cent. of the depth of the seam below the surface, and multiply the sum by the thickness of the seam in feet. The product obtained will be the required width of barrier pillar, in feet.* Thus, for a 6-foot seam lying 800 feet below the surface the required width of barrier pillar would be $6(.01 \times 800 + 5) = 78$ feet.

QUES. 17.—When extracting a range of pillars of an average thickness of 10 feet, how would you proceed with the work to insure the safety of the workmen and the mine? What should be carefully considered before the work of drawing pillars is begun?

ANS.—The details of this work will depend much on the nature of the roof, hardness of the coal, thickness of the seam, and depth below the surface; but, in general, the work on the several pillars should be kept in line and proceed regularly without cessation. Experienced miners should be employed in pillar drawing; no timber should be left standing in the waste; a close watch should be kept for slips and roof cracks. Only safety lamps should be used in pillar work where gas may be expected in the roof. Before beginning to draw back pillars, the probable effect on adjoining workings and the surface or overlying seams should be carefully studied; also, whether their removal will cause the possible loss of certain coal.

QUES. 18.—How should you determine when a hoisting rope is unsafe, and what portion of the rope would you consider the weakest part, or the most liable to give out first?

ANS.—Hoisting ropes should be tested at regular short periods, say once in from 3 to 6 months, by lifting a load off the shaft bottom at least double the weight that may be hoisted at one time, in the regular operation of the mine. This load should be raised a few feet above the landing and held there a few minutes and then lowered again to the landing; this should be repeated two or three times, while the effect on the rope is closely observed. Again, with the load ordinarily hoisted, the engine should be started suddenly, with a few inches of slack rope to test the resistance of the rope and end fastenings to such starting strains. All hoisting ropes used for hoisting men should be examined closely each day by a competent man allowing the rope to pass through a bunch of waste held in his hand, as the cage is hoisted and lowered slowly, the purpose being to detect by this means any loose or protruding wires. The rope for a few feet above the cage fastening is subject to more severe usage than any other portion of its length, owing to sharp bends when rope is slack, severe shock when engine is started suddenly, exposure to injury from immersion in mine water, abrasion, and accidental blows incident to handling of timbers and other material in the shaft, and last but not least, the effect of the swaying back and forth of the rope hanging in the shaft, which effect is most felt at the cage. For these reasons, this portion of a hoisting rope is liable to show the first signs of weakening.

QUES. 19.—(*a*) What are the distinguishing features of, first, a mine post properly stood; and second, a set of mine timbers, or a timber set? (*b*) What is your opinion of the timbering done in the anthracite mines, based upon your own observation? (*c*) What would you suggest to obtain the best results in timbering, from a standpoint of safety and economy?

ANS.—(*a*) When properly stood a mine post is vertical, in a flat seam, or *underset* (inclined a few inches up the pitch from a normal to the floor), in an inclined seam. The amount a post should be underset depends on the inclination of the seam. All mine posts should be squared at each end and have a firm bearing at the roof and the floor. To distribute the thrust of the post over a greater area of roof, give a more uniform bearing on the timber, and protect the head of the post, a cap piece of soft pine, 18 inches long and 1½ or 2 inches thick, should be used above the post. The chief features of a good timber set are the correct notching and even bearing of the two upright legs and the cross-bar; the slight inward inclination of the legs; the solid foot-hold cut in the floor or sides of the entry; and the proper wedging of the frame against the roof so that the roof pressure will be transmitted to the legs, and not be thrown on the center of the cross-bar. (*b*) This calls for the opinion of candidate based on his personal observation. (*c*) To obtain the best results with respect to safety and economy, timbering should be done promptly, as required. There should always be kept on hand a good supply of props, caps, and other timbers of the sizes demanded in the mine. Entry timbering should be done by experienced timber men, and all post timbering done by the miners at the working face should be inspected by the mine foreman or his assistant to see that the work has been properly done.

QUES. 20.—(*a*) To what principal causes can the loss of life occurring in the anthracite mines be attributed, and what is the percentage for each cause? (*b*) Give briefly that portion of the Anthracite Mine Law designed to prevent fatalities from each of the above causes. (*c*) What are your ideas as a candidate for mine inspector, for the prevention of mine accidents?

ANS.—(*a*) The chief causes of mine accidents below ground and the average percentage for each cause are as follows: Falls of coal and slate, 50 per cent.; blasting and powder, 15 per cent.; gas, 10 per cent.; mine cars, 15 per cent.; falling down shafts or slopes, 5 per cent.; miscellaneous, 5 per cent. (*b*) Art. 11, requires the mine operator to furnish the miner with all necessary props and timbers as required and ordered by him. Art. 12, rule 14, requires each miner to keep the roof and sides of his place securely timbered and to do no work under loose top; and rule 55 prohibits the cutting of props or timbers in position to support roof or sides. Rules 11, 26–36 inclusive, and 38, relate to the blasting of coal and rock in mines, the storage and handling of powder, the extinction of gas (feeders) ignited by a blast, and the examination of a working place before and after firing. Art. 10 specifies the methods and means to be used in the ventilation of a mine, of which work (Art. 12, rule 3) the mine foreman is to have the full charge. Rules 4–10, inclusive, specify the manner and time of examining the mine for gas, and provide for the withdrawal of the men in case of danger, and the use and custody of safety lamps. Rule 37 forbids the removal of gas by brushing. Rules 16, 21, and 40–52, inclusive, relate to the safeguarding of the lives of workmen in mines in connection with the movement and handling of mine cars. Art. 4 relates to shaft and slope openings and provides for various appliances designed to minimize the danger to men working in and around shafts and slopes. (*c*) This question calls for the personal ideas of each candidate, in respect to the prevention of mine accidents. A good answer can be expressed briefly as follows: Simplify and enforce mine regulations and laws adapted to the safe operation of each mine, with suitable penalties for infraction thereof. Restrict mine labor, inside and out, to those of lawful age who can speak, read, and understand English, and hold the certificate of a properly authorized examining board clearly stating their qualifications. Require the suitable certification of all classes of mine workers and mine officials charged with the direct operation of the mine and allow no interference with their authority. Educate all miners and mine officials to a knowledge of the principles of mining and the dangers common thereto. Watch closely the operation of each mine.

Ques. 21.—Name the safety appliances required by law to be used in and about the anthracite mines and state what special care should be taken of them.

Ans.—The escape shaft (Art. 4, Sec. 3) must be fitted with safe and available appliances for escape from the mine. The tops of all shafts and slopes, if dangerous (Sec. 6) must be fenced or provided with vertical or flat gates; likewise (Secs. 7, 8) every abandoned opening must be securely fenced. All working shafts and slopes (Sec. 9) must be provided with suitable speaking tubes and signal apparatus. Cages for hoisting or lowering men (Secs. 10, 11) must be provided with hand rails, efficient safety catches, and overhead covers; and (Sec. 12) bridle chains. Winding drums of engines for hoisting men (Secs. 14, 15) must be provided with an efficient brake and side flanges to prevent the rope slipping off the drum, also an indicator to show position of cage, car, or gunboat in shaft or slope. The top of any shaft being sunk (Secs. 16, 18) must be so arranged that no material can fall back into the shaft when the bucket is being dumped; and (Sec. 19) a safety hook or clevis or other safe attachment must be used to attach bucket to chain or rope; and (Sec. 20) guides must be used in shaft to keep bucket from swinging. (Sec. 22) All blasts in sinking a shaft must be exploded by an electric battery. Art. 5 provides for (Sec. 3) safety valves on all boilers; (Sec. 4) a steam gauge in the boiler house; (Sec. 5) guard rails about all machinery. Art. 12 requires (rule 49) safety holes at bottom of all slopes and planes, and (rule 43) on haulage roads of a width not sufficient to allow persons to pass cars with safety; (rule 50) safety blocks at head of all slopes and planes and at top of all shafts.

Ques. 22.—A fan is exhausting 180,000 cubic feet of air per minute from a mine; the area of the port of intake is 60 square feet; what is the pressure necessary to blow air into the fan?

Ans.—Theoretically, assuming there is a perfect vacuum within the fan, the pressure necessary to blow air through the intake orifice of the fan, making the usual allowance for *vena contracta*, is calculated by the formula

$$p = \left(\frac{v}{18}\right)^2 = \left(\frac{180,000}{60 \times 60} \times \frac{1}{18}\right)^2 = 7.7 + \text{ lb. per sq. ft.}$$

This formula, as applied to fans, and the blowing-in or blowing-out pressure of a fan as calculated, have no practical value, however, for the reason that there is not a vacuum within the fan; and further, the relatively large area of the intake orifice, as compared with the area of the passage in fan, and the shortness of the fan ducts greatly modifies the *vena contracta*, and invalidates its application in the formula. The question is not therefore a practical question.

Ques. 23.—How can the dangers attending the firing of blasts in a mine be reduced to a minimum?

Ans.—By faithfully complying with all the requirements of the anthracite mine law, in respect to blasting; and further, by observing due caution when returning to the face after a blast has been fired, or when the explosion of a shot is delayed. When fuse is employed the miner should not return to the face when a shot fails to explode. Fuse has been known to hang fire in some instances for several hours and then explode. This may occur when the fuse is injured in tamping or by some other means so that the trail of powder is broken, and the tape is left to smoulder till it ignites the powder beyond the break.

Ques. 24.—Name the several ages of boys and men mentioned in the Anthracite Mine Law, and the requirements attaching thereto; also, distances specified in the law.

Ans.—The ages mentioned in the law and their respective references are as follows: Age of candidates for office of mine inspector, 30 years or upward (Sec. 9, amendment to Art. 2, approved June 8, 1901). The same requirement applies alike to the Chief of the Department of Mines (Sec. 3, act approved April 14, 1903). Breaker engineers must be at least 18 years of age (Art. 5, Sec. 6); and oilers of machinery at least 15 years (Sec. 8). No boys under 16 years of age may be employed in the mine; and none under 14 years in any breaker or around the outside workings of any mine (act approved May 2, 1905, Sec. 1); and no minor of any age may be employed inside or outside of any anthracite mine, in any capacity, without the filing of an employment certificate (Sec. 3). Hoisting engineers to hoist or lower men must be at least 21 years of age (Art. 12, rule 18); no person under 16 years of age may run a car out of any breast or chamber, or on any gravity road (rule 48). For admission to the Miners' Homes of Pennsylvania, miners must be at least 60 years of age (act approved April 22, 1903, Sec. 7); and wives of miners, at least 55 years (Sec. 8). The distances specified in the mining law are as follows: The two openings of a mine must be not less than 60 feet apart underground and 150 feet apart at the surface (Art. 4, Sec. 1); no inflammable structure may be erected over or nearer than 200 feet to any mine opening (Sec. 5). The hoisting frame over a shaft, in sinking, must sustain the sheaves or pulleys at a height above the tipple not less than 20 feet (Sec. 16), and must be erected before the shaft is sunk deeper than 50 feet (Sec. 17); such shaft when deeper than 100 feet must be provided with guides extending to within 75 feet of the bottom of the excavation (Sec. 20). No boiler may be placed under or nearer than 100 feet to any breaker or building where men are employed in the preparation of coal (Art. 5, Sec. 2). A heading or cross-cut must be driven in every chamber not more than 60 feet from face of chamber (Art. 10, Sec. 15). Any heading approaching a place likely to contain much water may not be driven more than 12 feet wide and a drill hole must be kept 20 feet in advance of such heading (Art. 12, rule 15). Any box containing powder must be kept 10 feet away from all tracks, if possible (rule 27); and no lamp or other fire may be brought nearer than 5 feet to such box when open (Sec. 28). Safety holes on haulageways must not be more than 150 feet apart (Sec. 43); a 2-foot space must be provided on one side of track where sprags are used (rule 47); bumpers must be long enough to keep cars at least 12 inches apart (rule 52).

Ques. 25.—What do you consider to be the dangerous points in a breaker; and what would you recommend to lessen such dangers? State fully.

Ans.—The rolls are a very dangerous part of the breaker, these should be covered as far as practicable, and further guarded by a secure fencing that would not permit an accidental slip of the foot to result in accident. Other dangerous places are conveyers, or scraper, lines, belts, and rope drives, pulleys, or large sheaves. These should all be so protected that accident would be impossible.

Ques. 26.—At a colliery where there are two fans, one blowing, the other exhausting, both working under apparently similar conditions, though producing different results, explain the successive steps you would take to determine which is the better fan.

Ans.—Two fans arranged tandem, the one blowing and the other exhausting on the same current, never give satisfactory results. The fans may be exactly alike in all their dimensions and in form, and run at the same speed, but one or the other of these fans, depending on the natural conditions in the mine, will appear to do practically all the work while the other simply churns the air. If the two fans referred to in the question are exact duplicates in respect to form, dimension, number, and arrangement of blades; and only differ in respect to their connection with the atmosphere and the mine, they must be considered and *are* equally good fans. The question as to whether the exhaust or blowing system should be adopted in any particular mine is a question to be decided by the conditions existing in that mine with respect to haulage and ventilation. In mines where the coal moves with the air on the main roads, the blowing system must be used to avoid the use of doors on the main roads; and, for the same reason, the exhaust system must be employed where the haulage is on the intake airway. In general, conditions permitting its use, a blower is more efficient than an exhaust fan, because working on generally

denser air, but this is not always true. A more practical question would be to ask how to determine what size and speed of fan is best adapted to a certain given circulation.

QUES. 27.—In a certain mine, 100,000 cubic feet of air is passing per minute, under a water gauge of 1.6 inches, and the indicated horsepower of the engine is 50 horsepower, the fan making 50 revolutions per minute; what will be the quantity of air passing, speed of fan, and horsepower of engine, if the water gauge is increased to 3.6 inches?

ANS.—This is another difficult question to answer because the question fails to state the cause of the increase in water gauge. Is it due to an increase in the power of the engine and speed of the fan? If so, the conditions in the mine remaining unchanged, the quantity of air will vary as the square root of the water gauge; or the quantity ratio will equal the square root of the water-gauge ratio, and the increased quantity x will be

$$x = 100{,}000\sqrt{\frac{3.6}{1.6}} = 100{,}000\ \sqrt{2.25} = 150{,}000 \text{ cu. ft. per min.}$$

The quantity ratio is therefore $\frac{150{,}000}{100{,}000} = 1.5$; and owing to a slight decrease in the efficiency of the fan when passing this larger quantity of air the speed ratio is equal to the fourth root of the fifth power of the quantity ratio; or the increased speed is

$$x = 50\ \sqrt[4]{1.5^5} = 50 \times 1.66 = 83 \text{ rev. per min.}$$

Practically the power varies as the cube of the speed; or power ratio = cube of speed ratio; and the increase of power necessary to increase the speed of the fan under these conditions is

$$x = 50\left(\frac{83}{50}\right)^3 = 228 + \text{H. P.}$$

These results will, however, be modified by the adaptation of the dimensions and style of any particular fan to the given speeds. If the fan is designed for a speed of 50 revolutions per minute, its efficiency will be less when run at a higher speed; but if designed for a higher speed its efficiency may increase as the speed is increased, which makes the question unanswerable with data given.

Again, the increase of water gauge from 1.6 to 3.6 inches may be caused by a fall of roof, or other obstruction to the flow of air in the mine, or to a change in the circulation increasing the mine resistance without increasing the area of passage. In this case, the air will be decreased, assuming a constant power, in the inverse ratio of the pressure; or the quantity would be $100{,}000 \times \frac{1.6}{3.6} = 44{,}444$ cubic feet per minute. But this decrease of the quantity of air passing through the fan will increase its efficiency, and the quantity of air, under these conditions, will probably reach 50,000 cubic feet per minute. The power applied to the fan shaft remaining constant, the speed of the fan will be slightly increased under the conditions named, say to, perhaps, 52 or 53 revolutions per minute. Such questions as these being wholly indeterminate should not be asked in a practical mine examination. In this case, the cause of the change of pressure should be given, and its general effect on the quantity of air passing, speed of fan, and power required to produce certain specified results should be asked.

QUES. 28.—(*a*) What is meant by the symbols CH_4, CO_2, CO, and H_2S? (*b*) Why is CO_2 heavier than CH_4 (volume for volume)? (*c*) How are these gases generated and what dangers attend the presence of each? State fully.

ANS.—(*a*) They are the chemical symbols, representing the chemical composition of methane (marsh gas), carbon dioxide, carbon monoxide, and hydrogen sulphide, respectively. (*b*) Because the density of carbon dioxide is greater than that of marsh gas. The density of a gas is one-half its molecular weight; thus, CO_2, $\frac{1}{2}(12+2\times16)=22$; and CH_4, $\frac{1}{2}(12+4\times1)=8$. (*c*) This question is fully answered in reply to Ques. 32, page 576, MINES AND MINERALS, July, 1909.

QUES. 29.—State briefly but fully (*a*) how, when, and where must a mine foreman or his assistant measure the air, and when and how must this be reported to the mine inspector? (*b*) Explain fully each step you would take to satisfy yourself in regard to the quantity of air in circulation, and the system of ventilation employed, in any mine; and how would you determine that the reports made to you were practically correct? (*c*) Explain the anemometer, barometer, and water gauge; and state how each of these instruments is used.

ANS.—Art. 10, Sec. 15, of the Anthracite Mine Law requires the mine foreman or his assistant to measure the air-current with an anemometer or other efficient instrument once every week, at the inlet and outlet airways; also, at or near the face of each gangway, and at the cross-heading nearest to the face of the inside and outside chambers where men are working, on each gangway; such measurements to be entered in the colliery report book. (Sec. 16) A report of these air measurements must be sent to the inspector before the 12th day of each month, for the preceding month, together with a statement of the number of persons employed in each district of the mine. (*b*) Examine the colliery report book and compare with the monthly report sent. Visit the mine without previous notice to the mine officials. Note carefully the speed of the fan as registered on the chart of the recording gauge. Measure the air carefully at each of the points mentioned before; and check the correspondence of the inside and outside measurements on each gangway; and especially the correspondence of the main intake and return measurements and the sum of the measurements taken on the gangways. The system of ventilation should be carefully studied by observing each split of air throughout its course to ascertain if any improvement is possible. This examination should reveal any incorrectness in the monthly reports. (*c*) This question is fully answered in reply to Ques. 8, page 605, MINES AND MINERALS, May, 1910.

QUES. 30.—The return airway in a certain mine measures 6 ft. × 10 ft. in section. The air in this airway has a velocity of 400 feet per minute, and carries marsh gas sufficient to make the air just within the explosive limit. What quantity of air must be added to make it (the gas) detectible?

ANS.—It is difficult to understand what this question intends to ask. There are two explosive limits to the mixture of marsh gas and air; these are called the lower limit (1 volume gas to 13 volumes air), and the higher explosive limit (1 volume gas to 5 volumes air). The gas at both of these limits is very much in evidence and needs no addition of air for its detection. However, assuming the reference here is to the lower explosive limit, for every volume of gas in the mixture of gas and air, there is $1+13=14$ volumes of mixture. The volume of the return current is $6\times10\times400=24{,}000$ cubic feet per minute, which contains $24{,}000\div14=1{,}714+$ cubic feet of gas. Then, assuming that air is to be added till the mixture ceases to give a flame cap in an ordinary unbonneted Davy lamp, which takes place commonly when the mixture contains 2 per cent. of gas, the volume of the current for a 2-per-cent. mixture would be $1{,}714\div.02 = 85{,}700$ cubic feet per minute. To obtain this it would be necessary to add $85{,}700-24{,}000=61{,}700$ cubic feet of air per minute.

CHEDDITE

Cheddite, an explosive that has been extensively used for the past 10 years in Europe, is about to be introduced in Canada. The explosive will not freeze and is practically non-gaseous. It will burn in the open air without explosion. Nitric, hydrofluoric, and sulphuric acids when poured over the powder do not cause it to explode. Nitric acid has no effect on it whatever, but it effervesces under the action of hydrofluoric acid and burns brightly when sulphuric acid is poured over it. When it is charged in a drill hole and exploded the smoke is not injurious and men can go back at once to their working places without even obtaining a headache. This explosive will be manufactured near Haileyburg, Ontario, Can.

SAMPLING COAL

THIS issue of MINES AND MINERALS commences a series of articles on "Coal Sampling" that will appeal to those interested in selling or purchasing coal on the heat-unit basis, and also to those employed in testing and sampling coal so purchased.

To such people the matter of sampling is of extreme importance, for while a fair average sample may be taken from a coal bed, there is little hope of coal reaching the tipple or the consumer in this state of perfection. Hand samples can no more readily furnish a fair average sample of coal than of ore, even should the personal equation that always enters into this method of sampling be eliminated. The method of sampling by stretching the knotted rope lengthwise of a car is also faulty, for even should the sampler take a weighed quantity from under each knot, the sample fails to furnish an approximate idea of what is underneath that taken.

The present state of perfection in the mechanical sampling of ore was reached after years of experimenting. It is not to be expected therefore that those unacquainted with rules governing sampling can at once design a mechanical coal sampler. One of the first principles established in mechanical ore sampling, and one which applies equally to coal, and to which coal sampling must conform, is that a fair average sample cannot be taken where the whole of the stream of ore is taken part of the time. Grab samples, rope samples, and the mechanical sampler illustrated on page 85 take the whole stream of coal part of the time, and according to the rule are unreliable methods of sampling.

SOUTHERN GOLD MINING

THE general impression prevails that southern gold properties are more precarious investments than even those in the West. It is true that the record of southern gold mining has not been such as to inspire confidence, yet there are substantial reasons why this is so that ought to be investigated before condemnation. While gold was mined in Virginia, North Carolina, South Carolina, and Georgia before the Civil War, it was done by planters who used their slaves between crops to wash gold in a desultory way. Up to the present time, with two or three exceptions, no systematic quartz mining has been undertaken. One of the exceptional cases is that of Adolph Theiss, who, when he encountered refractory ore improved the old chlorination process and gave the world the perfected one now in use. The majority of the quartz mine enterprises were failures owing to refractory ore, which at the time they were being developed could not be handled by mills and there were no nearby smelters to which it could be sent. The South then became the "mecca" of the patent-process man, which further blackened its reputation. In many cases if the ore be crushed and panned the gold can be seen, and this alluring bait induced people of small means to erect stamp mills

to recover the gold by amalgamation. Stamp mills having proved abortive in the hands of eastern men, expert stamp men were brought from the West, who also failed utterly to recover the gold. The Western mill men would then introduce a Huntington mill or possibly an arrastra under the belief that this surely would recover the gold, and because it did not they, too, condemned the field.

The adventurers by this time, either from lack of capital or faith, would become disheartened and shut down, or if possible sell to some sure-thing man, and on the latter's failure another black mark was chalked up to southern gold properties.

Since the war the Sawyer Mine, in North Carolina, has changed hands several times. It has high-grade ore that will run up to $100 or more, and to recover the gold, arrastras, Huntington mills, grinding pans, stamps, bumping tables, buddles, and possibly other contrivances, have been unsuccessfully employed. There is no question but that this mine, if located in Gilpin County, Colo., would have been a great success. Most southern gold mining adventures have been made on so small capital and under such conditions that $100 ore could not, in some instances, make them succeed, yet the ore is not more refractory than some Colorado ores.

There have been no large investments to build up the industry in the South, although the ore is there and can be as readily recovered at this time as in the West. While a number of things have injured the mining reputation of the South, probably none have greater influence in condemning the gold properties from a business point than the legal guerrilla-warfare litigation that can pursue non-residents through the courts, and which is instituted by shyster lawyers, with no expense to their clients, in the hope that to escape long years of litigation the non-residents will compromise.

One of the most interesting attempts to reestablish gold mining in the South is now being made by Leo Von Rosenberg, a well-know mining engineer in New York City, who has opened several tracts of gold-mining lands comprising more than 1,000 acres in Georgia, and subdivided them into smaller lots of 1,500 ft. × 600 ft. each. These claims he is throwing open to prospectors for development under lease and bond. The company owning this property has more land than it can develop, and mining conditions are exceptionally favorable, there being plenty of water, perfect climate, permitting work throughout the year, and all the timber necessary for mining purposes. The idea is to give each prospector all the ore within the lot to a depth of 100 feet, or, as the case may be, 150 feet. All such ore as he may find worthy of extraction he may do with as he pleases. The company has a milling plant and will be ready to mill any ore under certain agreements. After the prospector has reached the prescribed depth he will be at liberty to buy the claim or continue mining by paying a royalty on all ore removed. The ownership of large tracts of mining lands by individuals or companies in the South has prevented thorough and systematic vein prospecting.

Mr. Von Rosenberg believes that, if the above proposed plan were more generally followed in the South, it would probably result in opening up a number of paying mines. As it is, large areas are tied up with no work being done. If this land were situated in any of the mining sections of the West and opened for location, hundreds of claims would be staked out and an army of prospectors would be at work digging for ore.

STANDARD ENGLISH

THERE is in North America an established English language replete with mining terms to such an extent that educated mining engineers can judge nearly the caliber of the man writing on mining subjects.

As an illustration, a friend handed an experienced mining engineer a prospectus, with the remark that he was capable of reading between the lines and telling whether the venture was material or visionary. After reading a few minutes the engineer said: "I know neither the property nor the promoters, but this I do know, the man who furnished the stuff in this prospectus was illiterate, and not a mining engineer, although probably a colonel or 'mining expert.'"

This diagnosis was correct, as all those who invested in the venture now declare.

The experienced engineer is able to tell if he is reading an article by a young enthusiastic engineer or an entirely theoretical office man, from the words employed. The young engineer, while he may be technically correct in his writing, will almost invariably interject a copious supply of adverbs and a number of localisms to show he is a man of experience. The office engineer will furnish a long diatribe on immaterial things and straddle the material matters, so that he can fall safe either way; in other words his inconclusiveness marks his deficiency, and to cover this, technical verbiage and adverbs abound. Mining matters can be stated usually in such plain English that a layman with a little help can understand them; and as most mining engineers write for laymen it is good policy to return to first principles.

Frequently some one says language must conform to usage. "Mama, the iceman have came" is the established vernacularism in some parts of New York City; however, if you accept it there is no particular reason why you should have studied grammar; and when a mining engineer writes of coal *veins* he puts himself in the same class, for he never was taught in his mining school that there were coal veins. So far the people in these United States have spoken better English with fewer dialects than the inhabitants of the British Islands and there is no reason why they should adopt old English localisms that originated in fun or ignorance. We hear of "inbye" and "outbye." The former had

its inception from some old miner who remarked "are you going in, bye," instead of "are you going in the mine, boy," and "outbye" followed naturally. We hear also of "pit wagons" meaning mine cars, and if it continues we shall hear of tubs, and boxes, which in England have the same significance, according to the locality. Tubs were used in coal mines, as were boxes and wagons, before rails were introduced. They were probably never used in America, although mine cars have been an established part of mine equipment.

Pit means, in our idiom, a deep hole or vertical excavation, not a horizontal excavation, yet men who know better will speak of a shaft mine, and will call a drift mine "a pit," and drift portals "pit mouths." Another innovation is "mine workings," which has about the same significance as "old workings" in that it shows that the mining engineer that uses it is coming down to the lazy tongued miners and not raising the miners' intellect.

As T. A. Rickard said in his article on the "Standardization of English": "When new words are used to express new ideas there is no objection to their introduction." It is, however, a serious perversion of American English for an educated engineer to adopt localisms introduced by some one to represent an old thing which to him was new; and wherever they are used it shows a lack of experience and presumably ignorance in mining.

As previously stated, the experienced mining engineer estimates pretty closely the caliber of another mining man by his written expressions, for which reason, if no other, care should be exercised by mining engineers in the use of *mining terms*.

Book Review

Coal Cutting With an Electric Puncher, by John L. Wagner. This pamphlet is illustrated and is the gist of the lecture given by Mr. Wagner before various societies on the comparative advantages of the different methods of undermining coal, and the most economical application of power to this kind of work.

Who's Who in Mining and Metallurgy, 1910. Founded by George Safford. Published by *The Mining Journal*, London, England. Price 15 shillings.

This is the second edition and is much enlarged. Of the 272 pages, 147 are devoted to biographic paragraphs, and 125 to technical and professional societies. This book was not originated as a biographical hold-up, in other words you do not have to purchase it, although if you do the exchange will not be regretted, for it is the Bertillion system of the engineer and the editor's Rogue's Gallery. "Who's Who in Mining and Metallurgy" took its first list of mining and metallurgical men in America from "Who's Who in America." The second edition, however, increased the number of names considerably, and while it is not yet thoroughly representative it will become so in a few more editions.

There is no professional advertising, but there is a record of engineers which will greatly interest other engineers and will be found of service and satisfaction For example, some one writes on a mining or metallurgical subject. The reader wants to know more of the man and therefore refers to his past in "Who's Who in Mining and Metallurgy."

Map of West Virginia, showing coal, oil, gas, and limestone areas, I. C. White, State Geologist, Morgantown, W. Va. Map can be procured by sending 50 cents to the Geological Survey of West Va.

Proceedings of the Engineering Association of New South Wales, Vol. 24, 1908–9. Contains a number of valuable papers. Those that will appeal most to mining engineers are: Labor-Saving Devices, by G. A. Julius, B. Sc., M. E.; Description of a New Zealand Coal Mine, by C. J. Holroyde. The other papers are: Coolgardie Water-Supply Scheme, by R. J. Vincent; Water at Coolgardie cost from £4 to £1 5 shillings per 1,000 gallons. This paper describes the method of installing a water supply and overcoming obstacles eventually reducing the cost to 2 shillings. It is both interesting and instructive.

Algea in Reservoirs, by James Faulkiner; 'Modern Methods of Steamship Construction, by Walter Reeks; Commercial Motor Vehicle, by E. F. Boult; Design and Use of Speed-Reducing Gear, by Henry Shaw and James McNamara.

Henry V. Ahrbecker, M. I. Mech. E. secretary, 5 Elizabeth Street, Sydney, New South Wales.

Principles of Chemical Geology, by James Vincent Elsden, D. Sc., F. G. S., is made up into 222 pages, 10 mo, with index. There are 10 chapters and 44 diagrammatic illustrations. Published by The MacMillan Co., New York City, and Whittaker & Co., London, England. Price $1.60 net.

The main object of the book is to present in a concise form the application of the principle of equilibrium to certain geological phenomena. To the student of geology nothing is at first more bewildering than the multiplicity of changes which rocks and minerals undergo in nature. It is to chemical and physical laws that we are accustomed to look for an explanation of these transformations; but until comparatively recently many of these explanations were vague and hypothetical, owing to our ignorance of these laws. To elucidate and stimulate interest in this branch of geology, Mr. Elsden has divided the subject into 10 chapters, of which the following are synopses: I, Equilibrium between the crystalline and amorphous states, based on Le Chatelier's principle that "any external change in the factors of equilibrium of a system is followed by a reverse change within the system." II, Equilibrium influenced by viscosity plays an important part in retarding the transition of minerals. III, Diffusion as a factor of equilibrium in geological transformations may be due to gases, liquids, or solids. IV, Surface tension as a factor of equilibrium is considered as one of the most important features in supersaturation. V, Vapor pressure as a factor in equilibrium is based on experiments that show that many solids possess an appreciable vapor pressure at moderate temperatures. VI, Equilibrium conditions of polymorphous forms, that is where transformation of a mineral from one crystalline form to another occurs with differences in specific gravity, melting point, and other physical properties. This subject possesses geological interest owing to the effects produced by dynamical metamorphism. VII, Equilibrium in solution. From the point of view of the phase rule, unsaturated solutions are trivarient systems that possess three degrees of freedom, and can only be defined by the three variable factors, pressure, temperature, and concentration. VIII, The eutectic theory is elucidated from ice to its projection on a plane triangle, making it necessary to examine how far the eutectic theory may apply. IX, The theory of solid solutions applied to geological problems, covers 23 pages, and forms one of the most interesting chapters. X is on the conditions of chemical equilibrium in geology. The book is interesting throughout and will appeal to the advanced mineralogist, physicist, chemist, and geologist. The subject is large and Mr. Elsden has covered it admirably, without entering the domain of geochemistry.

CORRESPONDENCE

Putting Out a Mine Fire

Editor Mines and Minerals:

SIR:—I would like to hear from your readers regarding the means and methods they would follow in putting out the fire

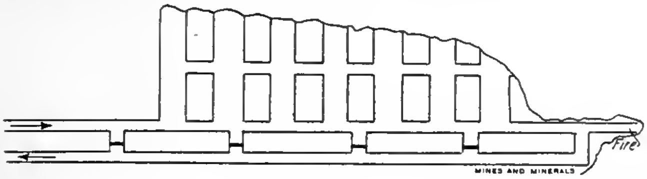

FIG. 1

shown in the accompanying Fig. 1. The fire is on level workings in a shaft mine 130 feet deep. It started at the face of the entry where shown. The rooms give off gas. H. P. J.

Scranton, Pa.

To Find Percentage of Grade

Editor Mines and Minerals:

SIR:—Please answer through your Correspondence Column the following question: What per cent. grade does a slope represent that is driven at an angle of 10 degrees?

Denver, Colo. SUBSCRIBER

ANS.—Look in the table of natural sines and cosines in Coal and Metal Miner's Pocketbook, and find sine 10° = .17365. This is the grade for 1 foot. As per cent. means by the hundred, 17.365 is the per cent. grade.

Ventilation

Editor Mines and Minerals:

SIR:—Can any of your subscribers give a formula for the following problem? A pair of single entries each 1,000 feet in length are ventilated by pipes 18 inches in diameter; at a dis-

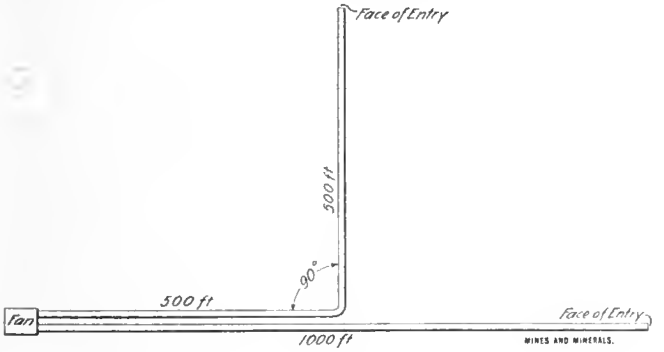

FIG. 2

tance of 500 feet, as shown in Fig. 2, there is a branch pipe 500 feet long at right angles. Can the same quantity of air be obtained in each entry, the rubbing surface and pressure being the same? G. E. D.

Dawson, N. Mex.

Railroad Rates

Editor Mines and Minerals:

SIR:—This side of the Rockies the railroads sure love the dear public. A ships a load of $50-per-ton ore; B ships the same amount of $300-per-ton ore. Because the ore of B is richer than that of A, he is compelled to pay higher freight rates. What kind of railway companies have you in the East? Must a rich man pay more per mile for traveling than a poor man?

Jawbridge, Nev. J. H.

The railroads in the East are even worse to their mining patrons than those in the West. There are several reasons why railroads charge a higher rate for rich ore. They are responsible to the shippers and must pay more damages in case of loss of richer than for the poorer ore. There is more loss in smelting the richer than the poorer ore, for which reason the smelter charges are more. The rich man is supposed to pay as much as the poor man for traveling, but he need pay no more unless he is so exclusive as to travel in a private car. In case of accident the heirs of the rich man would receive more damages than would the heirs of the poor man, a principle of justice (?) the reverse of freight rates on ore.—EDITOR.

Monazite

Editor Mines and Minerals:

SIR:—What is monazite? Where is it found and what are its associate minerals? How can it be detected? Has it any commercial value? W. SAMPSON

Singapore, India

Monazite is a complex phosphate containing cerium, lanthanium, didymium, and thorium. It is found in granitic rocks in North Carolina, Brazil, and elsewhere, in the form of sand, having a yellow, clove-red, or brown color. Thorium is the valuable part of the mineral and is used in the manufacture of gas mantels of the Welsbach type.

Monazite has basal cleavage; resinous lustre; a hardness, 5 to 5.5; and a specific gravity of 5.2 which heaviness causes it to collect as sand bars in running streams. Fused with soda, the mass treated with water, and filtered, the residue dissolved in hydrochloric acid, the solution gives with oxalic acid a precipitate which ignited, becomes brick red (oxide of cerium). The commercial value of monazite is not so great as to induce people to go into the business unless they have large rich deposits, easily recovered.

Siphon

Editor Mines and Minerals:

SIR:—Referring to the siphon problem in the July number, and the answer thereto, Messrs. J. L. P. and W. H. Jones are both wrong, as the effective head drawing water into the siphon, and which consequently will govern the amount discharged, is the degree of vacuum obtained at the summit of the pipe.

The velocity of the water in the shorter leg will determine the quantity discharged, and the head to produce this velocity cannot be greater than the height to which a column of water will be raised by the pressure of the atmosphere at the given locality.

The discharge cannot be calculated from the data given, as the distance from the surface of the water to the summit of the pipe is not given. ALONZO G. COLLINS

Philadelphia, Pa.

SPITZBERGEN COAL MINING

Consul-General Henry Bordewich, of Christiania, furnishes the following information concerning the coal mines at Advent Bay, in the Arctic island of Spitzbergen, in which Americans are interested:

The steamer Munroe, belonging to the coal-mining company, passed Tromso, northern Norway, bound for Spitzbergen with supplies, on May 18, and on May 30 entered that port on its return trip, having accomplished the voyage in 12 days.

The officers report that among the 100 men who passed the winter at work in the company's mines at Advent Bay there was very little sickness. The winter was unusually mild, and the work progressed under the most favorable conditions. About 8,000 tons of coal, pronounced of excellent quality, have been extracted and made ready for market. The excavations are now so deep that work in the mines can be carried on regardless of weather and seasons. Suitable buildings have been erected, and substantial wharves are under construction.—*United States Consular Report.*

THE ELIZABETH TUNNEL

*Written for Mines and Minerals, by W. C. Aston**

Methods by Which Highest American Hard Rock Tunnel Record Was Made

The city of Los Angeles, in California, is constructing an aqueduct about 217 miles long. Considerable of this work requires tunneling; in fact there are 105 tunnels whose aggregate length is 28 miles. The Elizabeth tunnel, which is 26,860 feet long, is being driven from both ends, termed the north and south portals. This tunnel has a cross-section 12 ft. 4 in. × 12 ft. 9 in., a grade of 1 foot in 1,000 feet, and a water capacity of 1,000 second feet. At the present time over 11,000 feet have been advanced from each end, and the work is being pushed forward at remarkable speed.

Upon opening the portal the ground was found to be soft, requiring timber, but as the work progressed, it rapidly hardened,

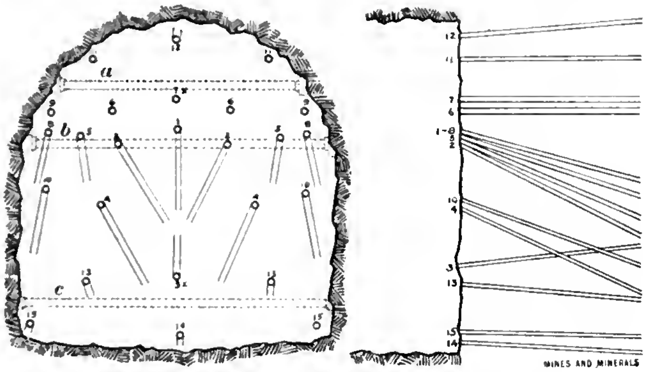

FIG. 1. ROUND OF SHOTS FOR MEDIUM HARD GROUND

and, with the exception of a few belts of softer material at irregular intervals, has remained hard, passing through many stages of massive, blocky, stratified, seamed, and folded formation, and varying through many alterations of granite, gneiss, and schist.

To be able to approach the same rate of speed through the hard rock at the south end that could be maintained through the softer rock of the north end, and at the same time not materially increase the cost, it was decided to systematize the work to a point where the operation would become as nearly mechanical as possible, leaving it elastic enough to admit the unavoidable breaking in of green men and enlarging or contracting the size of a shift. To do this it was decided to assign a specific duty, as far as possible, to each man in the heading, which that man was required to do every day when conditions were normal without waiting orders from the shift boss. All other men working in the tunnel, but not directly in the heading, were placed upon call by the shift boss for work in the heading when necessary, and all surface laborers except compressor men and blacksmiths, were placed upon a reserve list to draw from in an emergency or when ordered by the foreman.

The track boss reporting to the foreman, but working in conjunction with the shift boss with a crew varying from three to seven men and working only during the day shift, puts down all track, air, water, and ventilating pipe, cleans the ditch and keeps the dump in shape. The master mechanic is in charge of all outside labor and is held responsible for the upkeep of all equipment and tools, except the electrical, which are handled by an electrician. One mechanic overhauls all machines, hose, and heading tools for the three shifts, another one repairs all cars, replaces broken wheels and draw-heads, and oils or greases them. The first requisite for rapid work was a good track. The main line both inside and outside the tunnel was centered, ballasted, and connected in the yard by switches and sidings to the powder magazine, timber yard, saw mill and repair shop, using 30-pound rails, stub switches, and ground-throw switch stands.

*Superintendent of South Portal, Elizabeth Tunnel

All timber, lumber, pipe, rail, and heavy supplies were piled so that they could be unloaded from the freight wagons directly on to the piles and loaded direct on to the cars from the opposite side.

The general equipment varies but little from that in use at other tunnels being driven at the present time, and consists of the following:

Two compressors, 520 feet capacity, belt driven from electric motors; two motor-generator sets, 150 horsepower; one 50-horsepower electric locomotive; one 30-horsepower electric locomotive; nine water Leyner drills; 38 rocker dump cars, 32 cubic feet capacity; one drill sharpener.

In addition, the machine-shop equipment included a lathe, drill press, saws, blowers, motors, and the necessary tools for such work. Most of the destructible equipment was supplied in duplicate, and extra machine drills were furnished. Each shift was supplied with a tool box and all the tools necessary for its members' work. These tool boxes were locked and one man on each shift was held responsible. A station was cut in the tunnel where all repairs to machines, hose, tools, etc., were made. Wherever possible each individual is held responsible for the tools he uses.

When going on shift under normal conditions all tools, replacements, drinking water, etc., are loaded on a flat car attached to the end of the train and hauled with the men from the portal to the repair station inside where the machines, manifold, and hose are loaded on. Upon reaching the heading the six machine men pick down the back and sides, and shovel back only enough material to allow of placing the arch bar *a* and upper main cross-bar *b* in position as shown in Fig. 1. The nine shovelers immediately string out along the tunnel, cleaning track, carrying forward the tools, unloading the steel and drills, and piling material where it can be readily reached. A reel holding a double-conductor, armored, extension electric light wire is carried to the end of the permanent wire, unwound and dragged to the heading, and connected to a cluster of lights

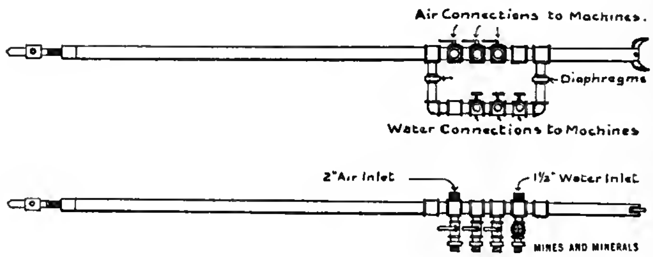

FIG. 2. COMBINATION MANIFOLD FOR AIR AND WATER

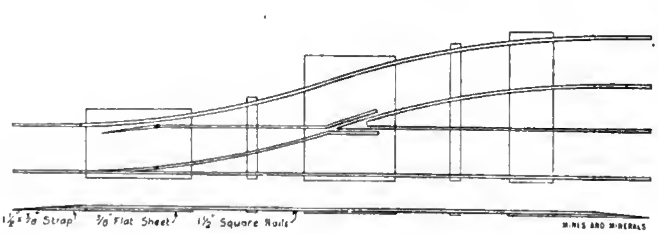

FIG. 3. PLATFORM SWITCH

which is fastened where it will give light to both machine men and shovelers. A compound manifold, shown in Fig. 2, carrying both compressed air and water, and mounted on a light screw cross-bar at a point as close to the drills as convenient, is next erected by the laborers and connected to the main pipe line by 100 feet of 2-inch armored air hose, and the same length

TABLE 1. SOUTH PORTAL ELIZABETH TUNNEL. DETAILS OF ANNUAL SUMMARY OF TUNNEL REPORTS FOR 1909

	Totals	Units	Total Cost	Unit Cost
Footage to date	7,585 feet			
Footage during 1909	4,476 feet			
Required progress	2,920 feet			
Daily footage (365 days)		12.26		
Required daily footage		8.00		
Increased footage over estimate	1,556 feet			
Daily increase over estimate		4.26		
Footage of untimbered section	3,274 feet			
Estimated cost of untimbered section			$131,385.62	$40.13
Actual cost of untimbered section			121,787.45	37.198
Footage of timbered section	1,202 feet			
Estimated cost of timbered section			62,491.98	51.99
Actual cost of timbered section			51,941.11	43.20
Average cost of timbering per foot progress				1.16
Total bonus footage	1,563 feet			
Total bonus pay roll			23,440.23	
Average cost of bonus per foot progress				5.23
Estimated expenditure			193,877.60	
Actual expenditure			173,728.56	
Amount saved over estimated expenditure			20,149.04	
Number of shifts worked	1,055			
Number of shifts lost	40			
Number of men days	21,452			
Men per foot progress		4.79		
Average progress per shift		4.24		
Number of holes drilled	21,066			
Total feet drilled	135,896			
Feet drilled per foot progress		30.36		
Total time drilling (in hours)	3,656.25			
Average time drilling per foot progress (in minutes)		49.01		
Average time drilling one hole 1 foot deep		1.61		
Pounds of powder used (including trimming)	143,659			
Average pounds per foot		32.09		
Number of cars mucked (32 cubic feet)	28,561			
Cars mucked per foot		6.40		
Leyner No. 9, drill repairs (3 machines per shift)			4,116.99	
Average cost of repairs per machine per foot				.30
Leyner No. 2 drill sharpener repairs (for 3,300 feet)			387.13	.117
Energy used, (kilowatt hours)	608,762	135.00		

TABLE 2. SOUTH PORTAL ELIZABETH TUNNEL. SUMMARY OF TOTAL TUNNEL EXPENDITURE DURING 1909

		Totals	Unit Cost
E. W. O. 333—A.	Engineer and superintendent	$ 3,851.24	.86
B.	Excavation	79,607.15	17.78

		Total expenditure	$15,348.27	25.25

of 1½-inch armored water hose, and to the other side of the manifold three double lines of small air and water hose are connected with the drills.

When the two cross-bars are up, one drill is mounted on the arch bar *a* where it drills three holes, the other two machines are mounted on the upper main bar *b* and drill 15 holes between them. For a while nippers passed the steel, but they were discarded, as it was found that it could be passed readily by the shovelers while the cars were being switched. The nine laborers work in squads of three while loading the cars, one squad loading into the 32-cubic-foot rocker dump cars, shown in Fig. 4, another squad picking and loosening the dirt ahead of them, and the remaining squad resting near the switch.

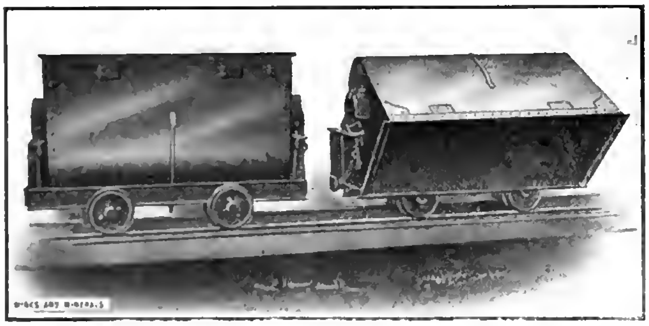

Fig. 4. Rocker Dump Cars Used in Tunnel

From this point the resting squad pushes the empty car as soon as the loaded one is hauled past them by the mule to a point where it is picked up by the electric locomotive and hauled with others to the surface in trains of from 12 to 15 cars each.

The main track and siding are both laid without being cut for frogs, and are connected by a platform switch, shown in Fig. 3. The tracks are made of 1½-inch square iron and riveted to ⅜-inch plates and straps, while the ends are tapered so the cars pass over them with but slight jolt. This switch is carried ahead from time to time and is always kept within 200 feet of the heading. Rails placed on their sides inside the permanent rails with the ball faced against the web of the permanent rail are used for extension track. Ties are laid as rapidly as the dirt is cleared away and these temporary false rails are pushed ahead over them. When the full length of rail has been pushed forward, the track crew cleans off the ties and as a loaded car leaves the temporary track, one rail is turned over to an upright position and both ends spiked before the returning empty car reaches it. While this latter car is being loaded, the remainder of the rail between the car and the permanent track is spiked, and the process repeated with the other rail, without holding up the loading for an instant.

Flat steel sheets are laid over the floor of the tunnel for a distance of 40 feet back from the heading. When the dirt is out, the upper main bar, *b*, Fig. 1, is lowered to its second position *c*; when the drills are late, a second long bar is placed as close to the ground as the operating of the machines will permit, and as each drill finishes its upper hole it is lowered down to this bar and drills the lifters, and if the ground is hard enough to warrant it, also drills two relievers and an up-cut hole. As soon as the upper bar is clear of the holes the blow pipe cleans out the holes drilled and by loading from top and both sides at once the fuse is often spit within 15 minutes after the air has been shut off from the last hole.

As the last change is made on the drills, the manifold is dropped to the floor, a man with a wrench goes to either end and as each machine finishes, the small hoses are uncoupled from the manifold, coiled, and placed on the car which stands just behind already loaded with the dull steel and tools. Machines, clamps, bars, blocking, and jack-bars, each go back in turn and as the last one clears the heading the mule starts away with the car in time to escape the dirt from the blow pipe, as it cleans out the lifters.

The powder charge varies from 15 to 40 pounds per foot of advance, according to the hardness or toughness of the ground.

The men now string out at regular intervals along the 100 feet of main air and water hose and carry them back to the point of safety, such pipe being too heavy to coil and place on the car. They then continue back to the cars, store their small tools in the tool box, board the cars, and wait for the machine men to spit the holes.

A No. 5½ Root pressure blower draws the powder smoke out through an 18-inch pipe until the heading is nearly clear, when the blower is reversed and fresh air blown in, about 15 to 20 minutes being required to clear the heading of gases.

Hinged tables are fastened against the sides of the tunnel and on the 7 a. m. and 3 p. m. shifts hot meals are spread for the crews. These meals are placed in a tight box in the mess-house kitchen and not opened until ready to serve. On the 11 p. m. shift the lunches are served cold.

With slight modifications as conditions changed, or equipment was replaced or improved, this system has worked very satisfactorily during the past year and up to the present time. It worked so well in fact that during the month of April of this year when both labor and machinery were at their highest state of efficiency the full heading complete was driven the remarkable distance of 604 feet, through a rock that was hard enough to require as many as 27 holes per round to break.

Each shift is required to drill and blast, the length of round being regulated by the nature of ground encountered in the first hole drilled.

Discipline and strict attention to business while on shift are required of every one, while at the same time a spirit of friendliness is fostered and every man made to feel that in a large measure the success is due to his own efforts and the interest he takes. We attribute the present efficiency of the men and progress at this portal to the above policy as well as to the close adherence to detail and system which is demanded of all concerned.

A bonus of 40 cents per foot per man for every foot driven over 2⅔ feet per shift is being paid, bringing wages up to a good figure above the scales usually paid in other mining camps and consequently giving us a better grade of men than could otherwise have been obtained.

Tables 1 and 2 give the heading base units for 1909, during which time 40 shifts were lost, but still the average of 365 days was 12.26 feet daily. Table 2*a* shows the general expenditures during 1909.

Tables 3 and 4 show the heading base units for the month of April, 1910, when 604 feet were driven in 30 days, and not only broke the American record for that time, but also the world's record for driving a full heading without bench, wings, or galleries.

PERSONALS

Frederick Burbidge, of Spokane, Assistant General Manager of the Federal Mining and Smelting Co., of Idaho, has resigned. He was general manager of the Bunker Hill and Sullivan Mining Co. for several years.

Fremont S. Rowe and F. Cushing Moore have been examining the Black Bear Consolidated Mine in the Coeur d' Alene district, Idaho.

H. C. George, of the Wisconsin State Mining Trade School, spent July in the Lake Superior copper and iron districts.

A. E. Seaman, of the Michigan School of Mines, has been studying the geological situation of Santa Eulalia, Chihuahua, Mexico.

J. F. Jones has been transferred from St. Louis to Birmingham, Ala., where an office has been opened for him in the Woodward Building by the Wagner Electric Mfg. Co.

Prof. E. C. Holden supervised the four week's work of the mining engineering class of the University of Wisconsin, in Idaho, this past summer.

J. P. Hutchins has A. P. Rogers, Norman Stines, and Ross Hoffmann, as assistants in testing the alluvial deposits in the Nerchinsk district, Siberia. He writes: "Doing business through an interpreter is bad, for he usually does it all for you and only tells you how he arranged it."

Bert. M. Meadows, for several years connected with the Charlotte Supply Co., of Birmingham, Ala., has joined the selling force of the J. Geo. Leyner Engineering Works Co., assisting their Birmingham representative, K. B. Stephens, in handling their drill and drill-sharpener business in the southeastern states.

C. K. Hitchcock, E. M., formerly with the Quincy, later with the Adventure Mining Co., has been made manager at the Lake copper mine of the Copper Range Consolidated.

George T. Holloway announces the removal of his office and laboratories from Chancery Lane to 9–13 Emmett Street, Limehouse, London, E.

Thomas E. Lambert has accepted the position of master mechanic for the Giroux Consolidated Mines Co., at Kimberly, Nev.

J. B. Tyrrell, of Ontario, Canada, has left for a short visit to London, England. His address in London will be, care of Mining and Metallurgical Club, St. Ermin's, Westminster, London, S. W., England.

Edgar G. Tuttle, E. M., has opened an office at 30 East Logan St., Germantown, Philadelphia. He will examine and report on mining properties, design mine and concentration plants and supervise the construction and installation of mechanical and electrical equipment, water-power development, etc.

THE AMERICAN MINING CONGRESS

The American Mining Congress will meet in thirteenth annual convention in Los Angeles, Cal., September 26, 27, 28, 29, 30, and October 1, 1910.

The call for the convention states the purpose to be to bring the representatives of the mining industries of America into conference for the public discussion of national and international questions which concern the welfare and progress of mining and allied industries.

The Los Angeles convention will be composed of the regular members of the American Mining Congress, the accredited delegates appointed by the respective appointing authorities, invited guests, and speakers.

Delegates may be appointed as follows: The president may appoint 10 delegates at large; governors of states and territories may each appoint 10 delegates; mayors of cities and towns, two delegates each; boards of county commissioners, two delegates each; boards of county supervisors, two delegates each; Boards of Trade, two delegates each; Chambers of Commerce, two delegates each; mining bureaus and exchanges, two delegates each; mining organizations, two delegates each; scientific societies, two delegates each; engineers' associations, two delegates each; state mining schools, two delegates each.

It is urged that the name and post-office address of each delegate appointed be forwarded promptly to the secretary, American Mining Congress, Denver, Colo., that advance information as to the subjects to be discussed and matters to be acted upon may be furnished them.

The American Mining Congress is an incorporated body, and only members of the organization can legally vote upon such matters as relate to the permanent business affairs of the congress, the control of which is lodged in a board of directors consisting of nine members, three of whom are elected annually, to hold office for 3 years.

The board of directors will be largely guided by the resolutions adopted by the congress in annual session, which body is composed of members and duly accredited delegates, and will maintain a working force continuously engaged in carrying out the directions of the congress as expressed in resolutions adopted at its regular sessions.

In the regular deliberations of the congress, the introduction and discussion of resolutions and other matters, serving upon convention committees, and in every phase of the meeting of the open body, the rights, duties, and privileges of the regular members of the American Mining Congress and those of the duly appointed and admitted delegates are coordinate in all respects.

Local convention arrangements are in charge of the Sierra Madre Club, of Los Angeles, assisted by the principal commercial bodies of the Southwest. The Sierra Madre Club is arranging to provide very desirable entertainment for all delegates and ladies, during the time not occupied by the regular program of the congress

AMERICAN SOCIETY OF ENGINEER DRAFTSMEN

On June 18 the first steps were taken to form a permanent organization to be known as the American Society of Engineer Draftsmen, embracing every branch of the profession.

The object of the society is the advancement of engineering knowledge and practice and the maintenance of a high professional standing among its members. Inasmuch as draftsmen are very closely related to and represent every branch of engineering, an organization of this character will exert a powerful influence on the future of this field.

Every effort will be made to increase the efficiency of members, by keeping them informed on current topics in relation to mechanical, electrical, civil, architectural, automobile, and aeronautical engineering.

The membership of the society will consist of honorary members, members, and juniors. Stringent conditions will be in force governing the qualifications for admission to each grade, thereby establishing a standard, which has hitherto been lacking in this profession.

The officers chosen for the first term are, President, E. Farrington Chandler; Vice-President, Wm. B. Harsel; and Secretary-Treasurer, Henry L. Sloan; each chosen for his special adaptability to the duties of their respective offices.

Those desirous of joining this society should address Henry L. Sloan, Secretary, 116 Nassau Street, New York City.

LOS PILARES MINE

*Written for Mines and Minerals, by Edward M. Robb, Jr.**

Form of Ore Body Delayed Filling Method of Stoping—Ore Transportation

Location.—The Los Pilares Mine of the Moctezuma Copper Co., is situated in the state of Sonora, Mex., about 75 miles south of Douglas, Ariz. The town of Nacozari, Sonora, shown in Fig. 1 is connected with Douglas, the port of entry for this section of the country, by the Nacozari railroad.

Between the mill at Nacozari and the mine at Povenir, a 5-mile, narrow-gauge railroad, having a maximum 4-per-cent. grade and 40 degrees curve, has been constructed to transport the ore. This mine road ends at the portal of the main adit of the mine, which is driven through a fine-grained andesite for a distance of 2,900 feet, where it cuts the northern end of the ore formation

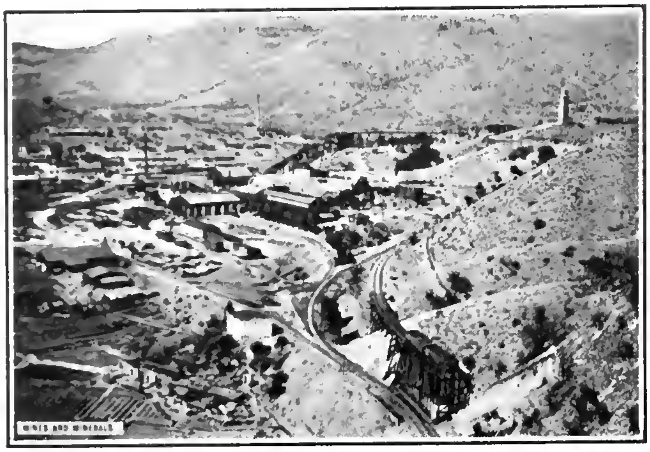

Fig. 1. Nacozari, Sonora, Mex.

and also one of the main working shafts, known as the Y shaft, shown in Fig. 2. It continues on through the ore-bearing formation until a distance of 5,000 feet is reached, where it connects with the main or Pilares shaft, at a depth of 570 feet below the collar and at the southern extremity of the ore body.

At Povenir there is an immense pear-shaped "horse" of rock 2,000 feet long and having a maximum width of 800 feet. The horse *a* as shown in Fig. 4 is surrounded by ore deposits *b* which vary in thickness from 0 to 200 feet. The interior of the horse has been shattered and at the core there are mineralized areas *c*, one of which is 300 ft. × 300 ft. There are seemingly no lateral connections between the ore deposits surrounding the horse and the ore deposit in its interior, each having a separate mineralized zone.

The country rock at, and in the immediate vicinity of, Pilares, is andesite overlain by a rhyolitic capping whose thickness varies from 200 to 600 feet. This is also true of the horse, which is rhyolite near the surface and adesite with depth, but within the pear-shaped area constituting the mineralized zone, the rock is brecciated, while the surrounding country rock is not.

The horse is capped by a brecciated, rhyolitic, iron-stained gossan, varying in thickness from 20 to 75 feet and carrying little or no copper. Occasional deposits of carbonate or sulphate of copper are encountered close to the surface and directly over the workable deposits of ore, but as they are generally of small dimensions and the copper minerals are not concentrated in them they are of very little consequence in the output. The first work on the deposit by its original locators was done in tunneling under some very prominent copper-stained rock pillars that are situated at the top of the hill and in the center of the mineralized zone, Fig. 3. These pillars are of the same rock that is characteristic of the upper workings of the mine, that is, brecciated rhyolite, but this instead of containing sulphides of copper carries micaceous hematite. From these pillars the mine first received its name "Los Pilares."

Below the gossan is the enriched mineral zone, also of variable thickness, but averaging about 100 feet. In this zone, the copper mineral changes from pseudomorphic chalcocite

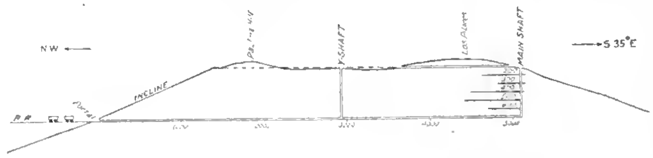

Fig. 2. Profile of Los Pilares Ridge

after pyrite, to pyrite and chalcopyrite with a slight coating of chalcocite. It is seldom, however, that a complete replacement of pyrite or chalcopyrite by chalcocite has taken place. A small quantity of bornite is also found within this zone.

Below the enriched zone are found the primary sulphides consisting entirely of chalcopyrite and pyrite. Throughout the entire ore body, from the surface to the lowest workings, the character of the deposit is the same; a shattered rock with the ores existing as the cementing material. Both the brecciated rhyolite near the surface, and the brecciated andesite below it contain copper minerals.

The peculiar shape of the ore body has been the subject of much speculation, but so far the only geologist of note to publish his conclusions has been Mr. Samuel F. Emmons†.

There is a dike x, y, z, Fig. 4, approximately bounding the southeastern portion of the ore body, but more and more approximately traveling the center of the ore deposit as it is followed to the northwest. This dike of disintegrated diabase. locally known as the *caliche*, has a width varying in different places from a knife edge to about 30 feet.

Near the surface this caliche has a slight dip to the eastward, making it a hanging wall of the ore body, but at the 300-foot level it changes its direction and dips to the west with increasing flatness from about 70 degrees on the 300-foot level to about 50 degrees on the 600-foot level. Beginning with the intersection of the dike at x and following it northward to y the ore is found wholly inside or to the west. For this reason the earlier mine workings were driven to parallel the dike believing

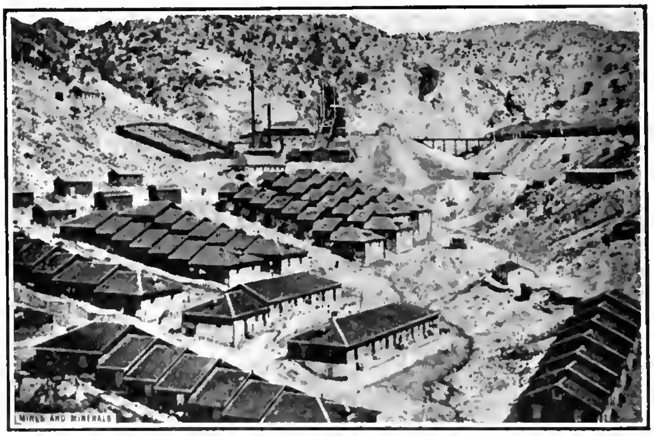

Fig. 3. Pilares Camp

that it was the ore indicator, and no ore would be found to the east of it. Later developments disproved this theory as in the northern half on the eastern side the course, the dike is through the center of the ore. In the northern portion of the deposit, large spurs and splits from the main dike, varying in width

*Mining Engineer Moctezuma Copper Co., Nacozari, Sonora, Mexico.

†See "Los Pillares Mine," Economic Geology, Vol., July-August, 1906, page 629.

from 1 to 25 feet and in length from small to great distances are found running into the eastern country rock. This dike has caused great difficulty in the mining operations, owing to its vagaries of direction and its tendency to slough and cave from above.

From the foregoing it will be understood that the ore body has a definite and fairly regular exterior boundary. The richest ore is apt to lie very close to this boundary, the grade of the ore getting poorer toward the center of the pear-shaped horse until the limit of commercial ore is reached. In what follows, the term "width" refers to the distance from the exterior boundary along a line at right angles to the same to the point at which the commercial ore ceases. This width of ore varies in different parts of the mine, and on different levels, from a few feet to more than 200 feet.

Mine Workings. Two main working shafts have been sunk in country rock about 50 feet outside the deposit from which it has been developed. These are the Pilares shaft *d*, shown by Fig. 4 at the southern extremity of the deposit and the Y or Esperanza shaft *e* at the northern extremity. The Pilares shaft at a depth of 575 feet connects with the Porvenir adit. It has three compartments each 4 ft. × 4½ ft. in the clear. Cages in two of the compartments are operated by electricity while in the third is an emergency cage, steam operated, and also water and air pipes. The Y shaft likewise has three compartments each being 4½ ft. × 5 ft. Two compartments contain electrically operated cages, while the third has been reserved for a permanent ladderway, water pipes, and air pipes. At the depth of 590 feet below the collar of this shaft, it connects with the main adit level but has been sunk 300 feet below this level. At the tenth level, 300 feet below the main adit, another main traction level will be driven, while the shaft will be sunk 60 feet further to allow for ore pockets, skipway, etc. From these pockets an automatically dumped 6-ton skip will hoist to the fifth level where it will dump into a chute to one of the ore bins on the main adit level 200 feet below.

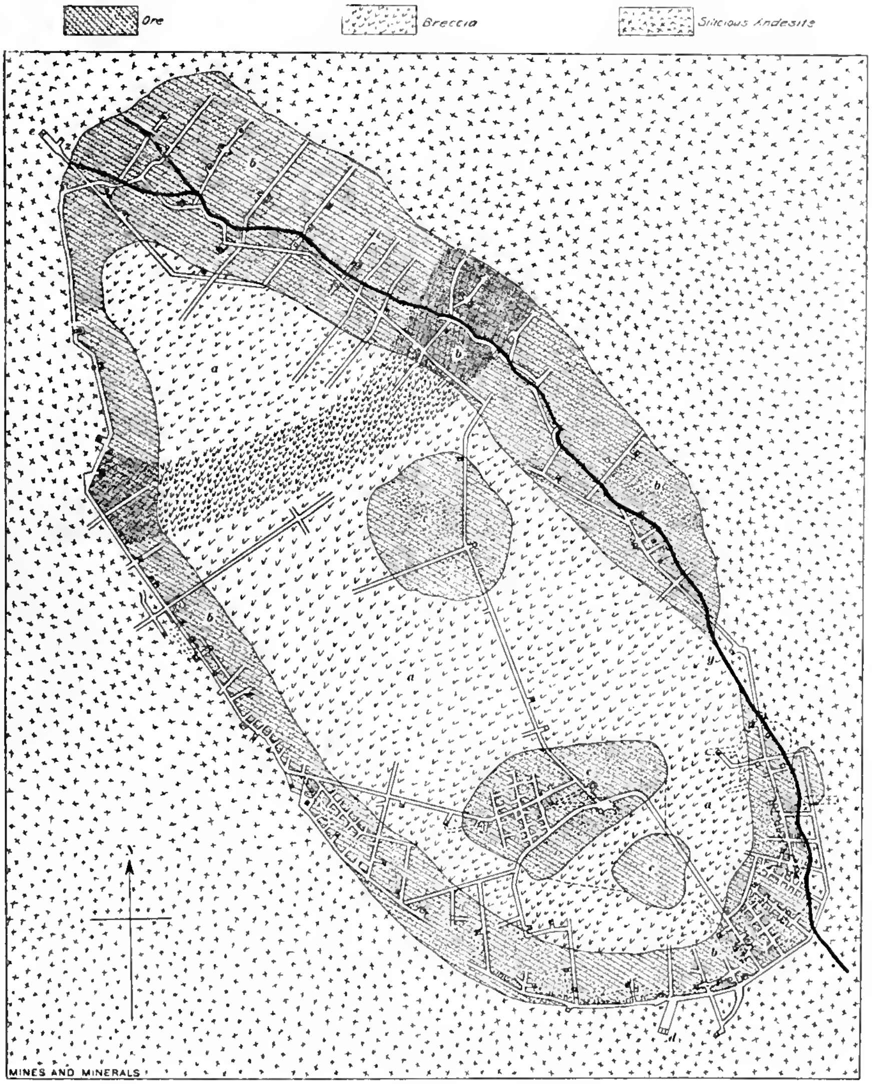

FIG. 4. ORE BODY, LOS PILARES MINE

Levels have been cut approximately every 100 feet from the surface down, with the exception of the adit level, the intervening distance between it and the level above being 70 feet on the Pilares shaft side, and 78 feet on the Y shaft side. Two-, three-, and four-track stations have been cut on all levels, leading from the shaft to the edge of the ore body. From these points, drifting to the east and west along the contact in the ore, as well as cross-cutting through the ore, has been done as indicated by Fig. 4.

The Pilares shaft, being the first sunk, and its stations first cut, it was necessary at the Y shaft to start all levels corresponding to those of the Pilares side and have connections driven from both sides.

In drifting to the west (from the Pilares side) there was found a well-defined regular wall extending northwest for about 500 feet and dipping to the southwest about 10 degrees. At this point, breaks and irregularities in the wall rock were encountered, making it difficult to follow, but at no time causing any uncertainty as to the confines of the ore. From this point, the main drifts were purposely run on lines placed inside the ore a short distance from the wall with cross-cuts driven at intervals (either in the center of a pillar or the center of a stope) to determine the position of the wall. If, by these cross-cuts, it was found that the drift was diverging too much from the wall, it would be turned more toward it. If, on the other hand, the drift encountered the wall, the latter would be followed, if it was well enough defined, if not, the drift would be slightly turned away from it into the ore and the same method followed as before.

On drifting to the right, or east, from the Pilares shaft, the same well-defined wall was found for a distance of 300 feet. At this point the previously mentioned caliche dike was encountered. In the first development of the mine, this dike was followed northwest driving the main drift in the ore and thereby leaving the dike rock as the foot or outside wall. It was very soon demonstrated, however, that this was impracticable and costly, owing to the sloughing tendency of the dike. The sloughing necessitated the timbering of all permanent drifts, and as the dike rock proved to be "heavy ground" the cost of timbering was excessive at this point. After this experience all permanent drifts on this side of the mine were driven away from the dike either in the country rock or else in the breccia below commercial grade to the west of the ore. In some cases

prospecting drifts along the dike, determined the position of the ore and permanent drifts followed later. Sometimes the method used on the opposite side of the mine was resorted to, that is, cross-cuts were driven at certain intervals, to determine the position of the dike, and then the main drift was driven ahead according to results obtained.

Mining Methods.—The width and length of the ore body, the kind of ground found in the deposit, the excessive cost of timber at the mine, and several smaller items, were the considerations which determined the method of ore extraction.

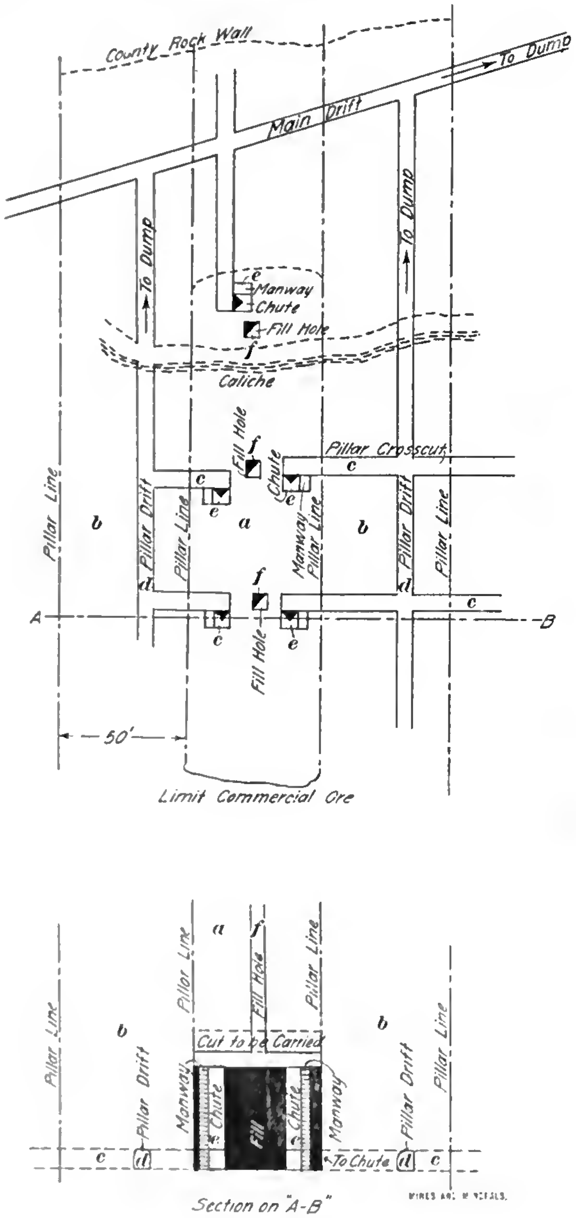

Fig. 5

The pillar-and-stope method is in use throughout the workings The whole deposit, or rather the commercial ore area, is divided up into a series of stopes and pillars, the widths of which vary according to the width of the ore and the character of the ground to be worked.

Pillars and Pillar Lines.—The pillars are bounded by imaginary vertical planes extending from the surface to the bottom of the workable ore. Separate maps like Fig. 4 are kept up to date for each level. On each of these maps, the pillars are accurately plotted, thereby showing the location of every stope and pillar, its dimensions, and also the courses of the several pillar lines.

When a stope is to be "sill-floored," the engineer will set pillar plugs on each side of the stope that calls for a pillar. The position of these plugs will be calculated with reference to their distances from their corresponding pillar lines. The distance from the pillar plugs to the pillar will then be given to the stope boss, and it is his duty to see that the pillar line in question is carried forward and the plugs cared for. For a height of two or three slices, these plugs will be changed by the eye by the stope boss; they will then be checked by the engineer and carried on as before. These pillars vary in width from 25 to 60 feet and are placed approximately at right angles to the country wall. Thus, each stope is bounded on two sides by pillars, while the wall rock on one end and the end of the commercial ore on the other constitute the respective third and fourth sides. When the ore zone is narrow, say from 40 to 100 feet, the above statement applies and the stope will vary from 100 to 150 feet in length along the length of the ore zone, and pillars vary from 25 to 60 feet in length also, measured along the length of the zone, depending on the nature of the ground. When the commercial ore zone is much wider, say 250 feet, the length* of the stope is either lessened and that of the pillar increased, making a stope 50 ft. × 250 ft. and the pillar the same size, or, in case of excessive width of ore, a third pillar is introduced running at right angles to the other two pillars and practically making two stopes between one set of pillars, whereas

Fig. 6. Leveling Waste Filling

if the ore had not been so wide, only one stope would have been excavated.

Sill Flooring.—The stopes may be "sill floored" by two methods. By the first method the entire stope area is cut out on the level floor, while by the second method a floor arch 15 feet thick is left above the floor level, and from the top of this arch the full stope area is carried up. The first method necessitates either a permanent drift in the pillar with cross-cuts running to the stopes and ending in shovelways or chutes, or necessitates the driving of permanent drifts outside the ore with cross-cuts run to chutes or shovelways in the stope; or both classes of drifts may be used for the same stope. The first method of sill flooring is generally used in bodies of high grade ore, or in weak ground. In the second method of sill flooring a permanent drift must be maintained through the stope and for that reason the drift is protected by the floor arch. This is the method used in the case of wide and long stopes, where the main development drift has been driven along the country wall and must be maintained in order to extract the ore. With this second method of sill flooring when the ore is 75 or 100 feet wide, an auxiliary permanent level is driven from the main level through the length of the stope and protected by the floor arch.

Three different methods of stoping are in vogue in this

* In this article the term "length" whether mentioned in connection with stopes or pillars refer to the dimension parallel with the country walls. This is done for the sake of clarity.

mine. First, square setting; second, slicing and continuous filling; and third, slicing and delayed filling.

Square-set timbering and stoping is well known and also but little used here, so it will not be taken up in detail. It is adopted in soft ground that is liable to cave. After extracting the ore and timbering with square sets, permanent levels may be either driven through the pillar or maintained through the center of the stope by lagging over the sets through the center line of the stope. The stope is then filled with waste up to the top floor of the square sets. Chutes and manways are carried up by lining a given timber set all the way up with 3″×12″ plank and dividing it into chute and manway compartments.

Slicing and continuous filling may be used after a stope has been started by either of the two methods of sill flooring. As an illustration of this method with the first sill-flooring system assume a stope *a*, Fig. 5, 50 feet along the ore body and 200 feet wide. Corresponding pillars *b* will also be 50 feet in length. At 50-foot intervals, cross-cuts *c* will be driven into the stope from the pillar drifts *d* on both sides of the stope in question. Working from the ends of these pillar drifts the entire

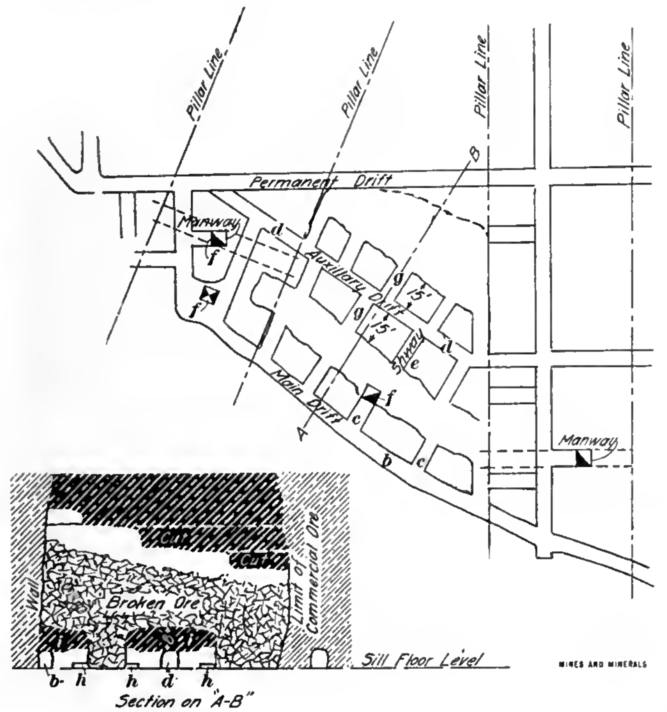

Fig. 7

area of ore within the pillar lines is removed by blasting to a height of 15 feet. This broken ore is trammed over tracks laid through the several cross-cuts from the pillar drifts and by extending temporary tracks from them into the center of the stope. The broken ore is shoveled into cars and taken out via these tracks. After cleaning out all of the ore, the temporary tracks will be removed. Fifteen feet from the pillar *b* inside the stope and adjacent to the extension of the pillar, cross-cuts *c* are built up the chute and manways *e*. This 15 feet of cross-cut is timbered after extracting the ore. The stope will then be filled with waste from the mill holes *f* to within a distance of 5 feet from the roof, the work of leveling off the waste from the different mill holes being done by shoveling and wheelbarrow work as shown in Fig. 6.

These mill holes *f* it will be noted in Fig. 5, are adjacent to the ends of the pillar cross-cuts. It is, therefore, obvious that they are raised to the level above simultaneously with blasting out the first slice. They thus serve not only for dumping down waste for filling, but to ventilate the stope.

Chutes and manways are kept built up sufficiently above the waste packing so as to prevent the filling from running into them. The chutes are generally cribbed with 6″×6″ timbers with a ⅝-inch notch on each end. This leaves a 4¾-inch opening in the crib between each corresponding pair of timbers. Large rock from the packing is built up around the outside of the chute to keep it in place, and the inside is lined with 3″×12″ plank. The manway, usually about 2½ ft. × 6 ft., is carried up along one side of the chute and is built out of 2″×12″ plank. A manway is sometimes deemed unnecessary for a chute, in which case the latter alone is carried through the fill. In the manway, a 2″ × 3″ diameter pipe is placed with its top level with the top of the manway and its bottom about 7 or 8 feet above the floor. This serves the purpose of letting drill steel down without cutting the manway lining and breaking ladders which would result from throwing down the steel. After the filling has been leveled off to its proper height, another slice varying from 6 to 12 feet in height at the breast is blasted from the stope. This slice is started by driving blind raises to the proper height and enlarging these till they intersect, this method enabling the drilling of flat water holes. It is often the

Fig. 8. Unfilled Stope

case that the same slice will be started in three or four different parts of the stope from blind raises. The ore broken in this method of slicing is put into the nearest chutes by shoveling and wheelbarrow tramming. After the slice has been finished, the stope is cleaned of its ore and waste filling is run in again and the same procedure followed as before.

When the ore shoot is narrow, say 30 to 50 feet in width, for quite a length along the country wall, and the ore is of comparatively low grade, the same method of extraction is used, only the main drift is usually protected by a floor arch. This so-called floor arch protecting the drift is shown at *i*, Fig. 7. The main drift is generally run along the country wall or close to it as at *b*. Cross-cuts *c* are driven every 30 or 40 feet at right angles to the main drift in the ore, the two opposite terminal ones being on the pillar lines. If the drift to be maintained is in the ore, then these cross-cuts may be driven at the stated intervals on either side of the drift, generally alternating from the left to the right side. Offset from each cross-cut and set out 8 feet from the center of the main-drift track, a 6′×6′ raise is driven to a height of 22 feet. After raising in each cross-cut the stated height, intermediate drifts

and cross-cuts 7 feet high are run from each raise making the floor of each drift 15 feet above the floor level. These intermediate drifts are connected together and the first floor of the stope is then excavated by enlarging them by blasting both ways till they intersect. All the ore between pillar lines is extracted to the country rock wall in one direction and to the commercial ore limit in the other. Should the ore prove to extend for 20 feet or more in width from the center of the main drift, an 8-foot pillar is left between the main drift and the ore, and an auxiliary drift *d* from the cross-cuts is driven parallel to the main drift. From this auxiliary drift the ore is sliced back, the broken material being trammed out of the various cross-cuts first driven from the main haulage drift. This work leaves a solid arch of rock 8 feet wide on each side and 8 feet thick over the main haulage drift to protect it. When this method is followed chutes are cribbed up from convenient points about 50 feet apart. For such small stopes two manways *f* usually suffice, which are placed adjacent to the two chutes at opposite ends of the stope.

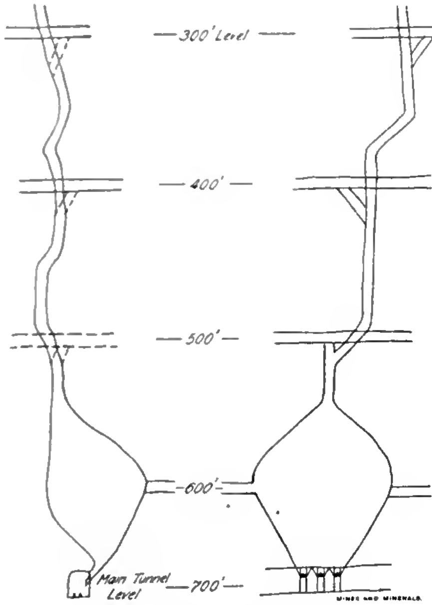

Fig. 9. Sections of Main Ore Bin

After the stope is completed and cleaned of ore, waste is let into the excavation and operations proceed as in the previous case. If the width of the ore is too narrow to admit leaving the ore pillars to protect the drift, it is, of course, obvious that the first system must be followed, after which the drift is timbered and waste filled in over it.

Slicing and Delayed Filling.—Where this method is employed the sill flooring of a stope is practically the same as in the continuous filling method. The ore extracted by this method of stoping has a better grade than that mined by the continuous filling method, and for that reason no chance is taken of mixing it with the waste filling. The ground is also much firmer, allowing a large stoping area without danger of caving and thus losing the stope. At intervals of from 12 to 20 feet cross-cuts from the main drift (which is generally on the wall) are driven into the ore for a distance of 20 feet from the center of the main drift. If the ore body is not wide, these cross-cuts will suffice to draw the broken ore of the stope, as there will not be too much space between the far side of the stope and the end of such a cross-cut which, because of its purpose, is termed a shovelway. If the ore body is wide, as in Fig. 7, an auxiliary drift *d* is driven through the ore at approximately right angles to the pillars and located about two-thirds the distance between the country wall and the limit of the ore. Cross-cuts *g* are then driven at intervals of from 12 to 20 feet from this auxiliary drift to both the left and the right, 15 feet long, and after leaving a 15-foot pillar between the side of the drift and the end of the cross-cuts, the remaining area of the stope is "silled" on the level floor. The pillar thus left forms the base of the floor arch over the drift, and is pierced by the cross-cuts which serve as shovelways. Turn sheets are then placed in the main drift in front of each cross-cut and from 6 feet to 8 feet of track laid in each cross-cut. A platform *h* raised 2 feet above the rails is then placed in the cross-cut at the far end of the track and a flat iron sheet placed on top of it, at the same time raising the roof above the platform about 1 foot. This track arrangement allows the car to be turned into the shovelway, leaving the main track open. The broken ore runs down on to the iron sheet over the platform from which it is shoveled, thus giving the car man an easier task in filling his car.

Fifteen feet above the level floor, the stope is cut out back over each drift, leaving it protected by the pillars and floor arch *i* as seen in the section shown in Fig. 7, but thus acquiring the whole area between the pillars overhead for stoping. From the top of the arch up, the stope is worked by two and three slices being carried forward at the same time. The broken ore accumulates in the stope and only enough is drawn from below through the shovelways to allow the miners to drill by standing on ore. Manways *f* are carried up through the center of the pillars limiting the stope on each side. From one manway 20 feet above the level floor an intermediate cross-cut is driven to the stope and at each succeeding 20 feet similar cross-cuts are driven. From the pillar manway on the other side, the first intermediate cross-cut to the stope is driven 30 feet above the level floor, and others at intervals of 20 feet above it. These manways and their connecting cross-cuts give an inlet and outlet to the stope for every 10 feet. By this method, a stope may be carried up 100 feet, or even 200 or 300 feet, before being drawn and filled. Again a stope may be worked from two or three levels at the same time, each level being driven up till only a thickness of 12 to 15 feet of solid ground separates two stopes. At this point the uppermost stope is drawn through its shovelways, after which the floor arches, etc., protecting the haulage drift are shot down. The solid ground separating the two stopes, one over the other, is then drilled with a large number of holes, say 50 to 60, from the top of the broken ore, the holes heavily loaded and shot down

Fig. 10. Dumping Station, Main Ore Chutes

thus making the two stopes one. By this method all the ore left for floor arches, etc., is eventually recovered except that on the lowest level worked. [From the above description of the slicing and delayed filling system, it will be evident that it differs from the well-known "filled stope" or "shrinkage stoping methods" mainly in its method of protecting a drift in the stope and its elimination of chutes by substituting shovelways for them.—Editor.]

These great stopes may, or may not be filled with waste rock soon after drawing off the ore. When the mine was first

opened they were sometimes left standing empty for months without accident. In recent years, however, the tendency is to fill as soon as possible after drawing the stopes. As illustrative of the standing qualities of the rock, no better example can be cited than that of the old No. 1 stope worked out during the first years of mining. This was located near the Pilares shaft, was 100 ft. × 100 ft. in floor plan and was worked up from the 400-foot level clear to the oxidized capping, a vertical distance of 280 feet. Although the capping was here only 25 to 30 feet thick, the empty stope stood for 18 months without caving before it was filled. Fig. 8 shows the top of a great stope several hundred feet in height about to be filled. The cars of waste are dumped from the track seen in the foreground, the curved-up rails engaging the end wheels and preventing the car from dropping into the stope as it is dumped.

From the above description of the different methods of work at Los Pilares, it will, be realized that the particular method applied at a given point in the mine depends on a number of conditions. The size of the ore body, its richness and the standing qualities of the rock are the main determining factors. The maintenance of ore supply for the mill is another factor of prime importance to be considered. The continuous filling system allows the milling of the ore soon after mining, while the delayed filling system necessitates its accumulation in the stopes for some time.

Filling the Stopes.—In filling stopes mined by the slicing and delayed filling method, fill holes are run direct to the surface over the stope where they are widened out to a size of 12 ft. × 12 ft. On the surface this 12′×12′ hole is then further enlarged to a roughly funnel shape by churning holes from 12 to 30 feet in depth above the edge of the fill hole. These churn drill holes are sprung with dynamite, and shot with black powder, the rock breaking from such shots falling directly into the stope. By having the fill hole of this large size, it is seldom choked with large rock.

In the filling of stopes mined by the slicing and continuous filling system, another method is used. One main fill hole is raised to the surface from a level located 100 to 200 feet above the stopes to be filled. This main fill hole then serves for from three to five stopes or more. From the stopes to be filled, up to the level on which this main fill chute is located, from two to four fill holes are driven for each stope. These fill holes are placed either beneath the center of the track or inclined over to the center from one side. Bearer timbers are laid over these holes and the track run over the bearers. A 5-horsepower electric motor, with a train of 10 cars, of 1 ton capacity pulls the fill rock from the main fill chute to the particular stope and fill hole where waste is called for. In this main fill hole at a distance of 75 to 125 feet below surface (distance varying according to the point of approach or entrance) a grizzly station is cut and a grizzly put in over the fill hole. This grizzly is variable in size, ranging from 8 ft. × 20 ft. to 10 ft. × 10 ft. The mouth of the fill hole is chambered out to a convenient size on a side away from the hole leading to surface. Bearers of 12″×12″ timber spaced about 3 feet apart are placed across this hole. On them are bolted 40-pound rails so as to form openings of 15 inches square. All rock falling on the grizzly must be broken fine enough to pass through these openings. When boulders come down larger than 15 in. × 15 in., they catch on the grizzly and are broken up. This prevents the hole from "hanging up" between this grizzly point and the chute below and also eliminates any trouble at the chute in the loading of the cars.

Ore Transportation.—On the main tunnel level, and located so as to reach all stopes advantageously, six ore pockets or bins similar to the one shown in Fig. 9 have been cut out of the rock within the ore zone, each having a capacity of from 1,000 to 10,000 tons. Each one of these bins is provided with from one to three sets of two chutes each, one set of chutes filling a 30-ton Ingoldsby bottom-dump ore car. Two 10-ton General Electric traction motors running in tandem pull a train of from six to eight of these cars to the main tunnel mouth, Povenir, which is the terminal of the mine railroad. From here a 60-ton Baldwin locomotive takes a train of 14 cars to the concentrator at Nacozari. On each of the succeeding levels above the main tunnel level as far up as the 200-foot level, continuous connections have been made to each ore bin as shown in Fig. 9. With dump stations provided for each bin on each mine level, similar to that shown in Fig. 10, the ore from each working finds its way into the nearest dump. This does away with the hoisting of the ore, a costly item, necessary at most mines.

Compensating Mexican Labor.—It might be said that all work done underground is done by contract. All development work such as sinking, raising, drifting, and cross-cutting, is contracted to the native Mexicans at so much per foot driven; the company furnishing steel, powder, fuse, caps, etc., the contractor only having to keep his working up to regulation size and in some cases running his dirt to the chute. In case of encountering waste in a working, it will be dumped into a fill stope. Prices of the work per foot vary with the kind of rock and also depend on whether the drilling is preformed by machine or hand. In the stopes both machine and hand drills are used, the miner being paid so much per foot drilled with a machine, or so much per foot with hand steel. In the stopes the supervision of the holes is not limited to the number drilled but they must be drilled as "pointed" by the stope boss to the stipulated depth. Car men receive so much per car trammed, the price varying with distance traveled and whether the ore is shoveled from sheet iron, or a rough bottom, or drawn from a chute. In the stopes, shovelers dump wheelbarrows into chutes and are paid by the number of cars drawn from the chutes, which are counted up at the end of the day. As a check, the height of the ore in the chute is taken before starting to work and after finishing; the number of inches in the chute to the car being known. In filling stopes men are given a task of so many wheelbarrow loads per day for a certain wage. All wheelbarrow loads over or under this number are figured and paid for in proportion of the task to the wage. About 1,200 men are usually on the monthly pay roll with an average daily working force of 800 men. From 1,500 to 2,000 tons of ore is sent to the mill daily.

TARIFF ON SAWED TALC

Talc sawed into cubes for use in making gas burners and insulators, the sawing being not merely to remove foreign matter and to put the material in shape for transportation, but to put it into certain desired dimensions, has been advanced in value and condition, and is therefore excluded from paragraphs 519 and 614, tariff act of 1897, relating to crude chalk and to minerals not advanced in value or condition. Talc in the form of cubes, which is used in making gas burners, is dutiable as French chalk by similitude, under paragraph 13, tariff act of 1897. The merchandise was invoiced as crude talc which the importers claimed was entitled to free entry under the following paragraphs:

519. Chalk, crude, not ground, precipitated, or otherwise manufactured.

614. Minerals, crude, or not advanced in value or condition by refining or grinding or by other process of manufacture, not specially provided for in this act.

French chalk, a magnesian silicate, is defined as a variety of talc. The article is imported in the form of cubes, it having been finished by sawing and is chiefly used in gas burners and electric insulation. The sawing of the talc prior to its importation is not merely to remove foreign matter and to put in shape for transportation, as there is a demand in the trade for "finished pieces" of certain dimensions, and the material is ordered by the importer accordingly. Such sawing of the talc advances its value and condition.

THE SUPERIOR AND BOSTON MINE

Written for Mines and Minerals, by R. L. Herrick

System of Mining and Pump Arrangement at McGaw Shaft, Globe, Arizona

Among the newer mines of the Globe, Ariz., district, whose engineering features most impress the visiting engineer, is the Superior and Boston. It is located about 4 miles to the east of Globe, a short distance beyond the little mining settlement of Copper Hill. The accompanying illustration, Fig. 1, shows the main hoisting shaft of the property, the "McGaw," at the right, with shaft and smelter of its neighbor, the Arizona Commercial, at the left. Nearly all of the surface equipment of both mines showing in the view has been installed during the past year. Up to March, 1908, the property had been worked in a somewhat desultory fashion, but never adequately prospected. At that time, the property was examined by Frank H. Probert, of Los Angeles, and, based upon his report, a vigorous campaign of development was inaugurated, Mr. Probert being retained as consulting engineer.

With a comparatively small amount of work, the upper levels of the mine were quickly made to produce a considerable tonnage of oxidized ores while development at depth proceeded, and at this writing there is every prospect that large bodies of sulphide ores will soon be developed in the enriched zone. The present production of oxides is about 80 to 100 tons daily, assaying on the average of 6 to 8 per cent. copper or better. Satisfied with the future prospect of a heavy production of sulphides, however, the beginning of the year 1909 saw the start of installing a surface equipment, and a remodeling of the underground facilities which today make the property one of the "show mines" of the Southwest.

Mining Notes.—The McGaw shaft, shown in Fig. 1, is the main hoisting shaft of the property from which a drift on the 400-foot level connects with the old prospecting shaft, the "Great Eastern." Its depth is at this writing 640 feet, with sinking still progressing. As water enters the shaft at the rate of 350 gallons per minute, considerable difficulty was experienced at first in firing the shots, owing to the occasional soaking through of the best makes of waterproof fuse. After considerable experimenting, the difficulty was eliminated as follows:

The fuses to be used for a given round were cut to the required length, their caps crimped on, and the junction of fuse and cap protected by covering with the well-known rubber protectors. The whole length of fuse and cap was then dipped in liquid asphaltum and hung up to drip and dry. When dry in a few hours time the asphaltum forms a thin elastic layer, making the fuse perfectly waterproof. There have been no failures reported of fuse protected in this way.

The present mine production is made mainly from the stopes of the 550-foot level. Here the vein dips about 58 degrees and varies in thickness from 7 to 15 feet, but averages from 9 to 10 feet. The foot-wall is hard and smooth, but on the hanging wall the ore is "frozen" and there is no defined wall. These conditions are mentioned because of their bearing upon the novel method of mining, devised by Superintendent John D. Wanviz.

Until recently the ore has been mined by the common square-set system, but in the few months since the first trial of the new system, both the timber and labor, not to mention loss of ore fines, have been so materially reduced, with a consequent reduction in costs, that the new system may be fairly pronounced a success.

System of Mining.—Reference to the accompanying Fig. 2 will make clear the following data:

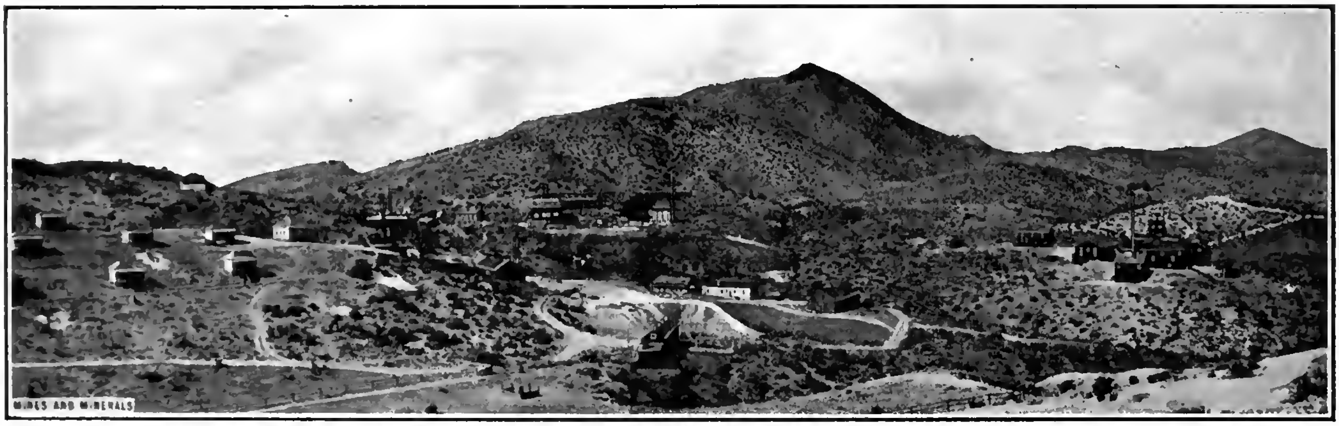

Fig. 1. Superior and Boston Mine, Globe, Arizona

Drifts 5 ft. × 5 ft. are carried 100 feet apart vertically or about 117 feet along the 58-degree dip of the vein.

Two-compartment raises are put up at 100-foot intervals to connect the drifts; the chute compartment is 4 ft. × 4 ft., and the ladderway 2½ ft. × 4 ft. These raises are on the foot-wall and are timbered only by two lines of stulls with head-boards and one set of lagging.

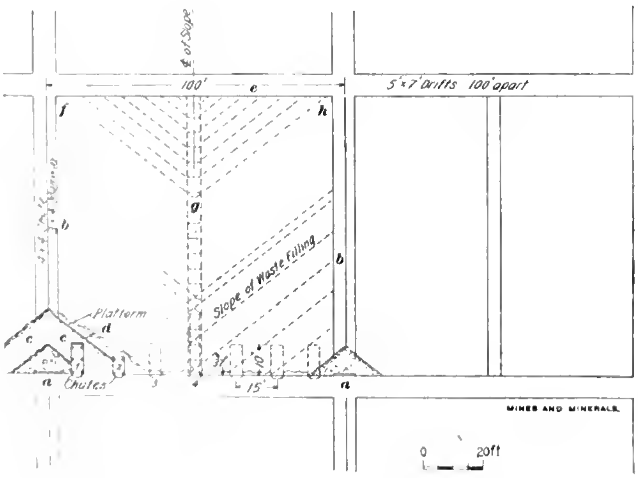

Fig. 2. Method of Stoping. Section Parallel to Dip of Vein

The division between the two compartments is formed by the first line of stulls which is plank lagged. The second line of stulls is carried on the other side of the ladderway compartment, but this is unlagged. The outer wall of the chute is thus constituted by a rock wall unstulled and unlagged and the outer wall of the ladderway is likewise constituted by a rock wall, but this is stulled. The main drifts are all timbered with drift sets spaced on 5-foot

centers and heavily lagged. Chutes 4-feet wide are spaced on 15-foot centers, the chute gates all being placed at once, but the chutes themselves are put up one by one as stoping proceeds above. The chute mouths afford one of the ways of access to a stope as it progresses, since there is always an irregular space 1 to 3 feet high between the ore back and the top of the drift lagging.

Stoping is started at the lower corners of two adjacent blocks formed by the intersection of a raise with a drift, such as *a*, Fig. 2. These two blocks are simultaneously stoped up along the raise and retreating from it horizontally as shown. At such a corner the back is drilled with stoping drills and broken down on to the drift lagging for a distance of 8 to 10 feet. The broken ore is at first discharged into mine cars standing in the drift below by pulling out the lagging and letting it run down.

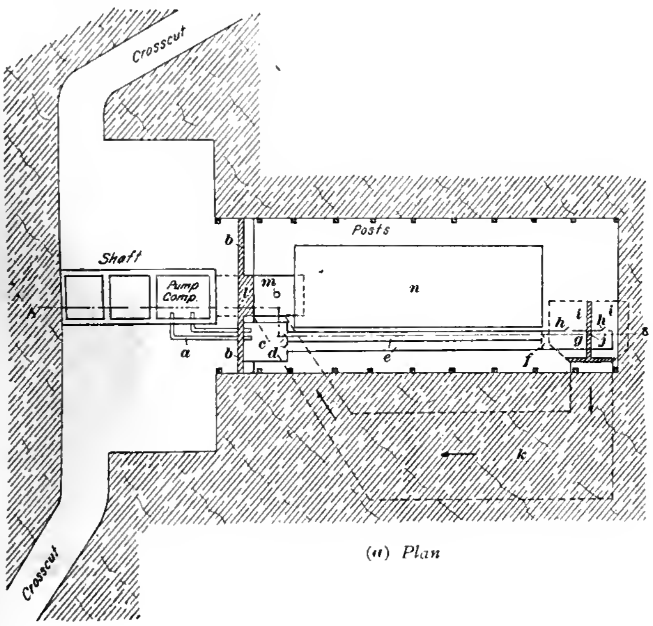
The first chute *1*, Fig. 2, is then placed. This chute is formed by carrying up two lines of stulls 4 feet apart along the strike of the vein and lagging them on the outside with plank.

Fig. 2 shows the stulls inside the plank lagging instead of outside, as in ordinary practice. The reason for this is found in the fact that when the chutes are abandoned they are not filled with waste, so that empty they have to stand the pressure of the waste filling on all sides of them.

The entire width of vein from foot to hanging wall is broken out between the rows of stulls. With the first chutes in place, the timber in the lower part of the raise *b*, is taken out and waste *c* for filling dumped down the chute from the drift above. This waste assumes a natural slope of about 37 degrees from the horizontal, and it accordingly spreads out from the foot of the raise into the stopes on each side of it at that angle, running farther and farther horizontally into the stopes as they are advanced and the pile of waste increases in height. In the first stage of the work, however, advancing toward chute No. 1, the waste is dumped down till the foot of its slope almost reaches the chute. Dumping waste then ceases for the time being. With the sloping floor of the waste now brought within 5 to 7 feet of the ore back, a sloping wooden floor *d* is laid down on top of the waste extending from the top of the chute to the manway of the raise. Its purpose is to receive the ore broken from the back and discharge it into the chute, thus serving the double purpose of separating the ore from the waste and eliminating all shoveling and tramming in the slope. It will be evident that since the waste will run at an angle of 37 degrees, the ore will certainly run on the wooden planks which are laid over the waste on the same angle.

The width of the plank floor *d* is everywhere made that of the vein from wall to wall, and its length, of course, increases up to a maximum of about 60 feet in extending from the center chute of the block up to the raises on either side of it. The floor consists of 2-inch plank in 15-foot lengths nailed together by cross-pieces to form sections about 2 feet wide. In laying down these sections over the waste, the ends are made to form a butt joint; i. e., the end of an upper section butts directly against the end of a lower section, to insure a clean run-off of the ore. With the floor laid down, the stope drills are put at work to break down the new back, stulls and planks being placed where necessary to afford a good secure footing next to the back. When drilling operations are completed, the stulls are pulled, thus recovering them for further use. The chute at the foot of the sloping floor is always kept nearly full of ore so that wear upon it may be kept at a minimum. After drilling and shooting the back, the ore is at once drawn down to the top of the chute, thus clearing the floor. A number of stulls are next put in as close to the back as possible and the sections of the platform are then raised and one of each placed see-saw fashion over the stulls so that the weight of a larger end of a given section causes the smaller end to press up against the ore back and thus be firmly held. With the platform sections thus disposed conveniently at hand for their next period of use, the top of the chute is now built up and more waste dumped down the raise till the foot of its slope has nearly reached the level of the chute top. The laying of the floor and the mining of another diagonal slice now proceeds as before.

An inspection of Fig. 2 will now make evident the fact that a given chute can be used at the foot of the sloping platform only till the angle of slope carries down the ore in line with the center of its top. After that the top is lagged over, the chute emptied of its ore, but not filled with waste, and it is abandoned. Fig. 2 shows chute No. 1 just abandoned and buried in waste with the use of chute No. 2 just begun. The illustration also makes it evident that of the seven chutes raised in a 100-foot block, all but the one in the center are limited to a height of about 10 feet, as at that height the angle of waste slope carries the flow past to the bottom of the next adjacent chute, which is likewise built up. By working from the two opposite lower corners of the block simultaneously, and thus advancing the diagonal slices toward the center line of the block, they finally intersect at the bottom of the centrally placed chute No. 4. From this point on, chute No. 4 receives all the



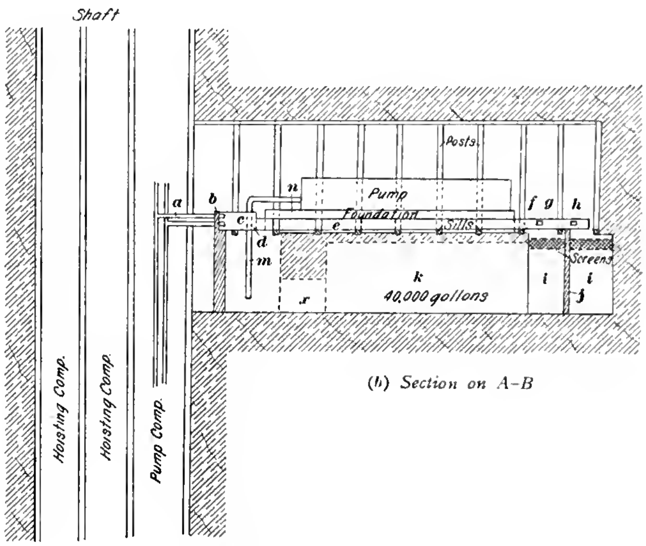


FIG. 3. ARRANGEMENTS OF SUMP AT SUPERIOR AND BOSTON MINE

ore of the block. It is built up from time to time just as the other chutes were, with the exception that it is more heavily and completely lagged by placing 2-inch lagging outside the stulls and 4-inch plank lagging inside the stulls which bear the wear of the chutes. Its height, as shown in dotted lines, is limited only by the floor of the drift *e* above. It will likewise be evident from the illustration that when the top of the waste filling has reached the approximate position of the dotted line *f*, *g*, *h*, the drift *e* must be abandoned for through traffic, or its floor supported on stulls. From this point on, the raises cannot be utilized for throwing down filling, so that waste is dumped from points along the drift itself advancing toward the center line of the block till the central chute reaches the drift and the block is entirely mined and filled.

During the mining of the lower portion of the block, access is had to the stope from the manways of the raises or from the chute mouths in the lower drift roof. After the diagonal slices have connected at the central chute, No. 4, however, access is had only from the drift *e* above by descending through the raise manways into the stope. No objection to this limitation of accessibility has yet been found in several months of work.

this is the case it is doubtful if the cost of timber in the Superior and Boston mining method much exceeds, if at all, that in the "shrinkage method."

Compared with the recently abandoned method of square-set mining, the total costs thus far are hardly more than one-third that of the square-set method.

Pumping Arrangements.—As the lower levels of the mine are developed, the quantity of water pumped is expected to increase above the 350 gallons per minute now handled. The pumping plant recently installed, therefore, was designed for future as well as present needs. The main pump station is on the sixth, or 550-foot level. The shaft at this writing is 90 feet below, and from it two sinking pumps lift water to the main-pump sump through 6-inch diameter pipes. The sinking pumps are of the Prescott duplex type, size 14 in. × 8 in. × 12 in.

In the design of the main station sump, several novel features were embodied which are detailed below. Reference to the accompanying illustration, Fig. 3, will make the situation clear.

In excavating this station sump, instead of the procedure commonly followed; i. e., sinking a short winze and blasting out

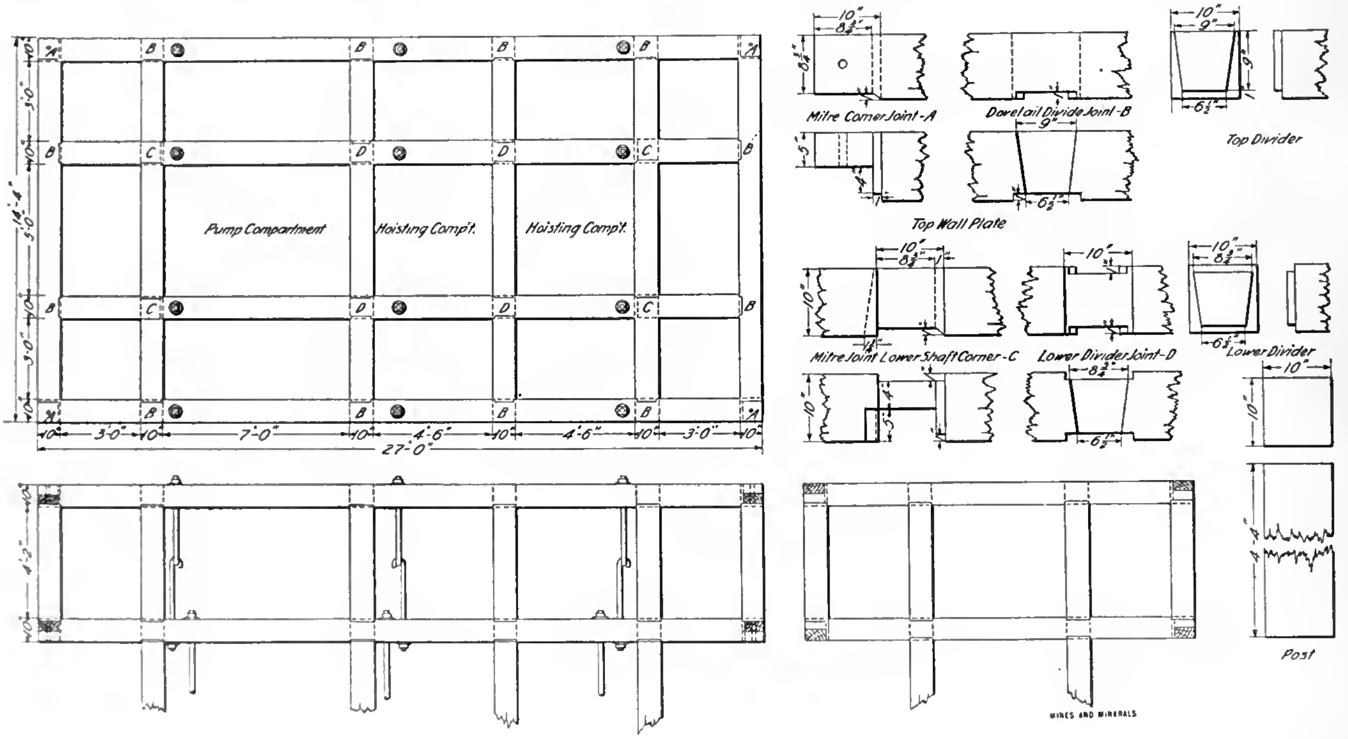

Fig. 4. Collar Set

If found desirable, however, the floor on one side or the other could always be kept down and over it the men could pass in and out to avoid danger of starting the loose waste.

From what has been previously said concerning the loose nature of the hanging wall, it will be evident that working the mine by a "filled stope" method, perhaps better known as "shrinkage stoping," would be inadvisable, because caves from the hanging wall would seriously dilute the ore with waste.

The system adopted, as described above, therefore, seems the next best method of reducing the use of timber to a minimum, eliminating tramming and shoveling in stopes, and recovering all the fine ore. The system has the advantage over "shrinkage stoping" of making all the ore broken available at once instead of only about 25 to 40 per cent. until such time as the stope is finished. Another advantage over "shrinkage stoping" is that the drift timber sets and chutes once placed require no reinforcement during the drawing of ore as is frequently the case in drawing a stope completed by the shrinkage method. Where

a sump from its bottom, the work was started from the main shaft itself. The pump station was cut out as shown in the plan Fig. 3, and the sump then started by drifting in beneath the station at a point two shaft sets below the station level.

This drift was cut out 10 feet high by 5 feet wide for a distance in of 12 feet. The height was then reduced to 4 feet, as seen in the sectional view (*b*) at *x*, and the direction turned 45 degrees, running it well to the side of the pump station, as best seen in the plan. The sump *k* was then excavated about 10 feet wide, 30 feet long, and 8 feet high, till opposite the end of the pump station, when a right-angle turn carried it again beneath the station floor, which was broken through, as shown in the plan. All of the rock excavated in this work was trammed directly to the shaft via drift *x* and dumped via a chute into a bucket run in the pipes compartment. In this way the usual hoisting by windlass at the top of the winze, as is commonly done, was entirely eliminated, so that the work proceeded more quickly and much more cheaply than ordi-

narily. With the excavation completed, a concrete dam l, Fig. 3, 3 feet thick, sealed the drift next the shaft. The dam was pierced only by a 4-inch diameter drain pipe set close to the floor and controlled by the usual valve. At the level of the station a concrete dam b was built from wall to wall of the pump station for a height of 2 feet above its rock floor in order to give additional storage capacity if ever needed in emergencies. This dam raised the floor of the pump station 2 feet above the floor of the shaft station. Another concrete dam and dividing wall j was built as shown at the rear of the sump, beneath the station floor, thus separating the main sump k from the main settling box i. At the top of the concrete wall j were placed the 8-mesh screens, best shown in the sectional view, Fig. 3. Then followed the construction of the plank receiving box c, and the double-compartment flume e, connecting with the settling box i.

In building the flume, its bottom was purposely laid on the rock floor just beneath the 12″×12″ transverse timber sills, so that the latter would form riffles for the flume. The heavy floor planks were then laid flush with the top of the concrete dam and over the flume and connecting boxes.

The course of the water will now be apparent. Arriving at the station level from the sinking pumps via the pipes a which pierce the concrete dam b, the water flows into the receiving box c. Vertically sliding gates d direct it into one compartment of the flume e. Here the riffles formed by the floor sills cause the coarse material to settle out at once while the finer silt finds its way into the main settling box i. By providing two compartments, both in the latter and in the flume, a given compartment may be cleaned while the other is running. The fine silt settles in box i, while the screens at the top of the wall j, over which the water flows, prevent chips, candle snuffs, etc., from going into the main sump k. The suction pipe of the pump condenser draws from the sump just beyond the screens, and its hot discharge returns to the sump at its further end just beneath the receiving box c. The pump suction pipe m draws from the sump close to the foot of the concrete pump foundation n. The aim of this unusual sump is to settle out all silt from the water and thus reduce wear on the pump valves, packings, etc., to a minimum. The advantage of getting the silt to settle in the riffled flume and settling box where it may be readily cleaned out, instead of in the inaccessible sump, is apparent.

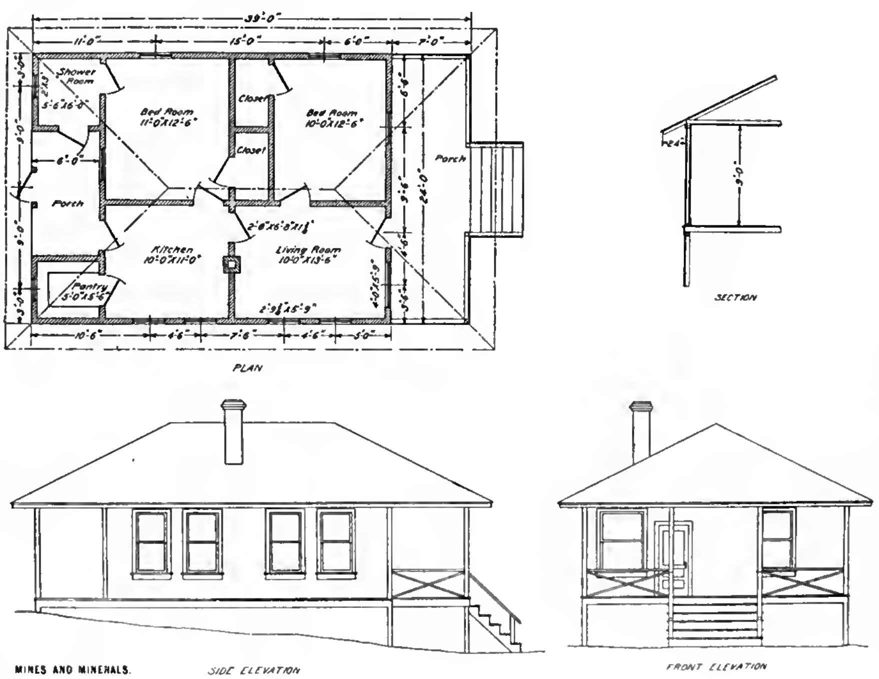

FIG. 5. MINER'S HOUSE

The main pump is a Prescott duplex, triple-expansion, condensing machine of the pot-valve type, size 16 inches and 25 inches and 42″×10½″×24″ stroke. Its capacity is 1,000 gallons per minute for a 1,000-foot lift. The column pipe is 12 inches in diameter, and between the pump and the pipe elbow at the shaft is set an expansion joint. The purpose of the latter is the absorption of the shocks and vibrations of the pipe due to the striking of the elbow by the water. These shocks, it is claimed, are apt to eventually cause the breaking of the elbow, thus seriously delaying pumping from the sump, as several mines in the Southwest can testify.

Before leaving this subject of pumping it may be of interest to call attention to a certain feature of the shaft construction which greatly facilitates the lowering of the heavy and bulky pump parts. This feature is the collar set of shaft timbers which is illustrated in the accompanying Fig. 4. While by no means new, the use of the collar set is not general and hence details concerning it may be of interest. The construction and framing of the timbers are plainly detailed in the illustration. It will, of course, be understood that from a constructive standpoint, the collar set takes the place of bearing timbers at the shaft collar, but gives considerably more rigidity to the shaft than bearers could. It remains only to remark upon the convenience the set affords. In lowering the heavy pump machinery it is of vital importance to get it properly centered at the start in order to avoid its being jammed between the timbers a short distance below. This centering is easily and quickly accomplished where a collar set allows a ready access to three sides of the compartment and an unhindered observation of the machinery from a roomy safe vantage point. The quick and easy repair of the shaft chairs at all times through such accessibility, whether hoisting is in progress or not, is likewise an obvious advantage.

Surface Equipment.—With the idea of considerably increasing the mine production, the hoisting, and indeed the entire surface equipment, has been designed for the future, rather than for the present output of 100 tons daily.

The boiler plant comprises two batteries of two units each, a unit consisting of an oil-burning Stirling boiler, water-tube type, of 250 nominal horsepower. There is a Cochran feedwater heater from which the boilers are fed by a duplicate set of Snow duplex pumps. The oil burners are of the Hammel type, to which the fuel is pumped by a duplicate set of Moore fuel-oil pumps.

Thus far the ore is hoisted in cars by cages, the hoisting being balanced, two of the shaft compartments serving this purpose. The hoist is a Nordberg, reversibly geared, duplex, size 14″ and 14″×28″. The two drums have a 7-foot diameter with a 36-inch face. This machine embodies some new features of design over the ordinary Nordberg type and is the only one of its kind thus far installed in the Southwest. The main new feature is the placing of both drums at one side of both the steam cylinders, an arrangement which has obvious construction advantages.

Compressed air is supplied by a Nordberg machine compressing to 90 pounds, and having a capacity of 1,200 feet of free air per minute. The compressor is of the two-stage, cross-

compound, Corliss valve type, with steam cylinders 13 inches and 24 inches and air cylinders 21 inches, and 12¾″×36″ stroke. It has two 300-square-foot surface condensers, and an attached 10″×12″ air pump.

Pipes and machinery in the pump compartment are handled independently of the cage hoist by another small hoist, provided for the purpose. It is noteworthy that for convenience all of the surface buildings are grouped about the shaft within a short distance of it and nearly inclosing it in a hollow square.

Besides machine and carpenter shops, comfortable change quarters with lockers, shower baths, etc., are provided for the men, all within 100 feet of the shaft. The greater danger of fire to all the buildings of such a group is anticipated by providing an ample number of fire hydrants conveniently disposed.

The Superior and Boston Co. has prepared for the comfortable housing of its married men by providing a number of model frame cottages. As the design is one which may appeal to others it is herewith reproduced in Fig. 5.

In the short time since active development was started on the property, under the supervision of Frank H. Probert, as consulting engineer, and the management of Superintendent John D. Wanviz, record progress has been made upon which the company is to be congratulated. The mine itself is expected by the writer to develop into a large producer of the Old Dominion class in a few years more, and as for its equipment, the visitor to the district is advised by the foregoing notes to actually inspect it for himself.

METAL MINING NEWS

Exports of manufactures in the fiscal year ending June 30 exceed those of any earlier year and imports of manufacturer's materials in 1910 were also the largest on record.

The statement issued by the Department of Commerce and Labor shows that 22 out of 50 of the principal articles of export are derived from our mineral resources. They are in the order of their relative importance to all exports in millions of dollars as follows:

Relative Importance	Article Exported	1909 Millions	1910 Millions
2	Copper metal	82.0	83.6
3	Illuminating oil	71.8	62.5
34	Paraffin	6.4	7.9
45	Crude oil	6.9	5.3
12	Lubricating oil	18.3	20.9
10	Bituminous coal	23.0	25.9
18	Anthracite coal	14.3	14.6
24	Rails	6.9	10.5
27	Pipes and fittings	8.0	9.6
32	Wire	7.3	8.4
38	Tools	5.9	6.7
43	Structural iron and steel	5.1	5.8
6	Mowers and reapers	14.1	11.1
30	Fertilizers	9.3	8.7
31	Electrical devices	6.1	8.7
36	Sewing machines	5.9	7.5
39	Locks, hinges, etc.	5.5	6.6
37	Typewriters	6.9	7.2
40	Electrical machinery	6.4	6.0
41	Metal-working machinery	3.6	6.0
44	Locomotives	3.5	2.4
50	Railway cars	3.5	2.2

To this is to be added the excess exports of gold and silver over imports which are for the fiscal year ending June 30, 1910, $75,273,310 in gold and $10,106,687 in silver. In the fiscal year ending June 30, 1909, the gold exports amounted to $92,527,574 in excess of imports. While the balance of trade is in favor of the United States on raw materials and manufactured articles, the exports of gold are made regularly to pay the expenses of American royalty, travelers, and expatriates. The interest on American securities held abroad is paid in part in gold but largely by bills of exchange.

Platinum in the form of sperrylite, a diarsenide, has been found in an abandoned copper-mine dump near Stobie Falls, Vermilion River district, Canada.

The Middlesbrough Steel Strip and Hoop Co., Ltd., is interested in a project for the establishment of an iron and steel plant, including blast furnaces and rolling mills, on Vancouver Island, near Victoria, British Columbia. The plant is to be placed close to deposits of magnetite at San Juan and Harris Creek, 60 miles northwest of Victoria. A sum of $110,000 has already been spent in preliminary development work at San Juan, and there is now a shaft 300 feet down with cross-cuts at 100-foot, 200-foot, and 300-foot levels. High-grade magnetite has been found at the 100-foot level, and the deposits are considered to be the largest workable on the Pacific Slope.

The Giroux Consolidated Mines is working 200 men, and appliances with machinery for development are now at the five-compartment Alpha shaft. It is said that ex-Senator W. A. Clark is interested and will extend the Clark San Pedro Railroad into the district through the Deep Creek country.

The control of the Giroux Consolidated lies in the Cole-Ryan syndicate, who also control the International Smelting and Refining Co., and the smelter of that company just completed at New Tooele. The ore from the Alpha shaft is direct smelting and not concentrating.

The Ely-Central Mining Co. is sinking two shafts, the Eureka and Clipper, from which cross-cuts are to be driven to the porphyry deposit supposed to be outside the boundary lines of the Nevada Consolidated. There is considerable confidence displayed in the outcome of this venture, for machinery has arrived to put the mines on a shipping basis. These mines it is also supposed will ship over the proposed Clark railroad.

To increase the daily capacity above its present 8,000 tons output, the Nevada Consolidated is having a few large locomotives constructed. Seven trains of 21 cars, each car carrying 55 tons of ore go daily to the concentrating mill at McGill. The smelter capacity is not equal to the quantity of concentrate made at this mill. This property is controlled by the Guggenheims, through their control of the American Smelting and Refining Co. It is stated that in May the Nevada Consolidated produced copper at a cost of 5.95 cents per pound. If so, this is a world-breaking record in low copper costs and was made in the face of the fact that only seven-eighths of the plant was in operation during the month of May. Had the plants operated full, production for the month would have exceeded a rate of more than 80,000,000 pounds a year.

It is reported that the South Utah Copper Co., the relict of the Newhouse mines and smelters, is to ship its product to the International Smelting Co. Previous to the break-down there was a contract between the American Smelting Co. and the Newhouse mines. It is assumed that the reorganization of the old company cancelled this contract.

The annual imports of iron ore into South Wales exceed 1,500,000 tons, of which Cardiff in 1909 received 662,000 tons. This ore, 50 per cent. in iron, comes from Spain and averages $5.10 per ton. The total output of iron and steel in South Wales is 900,000 tons per annum. The local demand for this iron and steel is for tin plates and galvanized sheets, of which South Wales is the leading district in the United Kingdom. Mainly owing to the great growth in the demand for oil cans, the tin-plate industry has not only suffered no reaction after the great boom of 1907, but has steadily increased in prosperity. Shipments from South Wales ports in 1909 were 375,969 tons, and during the first 5 months of 1910 there was an increase of 25,000 tons over the same period of 1909. Mills and machinery are working full time, additional mills are in course of erection, and workingmen have steady work at high wages.

The tin-ore deposits in the Malay Peninsula are virtually in the hands of an English proprietary company which precludes others from the right to mine, or, if they mine, to export or smelt at a profit. The United States buys their tin, coats oil cans with it, fills the cans and sells the whole thing to the natives. Reports say the natives use the empty oil cans for almost every conceivable purpose.

NEW MEXICO GOLD GRAVELS

*Written for Mines and Minerals, by J. A. Carruth**

The Rio Grande del Norte (Great River of the North) rises in the mountains that surround the San Luis Park, in Southern Colorado. This park lies at an elevation of from 7,500 to 8,000 feet. Its southern extension is in New Mexico, where it is known as the Taos Valley. On the east the main range of the Rocky Mountains rises abruptly many thousand feet, while further away from the river, on the west, lie the also high mountains of the Continental Divide. The San Luis Park and the Taos Valley are great level appearing plains between these ranges. In the San Luis Park the Rio Grande runs almost on the level of the country, having hardly any banks at all, but a few miles north of the New Mexico line it commences to cut into the sand and gravel of which the park is composed, and in a few miles it is several hundred feet below the level of the country, in a narrow gorge, usually from a half mile to a mile wide, and varying in depth from about 600 feet at the New Mexico line to over 1,000 feet in the White Rock cañon, 100 miles further south. Standing on the level plain in the Taos Valley there is no sign of a river, but moving ahead a short distance you come to a cañon 800 feet almost perpendicular, and the Rio Grande at the bottom looking like a little creek. From a higher point of ground the river can be seen as a black streak through the level plain for a distance of 60 miles. The most of the ground that has been washed out was gravel, though in the northern part of the valley there is considerable lava mixed with the gravel.

Deposits of Gold-Bearing Material of Great Depth and Extent, With Values Evenly Distributed

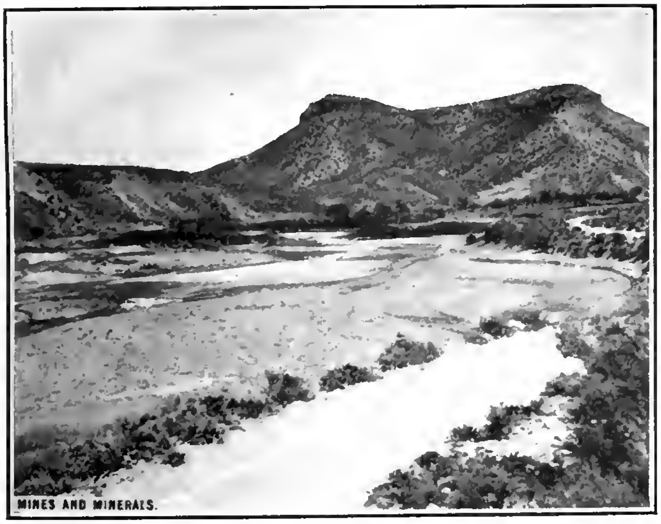

Fig. 1. Bluff near Cieneguilla

Fig. 2. View Looking Down Stream from Bluff

Commencing a little above the entrance of the Rio Colorado, or Red River, into the Rio Grande from the main range on the east, about 20 miles south of the Colorado line, these gravels are found to carry gold. The Red River heads in a highly mineralized section, and going south, in succession, are found the San Cristobal, Rio Hondo, Taos and Embudo rivers, all emptying into the Rio Grande from the east, and all carrying auriferous gravel. The western banks of the Rio Grande are not as rich in gold as those on the eastern side of the river.

In the early 80's Governor Norton, of Nebraska, and parties interested with him, secured the services of the late Prof. Benjamin Silliman, of Yale University and secretary of the American Association for the Advancement of Science, to examine and report on the section of land between the Red River on the north and Embudo Creek on the south, a distance of 40 miles. Professor Silliman spent 3 or 4 months in this examination, and his report, comprising over 40 typewritten pages, is very full and explicit. Extracts taken from it, give better ideas of the country, and its richness than can be had from other sources. After a little preliminary matter Professor Silliman says:

"Here are millions of tons of gold quartz reduced by the great forces of nature to a condition ready for the application of the hydraulic mining process, while the entire bed of the Rio Grande for over 40 miles is a sluice, on the bars of which the gold derived from the wearing away of the gravel banks has been accumulating for ages and now lies ready for extraction by the most approved methods of river mining.

"The thickness of the Rio Grande gold gravels exceeds in many places 600 feet, or nearly three times that of similar beds in California, while the average value per cubic yard is believed to be greater than in any other accumulations yet discovered. Only those portions of this area, however, which are within reach of the waters of the Rio Grande, and its affluents, are at present available.

"The area demanding our attention is confined chiefly to the valley of the Rio Grande from a point near the entrance of Embudo Creek from the east, about 45 miles north of Santa Fe, and following the course of the river for about 40 miles. The whole of this area contains vast accumulations of auriferous gravel, not less where I have measured it than 600 feet in thickness in many places. I have made a reconnaissance of the whole of this ground along the Rio Grande, and have examined with all the care possible in the time at command the character of the gravel and its content of gold, also, to some extent, the source from whence it has been derived, its geological peculiarities and its relations to water as the means by which it may be worked to advantage. Nothing, I am persuaded, since the discovery of California and Australia is comparable for its measurable reserves of gold available by the hydraulic process to these deep placers of the Rio Grande.

"I distinguish two chief varieties of gravel in these Rio Grande beds. First, that which may probably be called the gray or blue gravel, and second, the yellow gravel. The first is coarser than the latter and as a rule carries more gold than the second variety. A place of convenient access where these two distinguishing varieties of gravel may be seen is at Cieneguilla, about 54 miles from Santa Fe. At this point is a bold cliff of gravel surmounted with a cap of mal pais, on the face of which the strata of these two varieties of gravel are seen in the alter-

*Santa Fe, New Mexico.

nate beds. The cap of volcanic rock is about 30 feet thick, and the first bed of blue gravel beneath it, which contains abundant free gold, rests unconformably on the lower strata, which have been tilted up from the east to an angle of 10 or 15 degrees from the horizontal and curved at the same time. The yellow gravel here gives 8 or 10 colors to the pan, while

FIG. 3. VIEW LOOKING DOWN CAÑON

the blue is worth probably 50 or 75 cents per cubic yard. A photographic view of this remarkable cliff, which is approximately 600 feet high, would be highly instructive.

"One searches in vain for the light gravel, poor in gold, which forms the top dirt, for example, at the Malakoff shaft in the North Bloomfield gravel beds, in Nevada County, Cal., but the great mass of these heavy beds are compact auriferous gravel, and contain boulders of quartzite, with blue or gray stains and seams of magnetic iron and rusty quartz, with comparatively few granite or syenite pebbles, and fewer of porphyry or greenstone, and no volcanic debris or ashes. I estimate that the quartz and quartzite pebbles form at least 60 per cent. of the gravel in these beds.

"The vitally important question of the value of the gravel has received the careful consideration of a considerable number of good prospectors and miners accustomed to judge of the value of auriferous gravel. You have their written statements and opinions all agreeing as to the main fact that this auriferous gravel is unusually rich. They differ only as between 50 and 75 cents to the cubic yard, with examples of very much higher values than this. The average yield of these gravels as far as known is 50 cents per yard. The gold in these alluviums is diffused with remarkable uniformity so far as observed. It is bright, but not so thin and worn as in most of the California gravels. Much of it is, in fact, angular and rough, like quartz gold."

Fig. 1 is a view of the bluff mentioned by Professor Silliman. The dredging ground and river show in the foreground. The river flows on the left of the bluff and on the right is a deep arroyo The bluff is 900 feet to the surface, which is the level of the surrounding country. Both the bluff and the low bluffs on the left carry gold in good paying quantities.

Fig. 2 is a view taken part way up the bluff shown in No. 1, but is looking down the stream All on the right is gravel, but the cliffs on the left are 1,400 feet high and are quartz.

Fig. 3 is a view looking down the river cañon from the level of the country, or mesa, 900 feet above the river, on the west side. Indistinctly seen over the level mesa on the east side at the left of the view, is the main range of the Rocky Mountains, some 40 miles away The bluffs on the right are some of the foot-hills.

Fig. 4 is a view of an old channel of the river, about 300 feet above its present channel. It can be traced for a couple of miles.

Some years after Professor Silliman made his report, Cecil A. Deane, a Denver mining man spent an entire summer going over these gravel beds. His report, like Professor Silliman's, is too long for print in full, so extracts are given:

"At some remote period a vast overflow of lava, coming from the northwest, spread over thousands of square miles in this region, and is of unknown thickness. The Rio Grande has forced a channel through the basalt, and the bed of this stream is now hundreds of feet below the level of the adjacent plateaus. It is stated that in a distance of more than 100 miles there are but three places where the river can be crossed with wagons. From the east the Taos flows through a like cañon for about 8 miles, where it joins the Rio Grande. Not only over the great area between these two streams, but extending to the south and east of the Taos, and from the Red River on the north to the Arroyo Hondo on the south, a region embracing hundreds of miles in area, and resting largely on the nearly level surface of the lava, are found the largest now known deposits of auriferous gravel. The causes which produced such vast accumulations are not definitely known; for while the deposits plainly show evidence of attrition due to the force of water currents, they are in depth and width so great as to preclude the idea that such are wholly due to river action.

"Glacial forces, when other than present climatic conditions prevailed, may have produced such deposits, when vast fields of ice were forced down from the Sangre de Cristo range, crushing and grinding and moving forward from the mineralized rocks now found there in place on the western slope. The numerous moraines in the cañons of the Taos and Rio Grande could only have been so left by melting glaciers.

"Along the Rio Grande and its tributaries mining operations by means of ground sluicing have been carried on in a small way ever since this locality was first possessed by the Spaniards. Where the Taos joins the Rio Grande evidence of their workings is plainly seen in the ruins of a stone fort and their nearly filled up acequias. While the altitude is nearly 7,000 feet, yet because of this locality being sheltered by the encircling mountains, and because of its more southern latitude, placer mining can be carried on during fully 9 months of each year.

FIG. 4. OLD RIVER CHANNEL

"At a central point, about 5 miles northeast of Taos, is found abundant evidences of labor, probably employed in placer mining, yet so unusual in many respects as to warrant other conclusions: An area of some 3 by 5 miles, extending toward the southwest from the abrupt foot-hills of the Sangre de Cristo

Range, is so marked, and whereof no authentic record is now known to exist. Over these many thousand acres of gently sloping ground, now supporting only a dense growth of sage brush, nurtured by a very sandy soil of less than a foot in depth, we may observe parallel ridges of quartzite, water-worn pebbles and stones, the largest not exceeding one-fourth of a cubic foot. Such ridges are seldom more than 20 feet apart, from 1 to 4 feet in height, frequently extending in direct lines for several hundred feet, and at intervals having like ridges of similar stones connecting at right angles the opposite side.

"Excavations made among such low walls prove the absence of broken pottery, of flint arrow heads and of all other usually found traces of resident occupation. A probable solution is found in the fact that where the gravel has been undisturbed small quantities of gold occur, and it is a historical fact that in 1640 this locality was wholly under the control of the Spanish government, that for quite 40 years thereafter the native race was subjected to servitude of the most cruel nature, that during such period their foreign oppressors caused them to work in mines or in raising subsistence for captor and captive.

"It is stated that there is now among the archives of the Mexican capitol a document dated prior to the rebellion of 1680, made by the then governor at Santa Fe, asking the Spanish viceroy to furnish an armed escort to convey a shipment of gold dust, valued at more than $2,000,000, from a point north of Santa Fe, and that such troops were furnished and shipment safely made. So far as now known no evidences of extensive placer deposits are found north of Santa Fe except in this locality.

Even with the aid of the crude appliances as then used, with no cost for labor or supplies to be met, and such labor employed for many years, the gold product, even if yielding but a few cents per day for each laborer, the aggregate accumulation of the precious metal would be very great.

"Recently numerous tests have been made in this section to determine the depth of the gravel and its value in gold. The results of tests made of many yards washed in sluice boxes prove that the gold is uniformly distributed.

"When the limit of the lava overflow is reached the deposits of gravel are of unknown thickness. Some years ago Mr. A. Gusdorf, a merchant of Ranches, of Taos, sunk a well to a depth of 425 feet at his place for the purpose of securing artesian water. Throughout its entire depth gravel only was met, and the material removed proved the presence of gold for the whole distance.

"In a great majority of placer deposits obstacles are encountered which prevent their successful working; the supply of water may be insufficient, the gold-bearing deposits may be commingled with boulders of such size that the use of derricks and powder must be employed in their removal, or the fall be so small as to afford little space for disposal of debris after it is discharged from the sluices; but such obstacles are not encountered here; the supply of water is limited only by the cost to be met in making it available, no stones are found in these vast deposits exceeding one-fourth of a cubic foot."

All the available land on the Rio Grande is held at present by different companies who are making plans to be worked in the near future. One of these put down an air caisson in the river bed to bed rock, 33 feet, and the values were found to be very evenly distributed after the first few feet, the value at bed rock being $6.25 a yard, with an average for entire distance of $3.03 per yard.

The Mutual Placer Co., of New Mexico, has recently made arrangements for raising the funds needed to put in machinery. The photographic views shown herewith were mostly taken on its ground and give a good idea of the general appearance of this section. With good machinery all of the companies interested there will become good and long-continued dividend payers.

DETERMINATION OF LATITUDE

*Written for Mines and Minerals, by C. E. Rowe, B. S. (C. E.), E. M.**

It is often of interest to know the latitude of a place, and, furthermore, it is necessary to use the correct latitude in determining the meridian. If a solar attachment is used to find the meridian it is necessary to set off an angle equal to the latitude or colatitude of the station before the observation is made. If a direct solar observation for meridian is to be made, as described in MINES AND MINERALS†, the observation does not depend upon the latitude, but the calculation does. Good results in either method usually require the latitude of the station to be known within an error of ½ of a minute.

Method of Direct Observation Using an Ordinary Mining Transit

The method of determining the latitude, as here described, is simple both in observation and in calculation. The reader is referred to the article mentioned in the foot-note for certain details which are needed in the calculation.

FIG. 1

The Observation.—The direct solar observation for latitude is made with an engineer's transit at noon, that is, when the sun is at his highest position, and to make the observation the sun is followed until he reaches his zenith. The only data to determine are the vertical angle to the sun's center and the approximate standard time of observation. The accuracy of the resulting latitude will be exactly equal to the accuracy with which this angle is found.

For convenience it should be known approximately when the sun will be at the greatest height, which is usually not more than 45 minutes from noon by standard time, depending upon

* Head of School of Mines, University of Texas, Austin.
† Vol. XXX, page 488.

the location in the time belt and the "equation of time," which is the difference between *apparent* and *mean* time. Knowing this it will be unnecessary to begin the observation many minutes in advance.

The transit used should preferably have a full vertical circle so that a normal and reversed telescope observation can be taken, the average of which eliminates the error of adjustment as a level and the index error, but does not eliminate the error due to "leveling" the instrument. The leveling operation is finished when the bubble of the telescope vial, which is much more sensitive than the plate levels, stands at the center of its run when pointed in any direction. This is true whether it is in adjustment or not. A normal and reversed telescope reading can be taken because the sun remains at practically the greatest height for several minutes. Perhaps the best method of being sure that the sun has been observed at his highest point is to continue the observation until he begins to descend. If the meridian is known, the observation can be made when the sun crosses it, or if the longitude is known the exact time for making the observation can be calculated. Of the four things which an engineer may determine from solar observations, the latitude is usually the first required, and does not depend on the others. The meridian is the second, depending upon the latitude. Longitude and time are the third and fourth, being mutually convertible and depending upon the meridian for their easy determination.

During the spring and summer the altitude of the sun for

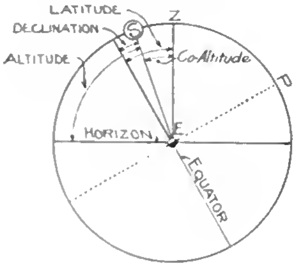

FIG. 2

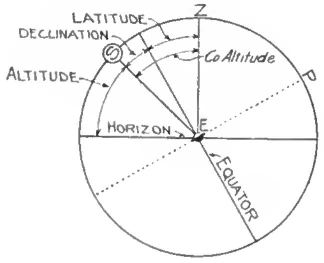

FIG. 3

the southern part of the United States reaches about 83 degrees (i. e., at latitude 30 degrees). On account of the interference of the plates in attempting to measure high angles, it may be necessary to use a prismatic eyepiece attachment to turn the sun's image out of the regular eyepiece at a right angle to the telescope. Furthermore, it may be necessary for the same reason to receive this image upon a screen held about 5 inches from the eyepiece, as shown in Fig. 1. The colored glass of the eyepiece is not used in this case. In order that the cross-hairs may be visible, the eyepiece must be drawn out a little further than when looking through it. Receiving the image directly on a screen‡ is objected to by a few surveyors, yet it is preferable to using the prismatic eyepiece for moderately high angles, because a notebook or some flat blank surface is always available for such a purpose. The glare from a small white screen does not affect the eyes more than the direct view through a colored glass, and a tinted surface is usually better than a white one in this respect. For low angles the best equipment is a piece of dark green glass set in the sliding cover of the eyepiece, since it is always at hand, requires no refocusing, and the view of the sun's image in relation to the cross-hairs is excellent.

The sun being about 32 minutes in diameter, some special method must be used for accurately obtaining the vertical angle to his center. There are four good methods:

1. In one observation a very small segment may be cut from the top of the sun's image with the cross-hair, and in the other an equal segment may be cut from the bottom, the average vertical angle being used.

2. A small segment may be cut from one side of the image with the vertical cross-hair and the segment can be quite accurately bisected with the horizontal cross-hair.

3. The instrument may be provided with solar hairs, of which the "Davis inclined square" is an excellent type for the transit, making it possible to accurately set upon the sun's center by cutting off four small segments of the image by means of hairs crossing the reticule at an angle of 45 degrees, as shown in Fig. 1, on the image.

4. If the observation is made by looking into the telescope through a colored glass, the horizontal cross-hair may be placed tangent to the sun and the vertical angle corrected for the sun's semi-diameter.

‡ Fig. 1, page 488, Vol. XXX.

The Calculation.—By reference to Figs. 2 and 3 the method of making the calculation is apparent. These sketches show a side view of the imaginary celestial sphere. The sun, S, is shown in Fig. 2, at north declination, and in Fig. 3 at south declination. The planes of the equator and of the horizon intersect the plane of the paper along the lines indicated. E is the earth, Z the zenith point, and P the north pole produced. The coaltitude of the sun is 90 degrees minus the true altitude. If we call north declination plus, and south declination minus, it follows from the sketches that

$$\text{Latitude} = \text{coaltitude} + (\pm \text{ declination})$$

The altitude of the sun is the vertical angle to the center, *minus* the correction for refraction. In the article March, 1910, MINES AND MINERALS, referred to in the foot-note, a table of mean refractions is given. The refraction may be calculated from the formula:

$$\text{Refraction} = 57 \text{ sec.} \times \text{cotangent apparent altitude}$$

The declination of the sun is obtained from a "solar ephemeris."

EXAMPLE.—On April 13, 1910, the average of a normal and a reversed observation gave the vertical angle to the sun's center as 68° 38.75′ at 12:35 P. M., 90th meridian time. Find the latitude of the station.

SOLUTION.—

Vertical angle by observation	= 68° 38.75′
Correction for refraction = 22 sec.	= .37′
True altitude	= 68° 38.38′
Coaltitude = 90° − altitude	= 21° 21.62′
Sun's declination at Greenwich *mean* noon (= 6 A. M., 90th meridian time)	= + 8° 49.60′
Difference for 1 hour = + 54.62″. Diff. for 6 h. 35 m. = (6.6h × 54.62) ÷ 60	= + 6.00′
∴ Declination at 12:35 P. M.	= + 8° 55.60′
Coaltitude (above)	= 21° 21.62′
Hence, Latitude = coalt. + (± dec.)	= 30° 17.22′

This is the result of an actual observation, and does not give exactly the known latitude of the station, the error being ¼ of a minute, which is fully as close as can be expected since the observation was taken with a 5-inch mining transit graduated to read only to minutes, but by estimation was read to the nearest ½ minute.

ST. LAWRENCE POWER PROJECT

There was a bill before the Canadian Parliament for development of power from the St. Lawrence River. It is stated that parliament will not sanction the erection of a dam in nor across the river, and no additional work in connection with the enterprise may be undertaken without the direct approval of parliament. Sir Wilfrid Laurier has denied that the government was in any way responsible for the bill or concerned with its fate, and states that the St. Lawrence is so bound up with the history of the country that any attempt to impede its flow is something like sacrilege. For the present he will not agree, for any consideration, to dam the river, although in course of time the demand for electric energy may become so great as to compel parliament, under the direction of the International Waterways Commission, to reconsider the whole question.

TRAIL SMELTER AND LEAD REFINERY

*Written for Mines and Minerals, by J. M. Turnbull, B. A., S. C.**

A Description of the Equipment, Methods of Smelting and Electrolytic Refining

The smelter and lead refinery of the Consolidated Mining and Smelting Co., of Canada, Ltd., are situated at Trail, in the West Kootenay district of British Columbia. A branch line of the Canadian Pacific Railway affords the works connection with a number of the mining camps of southern British Columbia.

Practically all of the lead ores and most of the other custom smelting ores of the interior of the Province are treated here, owing to central location, low freight and smelter rates, and diversity of operations.

For the year ending June 30, 1910, the ore smelted averaged 9,500 tons per week of all classes, of which 1,100 tons were lead and dry ores or concentrates. The metal production for the same period had a gross value of just under $6,000,000, of which over 40 per cent. is gold. This is $500,000 more than the previous year. The total production since 1896 having amounted to $43,700,000.

The first furnaces completed in 1896 had a capacity of 200 tons per day. The Canadian Pacific Railway bought them in 1898 and sold to the present owners in 1906. Lead furnaces were installed in 1899, and the lead refinery, with Betts patent electrolytic process, in 1902. Changes and enlargements have been almost continual, and although some disadvantages of arrangement have been inherited in this process, the plant as a whole is modern and efficient.

FIG. 1. GENERAL VIEW OF TRAIL SMELTER

The location of the plant, as shown in Fig. 1, is on the corner of a bench of land, which rises 200 feet above Trail Creek and Columbia River valleys. The sides of the bench are steep, permitting advantages to be taken of gravity on both slopes, comparatively little elevating of ore or materials being required. The slag is granulated and sluiced to the dump by means of an ample supply of water from several mountain creeks, which reaches the furnaces under a head of 140 feet. Slag disposal is thus cheap and easy.

The municipality of Trail is at present building a launder from the furnaces over the town, where the granulated slag will be used to fill in a large depression in the town site below the furnaces.

The compact clump of buildings on the left of the illustration is the refinery. Residences of officials are in the background. The storage yards and large sampling mill are in the center, as well as a 6,000-ton pile of coke. Further to the right and behind are the roasting furnaces and Huntington-Heberlein plant, while across the front from left to right are the old sampling mill, the blower room, the matte plant, and blast-furnace building, 225 ft. × 70 ft., and 70 feet high. The slag dump and part of the town of Trail are in the foreground, with the Columbia River in the rear.

The general equipment includes railway yards, with 3 miles of sidings, railway scales, ore bunkers, storage yards with a capacity of 30,000 tons, three sampling mills, five large copper blast furnaces, two lead furnaces, with seven rotary blowers, two O'Hara furnaces, six Bruckner roasters, seven Huntington-Heberlein furnaces, and 25 converters, a lead refinery, briquetting plant, assay office, machine, carpenter, and boiler shops, together with a large amount of smaller machinery and equipment, including an extensive installation of pumps, hydrants, etc., for fire protection.

Electric power is used throughout, being generated at Bonnington Falls, 33 miles distant, and transmitted at 20,000 volts to the works, where it is stepped down to 550 volts by a battery of transformers. The total power consumption is about 3,000 horsepower.

The ores received are weighed over a 100-ton recording Fairbanks scale, dumped into bunkers and drawn therefrom to the proper sampling mill. The bulk of the copper and low-grade ores is handled in the large mill, whose equipment consists of a No. 8 and a No. 4 McCully crusher, together with Vezin samplers, smaller crushers, rolls, etc. The first sampler cuts out one-tenth, following which, in order, are cuts of one-fifth, one-quarter, and one-tenth. The corresponding crushing sizes being usually 4, 2, 1, and ½ inches. One two-thousandth of the original ore is thus delivered to the quartering floor where it is quartered down by hand or in Jones riffles. Part of the final sample goes to the assay office and part is kept as a check until the shipper is paid.

The old mill has a smaller but similar equipment and is used as a reserve and for sampling special lots, or as convenience dictates.

The third mill handles lead and dry ores and concentrates. Its equipment consists of Blake and Farrel crushers and rolls, with Vezin and Brunton samplers, the capacity being 30 tons per hour. Oxidized lead and dry ores are first crushed to a 6-inch ring, the final sample being ¼-inch, and the reject going direct to the furnace charge bins. Galena ores and coarse concentrates are crushed to ¼-inch and bedded. In each case the samplers cut out one five-hundredth part and deliver it to the quartering floor. Fine concentrates are usually sampled by the fifth-shovel method and go to the lead beds. The large mill was designed so that all sampling could be done on one shift with resultant economy and more efficient supervision, and it is now being arranged to handle lead and dry ores as well.

The blower plant comprises seven rotary blowers operated by individual motors. The older ones are Connersville type while the newer ones, four in number, are of the later Root type. The largest delivers 33,000 cubic feet of free air per minute at a pressure of 36 ounces and consumes 350 horsepower. The total power required for the plant is 1,200 horsepower. A small

*Mining Engineer of the Consolidated Mining and Smelting Co., of Canada Ltd., Trail, B. C.

rotary blower in the roasting plant furnishes air for the converters.

The haulage and distributing system includes a high-line trestle running through the sample mills and having branch trestles over the storage yards, lead beds, etc. Twenty feet lower in elevation is the second haulage line. This runs below all the sample mill bins and into a tunnel under the coke and storage yards. The ore and coke are drawn through chutes directly into cars and run over the furnace charge bins which have a capacity of 4,000 tons. These haulage lines are connected by a pair of balanced elevators.

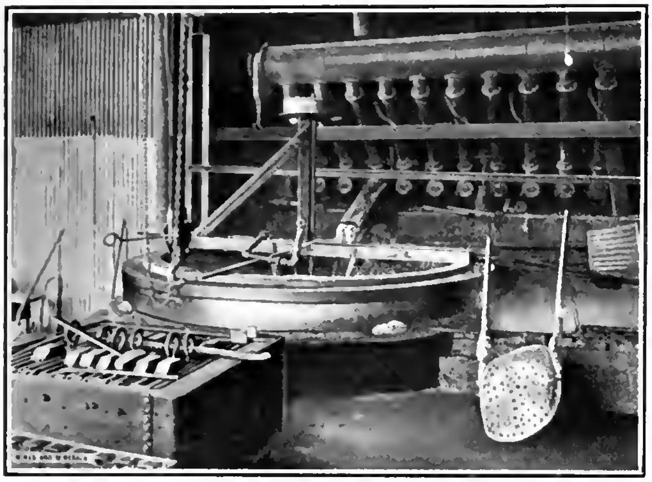

FIG. 2. LEAD WELL AND ANODE MOLDS

The third line, 25 feet lower, is on the level of the copper furnace feed-floor. It runs under all the furnace charge bins and has branches connecting it with the ground floor of the roasting and briquet plants. Each copper furnace has a track on either side on which the charge trains are alternately run.

An incline operated by endless chain connects the lower furnace floor with the second and third haulage levels to raise the bullion anodes, slag, matte, etc., to higher levels.

Ten Jeffrey electric trolley locomotives on the three upper lines are required to handle the traffic, hand tramming and shoveling being reduced to a minimum. Auxiliary hand tram roads are used where convenient or economical, as in the lead beds, etc.

A motor driving two 100-kilowatt generators is used to generate the necessary direct current. An auxiliary or reserve set of 85 kilowatts is on hand to prevent the serious complications which would follow a break in the haulage service.

A railway spur on a trestle 12 feet above the high line delivers coke to the storage yard, and a large store of coke, some 6,000 tons, is kept on hand to provide against contingencies at the coal mines. This trestle extends over the bins which deliver ore from their chutes directly into the mouth of the large sample mill crusher.

An extensive system of brick and metal flues is installed, connecting with two brick stacks, one for the copper and one for the lead furnaces. The copper furnace stack is 185 feet high and 144 square feet internal area. The flue dust, amounting to 2 per cent. of the ore, is briquetted and resmelted. The briquet plant includes two Chisholm, Boyd & White presses with pug mills, elevators, etc. Three to 5 per cent. of lime is used as a binder.

The assay office, built in 1902, is completely and modernly equipped. An electric motor drives the crushers, and electric heaters are used. It has four large coal-fired muffle furnaces, and a complete equipment for wet and electrolytic work. A great variety of assay and analytic work is called for, including that of lead-refinery products and solutions.

The machine, boiler, and carpenter shops are sufficiently equipped to handle all ordinary repair and construction work connected with the smelter.

The ore supply is drawn largely from the East and West Kootenay and Boundary districts of British Columbia, with some silicious gold ores from the state of Washington.

Rossland camp, 11 miles distant by rail, supplies about 4,000 tons of ore per week, averaging about 1 per cent. copper and 9 to 12 dollars per ton in gold, with 45 per cent. silica and 7 to 8 per cent. sulphur in the form chiefly of pyrrhotite. Most of this is from the Consolidated company's own Center Star mines. The Boundary district supplies 2,000 to 4,000 tons per week of self-fluxing ore, running about 1.3 per cent. copper and $1.50 in gold and silver. This is from the Snowshoe Mine on which the Consolidated company have a lease, and is shipped a distance of 110 miles in quantities to suit the demand of the smelter. The Consolidated company also owns a group of properties adjacent to the famous Granby mines with similar ore, but these are not operated at present, being held as reserves.

The largest and steadiest supply of lead ores comes from the St. Eugene mines, of East Kootenay, owned by the Consolidated company, which has been the largest lead producer of the province for some years. The balance of the consumption comes from a large and variable number of smaller shippers and includes high- and low-grade copper ores, galena ores, and concentrates, gold quartz ores, and gold-mill concentrates, with some dry silver and gold ores.

Coke comes from the Hosmer Mines, Ltd., near Fernie, B. C., a distance of about 249 miles, about 225 tons per day being used. Limestone is derived from the company's quarry at Fife, 68 miles away, and costs $1 per ton in the charge bins. About 225 tons per day are required, mostly as flux, a little being burned and used as a briquet binder. No other barren flux is used, except a little scrap iron on occasions.

The five copper blast furnaces are of the following sizes: Two 42 in. × 240 in., two 42 in. × 300 in., one 42 in. × 263 in. at the tuyeres. The height of charge is 9 feet above the tuyeres, with air pressure of 36 ounces. Two forehearths are used, the second catching only from .25 to .5 per cent. of the total matte.

An electric locomotive takes a charge train of five cars of 1,000-pounds capacity, usually one loaded with coke, one with lime rock, and three with ore. When Snowshoe ore is being charged, two such trains alternate with one carrying one car of coke and four of Snowshoe ore, which is limey. The cars are dumped one at a time into the side of the furnace, the train moving the full length of the furnace for each car dumped, thus distributing the charge evenly, coke first, followed by lime, and lastly ore. An electric recording gauge in the superintendent's office shows the time that each charge goes on each furnace.

FIG. 3. LEAD REFINERY

In the low-grade furnaces the charge is varied according to the ore, giving a slag of the following analysis: Silica SiO_2, 43 to 46 per cent.; iron (FeO), 14 to 15 per cent.; lime CaO, 20 to 22 per cent.; copper, .1 per cent., with trifling amounts of gold and silver.

The practice at present is to smelt the ores raw to a low-grade first matte, which carries a variable amount of copper, say about 15 per cent. This appears to be an efficient gold collector. Snowshoe ore can be smelted alone in one operation to a 45-per-cent. copper matte, but it is found more advantageous to run it on the high-grade furnace with the roasted low-grade first matte; part of it sometimes being put on the low-grade furnace, as circumstances dictate.

The first matte running about 15 per cent. copper, 27 per cent. sulphur, and 56 per cent. iron, is roasted in two O'Hara furnaces of 9 ft. × 95 ft., and 12 ft. × 97 ft. hearths, respectively, to about 10 to 12 per cent. sulphur, then blown in the lead converters to a product which runs 1 to 3 per cent. sulphur. The converter operation is described under the lead operation later.

The roasted matte is smelted in the high-grade furnace with Snowshoe ore and some low sulphur ore to a matte running about 40 per cent. copper, a higher percentage not being economical under the circumstances.

This matte is shipped to Tacoma, Wash., for further treatment, no copper converters being installed in the works as yet.

The high-grade slag runs about 40 to 42 per cent. silica, 26 to 28 per cent. iron (*FeO*), 16 to 18 per cent. lime, and 10 to 12 per cent. alumina, with .35 per cent. copper and .2 ounce in gold. Some of this slag is put on the lead furnaces, as noted later, and the gold partly recovered.

The first low-grade matte is granulated by being poured into a stream of water which is caught in a tank, the overflow from which runs through a series of settling tanks, the granulated matte being elevated into the matte plant, drained, and run to the O'Hara furnaces. The high-grade matte is tapped into pots, cooled, crushed, elevated into the matte plant, sampled, and shipped direct.

The lead smelting and refining is perhaps the most interesting part of the work. An excellent paper by Mr. A. J. McNab, general superintendent, appeared in the *Canadian Mining Journal* for July and August, 1909, describing the lead smelting and refining at that date. The following is partly abridged therefrom, and is brought up to the present date, Mr. McNab having kindly checked the information and facts given in the whole of the present article.

The lead ore supply is mainly heavy sulphide with comparatively little dry ore, the reverse of usual American conditions, the lead furnaces carrying a charge of from 35 to 45 per cent. lead, compared with the usual 10 to 15 per cent. More than 80 per cent. of the ore received will run from 20 to 75 per cent. lead, the balance consisting of dry gold and silver ore, a little oxidized lead ore, and pyritic mill concentrates.

The general procedure is to treat the heavy sulphides with lime rock, lead matte, etc., in the Huntington-Heberlein roasters and converters. The resultant lead sinter is smelted in the blast furnace with the addition of certain dry ores, etc. The bullion from the lead well is cast into anodes, the dross being skimmed and returned to the furnace. The anodes go to the refinery where they are electrolytically treated, the final products being pure lead, pure gold and silver, bluestone, and sometimes antimony.

In general it may be said that proper proportioning of the roaster and furnace charges is the most vital point in getting good results. Provided this is well done the particular percentages may, and often do, vary widely from the figures given. These figures represent the latest average practice, but do not hold for any length of time, owing to the variations in the ore supply.

The lead beds are made up with heavy ores and concentrates only, contain some 600 tons each, and carry about 38 to 40 per cent. lead. Other constituents of the roaster charge are added later, because, if mixed with the beds, it would be more difficult to alter the charge quickly.

The making up of the Huntington-Heberlein roaster charge is important, as a poorly proportioned charge will neither roast well, nor will the resultant product smelt in the furnace without considerable trouble.

The roast at present is being run on approximately the following analysis: Lead, 40 to 44 per cent.; iron, 10 to 13 per cent.; silica, 8 to 11 per cent.; lime, 7 to 10 per cent.; the zinc being kept under 10 per cent., if possible. The lead content has varied to date between 36 per cent. and 50 per cent. Ores of either percentage have been roasted and converted with satisfactory results by carefully proportioning the other ingredients, and it is probable these limits might be exceeded if occasion demanded. The iron should at least equal the silica, and had better be 1 or 2 per cent. higher. Two to 4 per cent. excess of silica over iron has led to serious furnace troubles, decreased furnace tonnage, slags higher in lead, and a tendency to run too hot. Attempts to correct this by varying the blast-furnace charge or altering the lime in the roast have not been very successful. The higher silica seems to make the charge more fusible, melting higher in the furnace, and thus causing trouble. Lime in the roast is usually 7 to 10 per cent., though it is possible that higher iron, if available, might allow of lower lime. This would save some money, as the iron would be in ore on which treatment charges are paid, whereas the lime costs both to roast

FIG. 4. LEAD REFINERY, OPPOSITE END FROM FIG. 3

and to buy. Pyritic concentrates and matte form part of the charge.

Properly made up, carefully fired, roasted, and converted, the product will be fairly hard, yellowish or grayish yellow, showing some litharge, and be easily broken up with little fines. In the furnace it will run with cool top and bright tuyeres.

There are seven circular Huntington-Heberlein roasting furnaces, 26 feet in diameter, with hearths revolving once in 3 minutes. Stationary cast-iron rabbles work the ore through in about 2 hours.

The firebox and discharge are on the periphery and the feed in the center, the heat thus increasing toward the finish. The feed carries 14 to 17 per cent. sulphur, and the roast 8 to 9 per cent. The capacity is 35 to 45 tons per day per roaster, but varies with the per cent. of sulphur. For good desulphurization in the converters, the roast should not run over 9 per cent. sulphur, and preferably 8 per cent., according to experience at Trail. The temperature, a dull red heat, requires close regulating to roast fully without fusing, as fused ore will rapidly crust up the furnaces, which must then be stopped and cleaned. The roasted product should consist of small, uniform, semi-fused globules, showing neither lime rock nor ore. The roast is elevated and dropped through a water spray into a brick bin. The moisture, about 5 per cent. thus imparted, seems to prevent the converter blast from blowing through too quickly and keeps the heat in until the converters are working uniformly, and the temperature becomes high enough to ensure fusing of the charge.

There are 24 converters, 8 feet $8\frac{1}{2}$ inches in diameter, with cast-iron diaphragms, made in four sections and bolted together. One-piece diaphragms tend to crack, and steel ones to bulge with the heat. A fire of slabs is started in the converters and when burning freely the charge of 10 tons of roast is dropped in from a hopper, and a 10- to 12-ounce blast turned on. The time of converting varies widely with the charge, averaging three charges per 24 hours, the blast decreasing to 2 ounces at the close. The heat from the oxidation of the sulphur, iron, etc., gradually works up through the charge to the top and burns out, leaving a solid mass of porous sinter. This is dumped on to an iron cone which breaks it up into large pieces. These in turn are broken by hand and fed to a 20″×20″ Blake crusher, crushing to 6-inch ring. The crushed sinter is elevated and goes to the furnace charge bins.

The chemical reactions of converting are somewhat obscure. Some lead is reduced and desulphurization is pretty thorough.

The two lead blast furnaces are, respectively, 45 in. × 160 in. and 45 in. × 140 in., at the tuyeres. They have smelted 260 tons per day, and will average about 190 tons of ore, besides by-products, matte, slag, etc., of from 20 to 30 per cent. of the charge. They are standard type, with brick crucibles water-jacketed to the top of the bosh, above which is a fire-brick shaft. The height of the charge is $17\frac{1}{2}$ feet above the tuyeres, and the blast used is 32 to 34 ounces. Smaller tuyeres set at 15-inch centers were substituted for ones set at 20-inch centers without much difference in results.

The bullion is tapped at the side of the furnace into a kettle of 50 tons capacity, from which it is pumped by a $1\frac{1}{2}$-inch centrifugal pump into vertical anode molds. Fig. 2 shows the kettle, molds, chain block with electric motor, and dross skimmer.

FIG. 5. INTERIOR OF TANK ROOM

Special frame cars holding 10 anodes are used, the cars going up the haulage incline to the level of the railway cars, in which they are transported to the refinery. The matte and slag run into a large receiver at the end of the furnace, the slag overflowing into the granulating launder, and the matte being tapped into pots.

The charge usually has about 85 per cent. of Huntington-Heberlein roast, varying considerably with the ores, and some oxidized and siliceous dry ore and lime rock. The coke is about $12\frac{1}{2}$ per cent. of the charge, not counting slag and easily smelted by-products. One hundred to 300 pounds of slag from the high-grade copper furnace is added to each charge to keep the charge open, the furnace action uniform, and reduce the percentage of zinc. The lead in the charge has been successfully run as high as 50 per cent., and averages about 40 per cent. Sulphur is kept below 4 per cent., the lower the better, as the matte fall is less. The speed of running decreases very markedly with a small increase in sulphur. About 30 to 40 per cent. of the sulphur in the charge is eliminated in the blast furnace.

The slag is kept at about 31 to 33 per cent. silica, 18 to 20 per cent. lime, 24 to 30 per cent. iron and manganese (FeO,MnO), 7 to 12 per cent. zinc (ZnO), and 8 to 16 per cent. alumina. It carries about .4 ounce silver and a trifle over 1 per cent. lead. With high zinc the lime is reduced to keep the slag fluid. It is not profitable to run siliceous ores to bring the slag much above 33 per cent. silica, as the furnace slows up too much. Alumina gives no serious trouble. The iron and manganese may vary between the percentages given without much difference in the running. Scrap iron is added occasionally, although it is not necessary when the charge is good, but is good medicine if things are not running smoothly.

One furnace is being run at present, producing about 75 tons of bullion per day. As high as 130 tons of bullion has in one day been made. An average analysis of the products is as follows: Copper, .22; manganese, nil; zinc, .098; antimony, .32; arsenic, .28; nickel, cobalt, and cadmium, nil; bismuth, .0133; lead, 98.5 per cent.; silver, 100 ounces; and gold, .1 ounce. Smelting campaigns last about 7 months, then if accretions have accumulated sufficiently to make it profitable to blow out and clean up, the alternate furnace is blown in.

The refinery is situated on flat land along the railway, about 200 yards from the main smelter buildings. Figs. 3 and 4 show the buildings from opposite ends. The long building on one side is the tank room, the slimes plant is in the center, and the bluestone plant on the opposite side. Fig. 5 shows the interior of the tank room with part of the new tanks in the foreground, and the melting pots and the molds in the middle distance. Fig. 6 shows the machine for making starting sheets with the corner of one sheet turned up from the cooling plate.

The general procedure in the refinery is as follows: The anodes are electrolyzed in tanks, producing refined lead and slime. The lead is melted, run into molds and shipped. The slime is treated in a separate plant with the production of fine gold and silver. Antimony, when commercial conditions warrant, can be saved from the slime by a special electrolytic process discovered by Mr. McNab. A by-product solution of copper sulphate is crystallized out in the bluestone plant, making a commercial product used by the farmers to kill the smut in wheat.

Three motors of 650 kilowatts total capacity are installed, which drive generators and furnish current at 3,500 amperes and 80 volts for the tanks. A smaller dynamo furnishes current for lighting and minor uses. Coal is used under the melting pots, evaporating kettles, and to furnish steam for heating, etc., but not for power purposes.

The tank room contains 240 tanks, 3 ft. × 8 ft. × $3\frac{1}{2}$ ft., made of coast fir, lined with asphalt, arranged in six double rows in a series of cascades. The electrolyte is kept in circulation by pumps. One hundred and eighty more tanks are in course of construction, which will raise the plant capacity from 75 to 100 tons per day and permit of lowering the current density. Each tank has a capacity of 20 anodes. An electric crane carries a spacing frame in which it picks up the anodes from two cars and lowers them to their place in the tank properly spaced. The anodes weigh 370 pounds each, and are cast

with shoulder lugs which rest on copper current bars on the sides of the tanks, the bodies of the anodes hanging down into the tanks. They are spaced $4\frac{1}{8}$ inches apart.

The cathodes are thin sheets of pure lead made on a special machine, Fig. 6, invented in the refinery. It consists of a tipping trough at the head of a $\frac{3}{4}$-inch plate of cast iron, steel surfaced, the size of the cathode, inclined at 1.8 inches per foot. The trough is filled with molten lead and tipped over the plate. The lead spreads uniformly over the plate and solidifies into a uniform sheet about $\frac{1}{16}$-inch thick, which is trimmed by running a knife around the edges, after which it is stripped off the plate. These sheets are hung on $\frac{1}{2}'' \times \frac{3}{4}''$ copper bars, bending the end of the sheet once around the bar. Twenty-one cathodes, spaced equally between and outside of the anodes, go in each tank. They are slightly larger than the latter to prevent short circuiting and are placed in the tanks by hand.

The electrolyte used is lead fluosilicate with free fluosilicic acid, averaging 12 per cent. acid (SiF_6) and 5 to 6 per cent. lead. This is stable with small losses. The acid is made in a special plant. Fluorspar, silica, and sulphuric acid are mixed in proper proportions in a cast-iron pan and the fumes condensed in towers with water sprays, the acidified spray water being used over and over until the strength is about 30 per cent. fluosilicic acid. Free sulphuric acid is removed by lead dross. The clean acid is added to the electrolyte as needed. About .5 to 1 pound of glue per ton of lead is added to the electrolyte daily, as without it the lead deposit would be soft and non-coherent and the tanks would short-circuit rapidly.

The tanks are operated with a current density of 16 amperes per square foot of cathode area. It is proposed to reduce this to 12 amperes, which experience shows will give better results. The voltage averages .32 volt per tank, the contacts causing a loss not over .02 volt per tank. A tank is worked out in about 8 days, 15 per cent. scrap going back to the melting pot after washing. Most of the slime adheres to the anode scrap, which is scraped and washed off in a special tank. Some slime settles in the electrolytic tanks, which are cleaned out once in a month. The cathodes are taken out, melted after washing, and cast into molds to suit the trade, the Chinese trade, for instance, requiring pigs of 190 pounds to suit the carrying capacity of the coolies.

An average analysis of 2,000 tons of shipping lead ran as follows: Arsenic and bismuth, nil; zinc, .0005; silver, .0013; copper, .00075; lead, 99.9938; iron, .00075; tin, .0001; antimony .0028. The average analysis of the slime is: Silver, 35 per cent.; antimony, 25 per cent.; arsenic, 20 per cent.; and copper, 8 per cent.; with some iron, bismuth, and silica, and traces of tellurium and selenium.

The slime from the tank room is taken in copper cars to the slime plant, where it is agitated in tanks with hot water. The wash water is afterwards drawn off and evaporated in steam coil tanks to recover the electrolyte contained. The slime is filtered and dried in large cars which are run into the furnace flue for the purpose. The slime is then melted in a water-jacketed reverberatory furnace lined with magnesite brick. The impurities are oxidized off and dore metal, running 960 to 975 parts gold and silver, is obtained. The fumes go through a series of inverted U cooling flues, which recover most of the volatilized metals, the condensed fume going to the blast furnaces.

The dore metal is parted in sulphuric acid. The silver sulphate is run into steam-heated tanks, where the silver is precipitated as a slime by bars of metallic copper. The silver and gold are collected, melted, and cast into bars. The silver bars weigh about 80 pounds each, and are 999 fine, the gold being 995 fine. The copper sulphate solution goes to the bluestone plant.

The McNab antimony process includes dissolving the antimony and arsenic from the slime by boiling with sodium polysulphide, and electrolyzing the solution with lead-sheet anodes and steel-sheet cathodes, the cathode deposit being a dense hard antimony, with 2 per cent. arsenic, which is removed by melting with alkaline fluxes.

In this case, the slime, after treatment with polysulphide, is roasted in a muffle furnace and treated with 10 per cent. sulphuric acid, which extracts 90 per cent. of the copper and 10 to 75 per cent. of the silver. This solution formed is heated with copper as before to precipitate the silver. The residual slime is then treated in the reverberatory as described.

Fine gold and silver are sold to the Canadian and American mints at Ottawa and Seattle. Fine silver is largely shipped to the Orient. Lead is sold in Eastern Canada and the Orient with smaller local markets.

Treatment rates vary widely on different classes of ores. The practice is to quote rates f. o. b. the smelter as far as is possible, making them independent of variable freight tariffs. Formerly inclusive freight and treatment rates were the rule.

The lowest treatment rate is \$1.50 per ton on low-grade, easily smelted, self-fluxing Boundary ores. This compares favorably with the widely advertised cheap costs of the Boundary smelters.

Rossland siliceous copper ores receive a \$3 rate, and other copper ores receive rates not far from this, depending on quantity and quality. Indirect deductions are usually about .4 per cent. from the copper wet assay, and 4 cents per pound from the New York price. The situation of the smelter making marketing costs comparatively high, 95 per cent. of the gold

Fig. 6. Casting Machine for Lead Cathodes

and silver is paid for at \$20 per ounce and New York price, respectively.

Lead sulphide ores are treated on a basis of \$8.50 to \$9.50 per ton for ore carrying 70 per cent. lead, adding 10 cents per unit for each per cent. under 70, to a maximum of \$10.50 to \$11.50. The lower are contract and the higher are open rates. Ninety per cent. of the lead fire-assay is paid for, if over 5 per cent., at London, England, prices, less 1 cent per pound marketing charge. Ninety-five per cent. of the gold and silver is paid for as above. Settlements are usually based on quotations 3 months from date of receipt of ore in the works.

Dry ores, iron concentrates, etc., receive a variety of rates, usually based on a \$3.50 to \$4.50 treatment rate with sliding scales. Excess iron is allowed for and excess silica is penalized at 7 cents per unit. Sulphur is penalized at 50 cents per unit. Zinc on all ores is penalized 50 cents per unit, for each unit over 8 per cent.

To give averages of variable smelting costs, without an extended analysis of conditions, would be of little benefit. It would require an article longer than the present one to do the subject justice and will not be attempted here.

The climate of Trail is moderately dry and mild, with snow for 3 months, and a warm summer with cool evenings. Operations are very seldom interfered with by the weather to a serious degree. A good class of labor is employed, many of the employes having been with the works for many years, and owning their own homes in the town. There has never been any serious labor trouble since the plant started. Some 550 men are employed, many of foreign extraction, but there are no Japanese, Chinese, nor Hindus.

SAFE USE OF ELECTRICITY IN GASEOUS MINES

Some years ago, when electric machinery was first being used in mines, the writer in conversation with the late Eckley B. Coxe, the great anthracite coal operator, said: "Mr. Coxe, in your experimenting and trying out of new methods and machines, have you done anything with electric machinery at any of your mines?" Mr. Coxe answered: "Electric machinery is all right for many purposes above ground, but I will not use it underground. While we have never had any gas at any of our mines, there is no telling when we will have some. We employ fire bosses, and daily examinations for gas are made. If I was sure that we never would have gas, I certainly would try out electrical machinery, but, as you know, where electrical machinery is used, there is always great liability to sparking, and an electric spark will ignite gas." Some two weeks later the writer met Mr. Coxe on a Lehigh Valley train, and he at once said: "Do you remember our talk about electrical mining machinery a couple of weeks ago? Well, I told you then we had no gas in any of our mines. Yesterday morning one of our fire bosses was quite severely burned while making his rounds. He was careless and did not use his safety lamp as he was instructed to, probably because he felt secure in the absence of gas on his many previous rounds. Now, you can see how reasonable my objections to electric machinery in coal mines are."

While the use of electrical mining machinery has become very common since then, it is frequently restricted by law to mines known as non-gaseous mines, and in Pennsylvania its use is positively forbidden "except where so insulated as to prevent the emission of sparks and flames."

Flame-proof types of electrical mining machines, which receive their power from insulated feed-lines, have been in use now for several years. But with such machines, and a well insulated feed-wire, the difficulty of making connections between the main feed-lines and the feed-wires of the mining machines still remained and was an element of danger. Now, however, this is removed by the use of the interlocking safety switch manufactured by the Interlocking Safety Switch Co., of Cleveland, Ohio.

This interlocking safety switch is an air-tight switch or junction box to be attached to the main feed-wires and fastened to the wall in butt entries at every second or third room opening. It consists of a cast-iron box which is filled with oil and the knives of the switch making and breaking the current in the oil makes it spark-proof. The plugs, which are fastened to the machine cables, are inserted in the switch nearest the room desired to be worked and are so arranged that when the current is turned on the plugs are locked in place and are absolutely immovable until the current is released, making it perfectly safe under the most dangerous conditions. It has been tested at the testing station of the United States Geological Survey at Pittsburg, Pa., and proved all that is claimed for it, and a prominent state mine inspector says, under date of March 1, 1910: "I think it is the best I have seen on the market." These switches have been in successful use at the Harwick Mine of the Allegheny Coal Co., in the Pittsburg region, for the past 2 years. The Manifold Mine of the Youghiogheny and Ohio Coal Co., the Pike Mine of the Peoples Coal Co., the mines of the Republic Iron and Steel Co., and the Ellsworth Collieries Co. are also equipped with them.

Many managers of gaseous mines have refused to consider the use of electric machines on account of the danger of sparks, notwithstanding they admitted the convenience and economy of such machines, and many managers of non-gaseous mines, held the same views as did Mr. Coxe, and for the same reason have not used such machines. This device has, with the production of flame- and spark-proof coal cutters, made safe the use of electric mining machines in both hard and soft-coal mines.

THE FRANZ SCREEN

Written for Mines and Minerals

The worst feature of those machines employing an endless screen for sizing mill pulp is the uneven wearing of the screen cloth. It is common experience that a certain portion of the screen cloth often wears through or breaks from bending, within a few days after its installation. The screen cloth must then be repaired by patching, and in course of time the number of patches becomes so great as to seriously interfere with the efficiency of the screen as a whole, necessitating the discarding of the screen belt.

The new Franz screen aims to eliminate the necessity of patching the screen cloth by presenting to the pulp flow a screening surface not consisting of a continuous belt of screen cloth, but of a series of screen sections, as shown in Fig. 1. When any of these screen sections becomes worn, that particular section may be immediately removed and quickly replaced by another. In this way the efficiency of the screening surface is at no time reduced by patches, and it will readily be seen that the expense of replacing a worn by a new screen section is considerably less than that of installing a whole new endless-belt screen. Fig. 1 plainly shows the method of construction. The series of sections are mounted upon endless rubber belts which pass over the supporting pulley wheels, the screen sections themselves being given a slight curvature, as shown in Fig. 2.

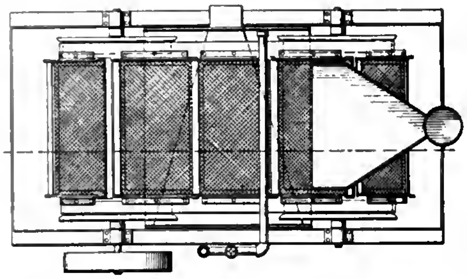

Fig. 1

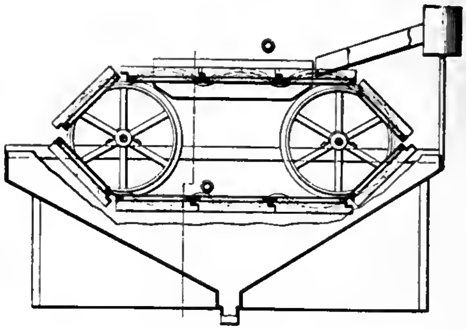

Fig. 2

The inventor of this machine is Mr. Frank Franz, master mechanic of the Hercules Mining Co., at Burke, Idaho, where several of these screens have been installed at the mill for more than a year with favorable results. In these machines the 30-mesh screen cloth on the machine treating about 75 tons per 24 hours lasts from 4 to 5 months, while the 12-mesh screen cloth on the machine treating 150 tons per 24 hours lasts from 3 to 4 months.

In addition to the machines treating this fine material there are two screens in use at the sorting plant where the ore from the mine is washed and sorted before going to the mill. The endless belts of these two machines are equipped with perforated metal plates, the perforations being 12 millimeters in diameter. At the time of writing, these plates have been in commission 7 months and still do not show any signs of wear, although the daily capacity is 300 tons each.

The production of Swedish pig iron in 1909 amounted to 443,000 tons, and the production of the steel and malleable iron was 150,000 tons. This is the smallest in many years. The export of iron and steel shows only a reduction of 17,000 tons.

THE HUBBELL ELECTRIC MINE LAMP

Written for Mines and Minerals

Ordinary incandescent electric lights are used in lighting mine roads, and that proposition is one which calls for little improvement. Such lamps are stationary, being supplied by electric currents from dynamos, so that, their use being limited to one place, the miner must, if he uses electric light at all in his travels and work, depend upon a storage-battery lamp. The main feature ot a portable electric mine lamp is the storage battery and its ability to hold a charge that may be relied on for a given period. The Hubbell storage battery has plates of silver and cadmium which are submerged in alkaline solution and then charged at the rate of 1 ampere for 8 hours, with a direct current of from 55 to 600 volts

FIG. 1

A simple rule for determining the positive from the negative wires, if no special pole-finding paper is at hand, is to place the two terminals about $\frac{1}{4}$-inch apart in a glass of water, when hydrogen gas will be given off from the cathode wire that is the one from which the current is leaving the water, and which is called the negative pole or terminal.

Electric hand lanterns have not been very successful in mining work, owing to the battery plates, which for a time would render good service, suddenly going wrong, particularly after a period of idleness.

Unlike the lead plates of ordinary storage batteries the silver and cadmium plates are said not to be injured by overcharging, by the reversal of the charging current, by periods of long idleness, or by complete exhaustion. The method of charging the lamp from an ordinary electric light wire is shown in Fig. 1. Next in importance to the battery is the lamp. This must have sturdy filaments in order to withstand the shocks that are incidental to mine use and which the best of care may not always avoid. The Hubbell electric lamp bulb has a tungsten filament designed and anchored in such a way as to resist ordinary shocks, but the makers have not stopped here, and have equipped their lamps with a safety emergency bulb which can be utilized in case of the service bulb becoming injured or burned out. The filaments are further protected by a combination switch and rheostat, which has a series of resistance coils that increases the life of the electric lamps, because the current is applied gradually without sudden overloading.

FIG. 2

The most valuable feature in connection with the electric lamp in mines is that it will not, unless broken suddenly, set fire to gas. To avoid such firing the lamp bulb under consideration is so supported that should the "bull's eye" be shattered, the bulb would leave the supports before crushing, and, becoming disconnected instantly, allow the filament in the lamp to cool.

Mr. James Hillhouse, Chief Mine Inspector of Alabama, was so impressed with this lamp when used by members of the United States Geological Survey after the Mulga and Palos mine disasters that he became anxious to know more concerning them, although supplied with another make of electric lamp.

The lamp shown in Fig. 2 is designed for general use about the mine and for rescue work; when supplied with a holder, as in Fig. 3, it makes an excellent headlight for a motor, or tail-light for a trip. These lamps utilize a four-volt battery, weigh 5.5 pounds, and have a lighting capacity of 12 hours. Another smaller lamp is made that weighs 3.25 pounds, has a two-volt battery, and a lighting capacity of 12 hours. The cost of operation of these lamps compared with gauze safety lamps is less than one-half; at the same time they are the safest safety lamps, and can be used with helmets where gauze safety lamps would blow up or go out.

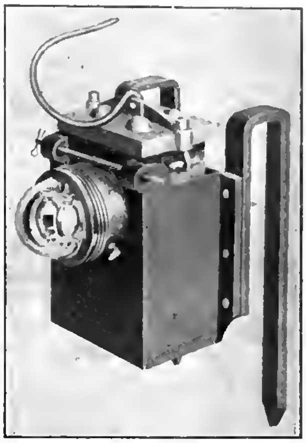

FIG. 3

A combination shot firer and lamp is shown in Fig. 4. This arrangement has a 6-volt battery of sufficient power to discharge five electric detonators simultaneously. By means of a red indicator light, the operator can from a position of safety ascertain whether he has an open or shut circuit, or a "hang fire," and is thus warned not to approach the blasting face.

The Hubbell lamps are manufactured by the Portable Electric Safety Light Co., Newark, N. J.

LUBRICATING BEARINGS OF HEATED ROLLERS

A certain manufacturer had an order for a machine that included three hollow gun-metal rollers, one weighing 1,386 pounds, the other two weighing 752 pounds apiece. These rollers are heated by gas to a temperature of about 700 degrees, and it was found that any oil or grease would carbonize and cut the journals in a very short while. In this predicament the use of graphite on the rollers was suggested. This was done, Dixon's flake graphite being used alone, and some months later the makers wrote the Joseph Dixon Crucible Co. that the scheme had met with perfect success.

FIG. 4

"The method of applying the graphite to the journals is very simple, the channels for conveying the lubricant to the journals are cut in the boxes about $\frac{3}{8}$-inch wide and $\frac{1}{4}$-inch deep, one on top and one at a little above and on each quarter. Besides this, a spiral groove of the same dimensions is cut for about two turns, commencing at about 1 inch from the other end of the box and near the bottom. These grooves are half round in section. Into the top straight groove, a $\frac{1}{2}$-inch pipe hole is drilled and tapped, a piece of $\frac{1}{2}$-inch pipe screwed into this with a reducing socket on the top end to $1\frac{1}{4}$-inch pipe. A $1\frac{1}{4}$-inch nipple with a $1\frac{1}{4}$-inch cap completes the cup. A piece of $\frac{3}{16}$-inch round C. R. steel with one end on the journal, with the other end up near the top of the cup, completes the device. The journals take about a dessert spoon full of graphite per day to each journal, the machine attendant occasionally removing the cap from the cup, churning down a little of the graphite with the $\frac{3}{16}$-inch rod." This experience may be valuable to readers of this matter in case they should meet a similar difficulty.

TRADE NOTICES

The branch managers and principal salesmen of the Taylor Instrument Companies held their annual "get-together" meeting July 11–13, inclusive, at the factory in Rochester, N. Y., reviewing general conditions in the thermometer industry and outlining new measures and policies for the coming year. Business for the past year has been most successful and although the present plant was occupied only in 1906, the growth has been so rapid as to necessitate material additions, to facilitate in the making and handling of "Tycos" products. A wood-working shop 100 ft. × 160 ft., a dry kiln, and a new wing being added to the main building, will make an addition of more than 40,000 square feet of floor space to the present plant.

The Wagner Electric Mfg. Co. announces the removal of its Charlotte, N. C., office to the Woodward Building, Birmingham, Ala., to be in charge of Mr. J. F. Jones.

The C. O. Bartlett & Snow Co., of Cleveland, Ohio, have leased the property recently vacated by the McMyler Mfg. Co. near their present works. It consists of buildings, yards, trackage, and complete power plant; and additional machinery is now being installed. The property is situated in the center of the city, and contains 76,000 square feet of floor space.

The Nelson Iron Works, of Nelson, B. C., has taken over the business and stock of the Rossland EngineeringWorks, of Rossland, B. C., and will succeed that company as British Columbia agents for the Sullivan Machinery Co., of Chicago. An increased stock of Sullivan rock drills, diamond drills, hammer drills, air compressors and supplies for these machines will be maintained at Nelson.

Factories, barns, etc., are probably more at the mercy of burning sparks and embers than other types of buildings, because they are usually covered with so-called ready roofings, and nearly all roofings of this type are made of wool felt, rag stock, paper, coal tar, and other highly inflammable materials. There is one roofing of this type, known as J-M Asbestos Roofing, which seems to overcome the objections to all others of this type. It is said to be so fireproof that it will withstand the flame of a blow torch for an hour without being injured. This roofing is made by the H. W. Johns-Manville Co., of New York, well known as manufacturers of asbestos products.

At the annual meeting of the stockholders of the Joseph Dixon Crucible Co., the old board, consisting of Geo. T. Smith, William Murray, William H. Corbin, Edward L. Young, Geo. E. Long, William H. Bumsted, and Harry Dailey, were unanimously reelected. The board of directors reelected the former officers; namely, Geo. T. Smith, president; William H. Corbin, vice-president; Geo. E. Long, treasurer; Harry Dailey, secretary; J. H. Schermerhorn, assistant treasurer and assistant secretary. William H. Corbin was also reelected as counsel.

The Jeffrey Mfg. Co., of Columbus, Ohio, has changed the location of its Denver office to rooms in the First National Bank Building. This company also maintains a corps of engineers at its branch offices in Chicago, St. Louis, Denver, Montreal, Pittsburg, Charleston, W. Va., Boston, New York, and Birmingham. There are also nearly 100 Jeffrey agencies in other cities in the United States and abroad.

The Western Electric Company reports that during the past twenty months it has sold over a quarter of a million of the No. 1317 type rural telephones. This is an unprecedented figure for these sales, and it is a certain indication that the rural telephone movement is progressing rapidly.

The Pan American Mining Company, which has offices in Philadelphia and mining properties in Dutch Guiana, S. A., is doubling the capacity of its concentrating plant. Allis-Chalmers Company furnished the Tremain steam stamps for the original plant and has orders for additional equipment.

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED JULY 5 TO JULY 26, 1910, INCLUSIVE

No. 963,611. Door for mines, quarries, elevator shafts, etc., Charles Matthews, Pittsburg, Pa.

No. 963,721. Ore cleaner, Alexander McDougall, Duluth, Minn.

No. 963,488. Ore-sizing apparatus, Charles Pierce Watterson, McGill, Nev.

No. 963,111. Process of treating precious metal-bearing materials, Paul W. Avery and Eugene C. Knowles, Deadwood, S. Dak.

Nos. 963,277 and 963,278. Ventilating apparatus, William Clifford, Jeannette, Pa.

No. 963,416. Extraction of zinc, Charles Skinner, Brand, Troon, Scotland.

No. 964,444. Centrifugal coal separator, Nelson Mowery, Wilkes-Barre, Pa.

No. 964,219. Waterproof fuse cap, Thomas M. Daniels, Chicago, Ill.

No. 963,787. Mine-ventilating system, David R. Martin Opelika, Ala.

No. 964,261. Ore classifier, Frank G. Janney, Salt Lake City, Utah.

No. 964,083. Ore concentrator, Lucien I. Blake, Boston, Mass.

No. 964,425. Ore concentrator, John F. Isbell, Salt Lake City, Utah.

No. 964,024. Ore-grinding machine, Charles R. Hotchkiss, Oakland, Cal.

No. 964,183. Rock crusher, De Witt C. Prescott, Chicago, Ill.

Nos. 964,429 and 964,430. Process of transferring material from a high to a lower level and piling the material, Arthur C. Johnston, Wyncote, Pa.

No. 964,733. Automatic car lock for mine cages, Julius H Alpenfels, Denver, Colo., and Harry A. Williams, Deadwood, S. Dak.

No. 964,635. Coke retort oven, Victor Dominique Fernand Fieschi, Douai, France.

No. 965,069. Process for making fuel briquets, Eugene Bonstein, Shickshinny, Pa.

No. 964,652. Hydraulic ore concentrator, John G. Kirksey, Milwaukee, Wis.

No. 964,567. Ore-separating machine, Aaron G. Seberg and Edwin G. Seberg, Racine, Wis.

No. 964,870. Treatment of ores, Charles Morris Johnson, Avalon, Pa.

No. 964,875. Rock drill, Harry Johan Hjalmar Nathorst, Gellivare Malmfalt, Malmberget, Sweden.

No. 965,054. Rock-drill extractor, William Edgar Weeks, Salt Lake City, Utah.

No. 964,605. Feeding mechanism for rock drills and the like, George R. Bennett, Denver, Colo.

No. 965,115. Rock-gathering machine, Charles C. Moore, Carthage, Mo.

No. 965,500. Miner's candlestick, Daniel B. Beaton, Cottonwood, B. C., Canada.

No. 965,808. Apparatus for testing drill holes, Matthias Garvey, Mineville, N. Y.

No. 965,760. Device for thawing explosives, George S. Sneer, Silverton, Col.

No. 965,830. Ore crusher, Isaac Lemon Mitchell, Cedar Rapids, Iowa.

No. 965,767. Fluid-distributing pipe for ore-treatment vats, Charles Edwin Draper Usher, Johannesburg, Transvaal.

No. 965,714. Process for extracting or separating precious values from ores, James S. Island, Toronto, Ontario, Canada.

No. 965,294. Jigging machine for dressing ores, Henry Richard Hancock, Burnside, South Australia, Australia.

No. 965,474. Rock drill, Edwin M. Mackie and Percival F Doyle, Franklin, Pa.

Mines and Minerals

Vol. XXXI—No. 3. SCRANTON, PA.—OCTOBER, 1910—DENVER, COLO. Price, 25 Cents

HYDRAULIC AIR COMPRESSION

Written for Mines and Minerals, by E. B. W.

It is now possible to supplement the article by C. H. Taylor in the April, 1910, issue on "The Cobalt Hydraulic Air Compressor," at Ragged Chutes, in the Montreal River, Canada. The principle on which the plant is constructed and the details of its construction having been fully described, it is the intention in this article to furnish information on this kind of air compressor which has not previously been given.

Further Particulars in Regard to The Hydraulic Air Compressor at Ragged Chutes

Hydraulic air compressors, being designed for the purpose of furnishing a predetermined quantity of air at a definite pressure per square inch, are calculated with the same degree of care which the mechanical engineer uses with a machine compressor. In the design of the hydraulic plant the engineer must include the quantity of water needed to entrain the desired number of cubic feet of air per minute; the diameter of the shafts; their different depths necessary to furnish the desired pressure and proper working conditions; the air chamber and its relative height with reference to the shafts, quantity of air compressed, blow-off and air-pipe connections; the diameter of the main pipe line and branches, relative to friction in the transmission of compressed air, and the consequent reduction in pressure.

There are matters which the engineer is unable to calculate, which nevertheless he knows will occur and must be anticipated in the design. He makes allowance for variations in the lengths of pipe due to differences in temperature; he attempts to regulate the shrinkage in the volume of air due to extreme cold weather; and the variations in the quantity of aqueous vapor in the air, etc.

In Fig. 1 is shown the spillway of the dam over which the surplus water flows. It is 660 feet long, constructed of concrete, and when it is remembered that the location is in the wilderness, where supplies must be delivered in the summer, the engineer at least will realize in a measure a few of the difficulties with which Mr. Taylor had to contend. The supplies were hauled on rafts up the river by gasoline boats, and some remarkable feats in transportation were performed in this way. The 20-inch pipe at the surface connecting with the air chamber 351 feet below ground is shown in Fig. 2. This is a seamless flanged steel pipe made in Germany, in 40-foot sections, and is extra strong, weighing 75 pounds per foot. No pipe line constructed without regard to the wide differences in temperature in Canada could survive a season, therefore concrete piles are constructed at intervals along the line to which the pipes are anchored, and between which expansion joints are placed. The valve on this 20-inch line which governs the flow of air is also in evidence in Fig. 2. The air flows through 9 miles of 20-inch diameter pipe from which there are two 12-inch diameter service mains, one of which circles the town of Cobalt, while the other goes out to the Nova Scotia Mine. At a point about 7 miles from the compressor, at the Waldman, another 12-inch pipe line branches to the Kerr Lake district. A 6-inch line also extends in the Gillis Limit from the Waldman to the Red Jacket on the other side of the main track of the

Fig. 1. Spillway and Dam at Ragged Chutes

Fig. 2. Air Pipe Line from Compressor

T. & N. O Railway. The tendency of aqueous vapor to saturate air during extremely cold weather is sometimes an aggravation to the users of compressed air, and to obviate this difficulty Mr. Taylor has altered the head pipes, with the result that there is practically no moisture shown at the exhaust of the machines, and hence the danger of freezing in winter is remote. In the first few days the air was turned on, it shut down 15 steam-driven compressors, and more will undoubtedly follow, as one

Fig. 3. Blow-Off from Compressor

mine manager finds that his power bill per month has been reduced $2,300. Mention was made of the blow-off when air accumulates above a certain pressure in the air chamber. In Fig. 3 this safety arrangement is shown, spouting water to a height of probably 150 feet, although under full pressure it spouts as high again. Another view of the valves at the junction of the discharge with the main air pipe is shown in Fig. 4. The concrete piers to which the pipes are anchored from time to time are constructed about on the plan shown. The blow-off is seen spouting to the rear of Mr. Taylor, the designer. Previous to the Ragged Chutes plant several other hydraulic compressors were designed and put in operation.

The first plant installed by Mr. Taylor was at Magog, Quebec, when in 1895 a 155-horsepower hydraulic power plant was built to supply power for the textile business.

The second was at Ainsworth, British Columbia, 2 years later, when a 550-horsepower plant was installed to supply hydraulic-compressed air for mining purposes. Then, in 1899, at Peterboro, Ontario, for the Dominion Government, Mr. Taylor erected the lift-lock dam, at which 45 horsepower of hydraulic-compressed air was used.

Two years later, at the Victoria mines in Michigan, Mr. Taylor installed what was his most ambitious and greatest undertaking in the hydraulic line until he came to Cobalt to harness the Montreal River. At Victoria a 500-horsepower hydraulic plant was put in operation and has worked with splendid success from the day that the water was first turned into the gigantic tunnel.

On a visit to Montreal over 4 years ago Mr. Taylor heard of Cobalt and after investigating the mining possibilities there and the probable need of power, he was convinced that Cobalt's mining proposition would need a large power plant, and he only waited until the development of the mining industry here had demonstrated the need for power. The Cobalt plant develops 5,500 horsepower and with a reserve capacity available will actually supply [illegible] 1,000 horsepower more than this amount if necessary.

The pressure of 120 pounds per square inch is so high it is not practicable to turn on the full force of the air at the mines until a reducing valve has been put in. The force of the air was shown when the different sections of the 20-inch main were "blown out." The valves were opened and a piece of boiler plate fixed in the opening, when all sorts of articles such as horseshoes, pieces of scrap iron, monkey wrenches, etc., hit the boiler plate with the force of bullets, cutting deep gashes.

The one apparent defect in the air delivered from the hydraulic compressed-air plant is that whenever the air is turned off underground the candles go out.

In regard to the difficulty experienced in keeping alight candles in the air supplied by the Cobalt hydraulic air compressor, a letter has been received from Mr. Geo. Hooper, Superintendent of the Victoria Copper Mining Co., Victoria, Mich., where all drills are run by air supplied by the Taylor system. The letter was written to Mr. Hugh Park, manager of the Nipissing, who had requested information on the subject. The following is an extract:

"I may say that since we have been using this air we have never had a man affected in any way by it. When we were using mechanically compressed air we were bothered continually by men being 'knocked out.' We have been working a stope during the past year 2,000 feet deep and 1,000 feet from the shaft, and stope is 100 feet high and 500 feet below ventilation, yet we have absolutely no complaint from the men on account of the air. The writer put in 5 hours on the third level without the least difficulty. Our pressure is 116 pounds per square inch and air conditions must be about the same. We have drifts and cross-cuts that are breasted over 2,000 feet from the shaft, so you can readily see why I say that your men must draw on their imagination.

"The only complaint we have to make is on the light question. I trust the 'Sunshine' will particularly relieve your difficulty and if your men receive any injury from the air you will be having a different experience from what we have had and I do not know where you can find a mine as deep as ours without ventilation."

An analysis of the air from the compressor made at Mon-

Fig. 4. Air-Pipe Valves and Anchorage

treal showed 17.7 of oxygen against 20.6 and 20.8 in the ordinary air of the laboratory in which the test was made.

An analysis made by Dr. J. T. Dunald, of Montreal, Official Analyst of the Dominion Government, of samples of compressed air marked "Buffalo Mine," received from Cobalt Hydraulic Power Co., May 30, 1910, gave oxygen, 17.7 per cent.; carbon dioxide, traces; nitrogen, 82.3; total, 100 per cent.

Various devices are being tried in place of candles. An

oil called "Sunshine" is being used at the Coniagas in lamps with two burners specially designed, and acetylene lamps are also popular. No difficulty is experienced in mines that are well ventilated and the trouble with the lights is only felt in long drifts and cross-cuts and in the top of stopes.

The theory of hydraulic compressors was made the subject of a paper before the recent International Mining Congress, from which the following is abstracted. The author is P. Bernstein, of Cologne:

"Water is passed from some source at level L_1 through a nozzle, which carries air, into a fall pipe and down into an air chamber, in which, at level L_2, the air separates from the water into the air chamber to escape through a special pipe. The water rises in the air chamber in which the fall pipe is placed, to the level L_3, at which point it is discharged. If the whole level difference is $H=L_1-L_2$, $p=L_3-L_2$, and $h=L_1-L_2$, so that $H=h+p$, then p is the pressure under which the air column stands. For a given head H, the head h and pressure p can be varied, and the pressure in general is not dependent upon the head of water; a large pressure could be obtained with a small head." The paper described experiments conducted by Professor Gutermuth, and the author, at Darmstadt, and also installations made by the Wasserkraft-Druckluft Syndikat, of Mulheim-on-the-Ruhr.

The nozzle used in these experiments consisted of a funnel surrounded by a ring pipe connected with the funnel by three rows of small radial tubes, and the air was taken up through small vertical tubes rising from the ring. The efficiencies were calculated for isothermal and for adiabatic expansion; the latter efficiency sometimes exceeded 90 per cent. Other experiments were made in installations of the firm in the Harz Mountains and elsewhere; in one of these—in the Victor colliery, near Rauxel—the discharged water had to be pumped up again. The air was free from oil and dust, and less wet than the air from mechanical compressors, because the compression took place under continuous natural cooling; and the author showed by comparative estimates that these simple compressors worked far more economically than plunger compressors driven by turbines, and compressors driven by electric motors in hydro-electric plants.

RECLAIMING ZINC-LEAD FINES

Written for Mines and Minerals, by Lucius L. Wittich

Sludge from a zinc and lead concentrating plant of 150 tons capacity per shift, containing less than 1½ per cent. of zinc blende and no galena, is treated successfully on a miniature jig operated by the inventor, L. B. Hunter, who has his remarkably small contrivance located near a roadway on the C.W. Squires land in the Galena, Kans., district.

While only a working model, the undersized jigging apparatus has a record of cleaning 200 pounds of concentrates in 8 hours time, and Hunter says he could make a comfortable income from handling dirt running 8 or 10 per cent. in ore. Candy and tobacco buckets are used as ore bins, the illustration showing that the bins are almost as large as the jig. The working principle of the Hunter model is different from anything else in the district, excepting the old style hand jig. In this model the principle of gravity jigging is obtained by an upward and downward movement of the cells, not the water, as is the case in the steam jigs of the district. In the steam jigs the movement of the water is the result of the action of plungers or pulsators; in the Hunter jig a similar effect is obtained, the inventor claiming, however, that his jig can be operated with less motive power, the cells being balanced. A full-sized jig, he states, can be operated with ease by a person turning a crank. In the illustration the crank is seen at the left-hand corner of the jig. As no effort has been made to manufacture the jig on a large scale the inventor is contenting himself with treating the slimes and sludge on the Squires land, selling an occasional bucket of concentrates and affording boundless entertainment for the throngs that visit the tiny plant which is considered the most unique mining venture in the district.

An assay of the concentrates of the Hunter jig showed zinc blende 54.80 per cent. with 1.5 per cent. of iron. Considering that the Galena camp blende at its best rarely exceeds 58 per cent., the percentage of recovery from the sludge is considered a rather remarkable showing.

The miniature jig consists of 4 cells, two on each side of a stationary shaft. No matter how great the load on the screens the cells are evenly balanced at all times and the power required to operate them, therefore, is reduced to a minimum. Cross-bars, balanced on the stationary shaft, extend to a revolving shaft on which are attached eccentrics. The cells are suspended from these cross-bars, while the vertical movement is obtained by the eccentrics on the revolving shaft, an alternate motion being given as the crank is turned. The two rougher cells are located at the upper end of the jig, the cleaner cells at the lower end. An equal amount of dirt is supplied to each set of cells. Each cell is 16 inches long by 10 inches wide, with $\frac{15}{16}$-inch strips of sheet iron set vertically across the screen, which is of one-millimeter mesh. The cross-strips, which are 4 inches apart,

Hunter Jig, Galena, Kan.

hold the mundic, or iron ore, bedding in position while the concentrates sink through to the hutch, from where they are drawn off. As many cells as desired may be used. The inventor says four are sufficient for ordinary purposes.

Only dirt that will pass through a one-millimeter mesh is used on the jig as it now is operated, although on a larger model much coarser material might be handled. Passing through the fine-mesh screen the dirt is fed on to the cells through a sluice. There also is a water feed from a launder above, leading from a barrel, to be regulated as required. The rise and fall of the cells when in operation is ¼ inch; the speed of operation being quickened or retarded at will. The screens in the cells are detachable and may be changed at a moment's notice. The flow of water from cell to cell is protected by canvas connections. The overflow is discarded as tailing.

The jig tanks, which may be of any size or shape, are held in position by 2″×2″ timbers.

TIN MINING IN CHINA

Consul George E. Chamberlin, of Swatow, learns that a company with a capital of 2,000,000 taels ($1,146,000) has been formed in Yunnan, China, to develop the tin mines of that province. Under the old system some 360 tons of ore has been mined annually, but with machinery it is expected that 30 to 40 tons of ore per day can be taken out.

PUMPING AT BISBEE, ARIZONA

*Written for Mines and Minerals, by C. C. Austin**

The development of mine pumping within recent years has brought about some interesting engineering problems. It must be remembered that in all underground work the engineer is hampered by close quarters. Much of the machinery must be specially designed to meet the conditions; there must be no part of any machine too large to go down the shaft and through the drifts to its place. Arrangements must be made to keep the pumps running continuously, as the flow of water into a mine is continuous and would soon overflow the workings, if not disposed of.

The Junction Plant of the Superior and Pittsburg Copper Co.

One of the most notable undertakings in this line of engineering is the installation at the Junction shaft of the Superior and Pittsburg Copper Co., at Bisbee, Ariz., of one of the largest high-duty mine pumping stations in the world. It has a normal capacity of 7,200,000 gallons in 24 hours against 1,000 feet head, with provisions for 2,160,000 gallons additional when needed. The station, piping, and accessories were designed and erected under the supervision of Mr. W. E. McKee, the company's superintendent of machinery.

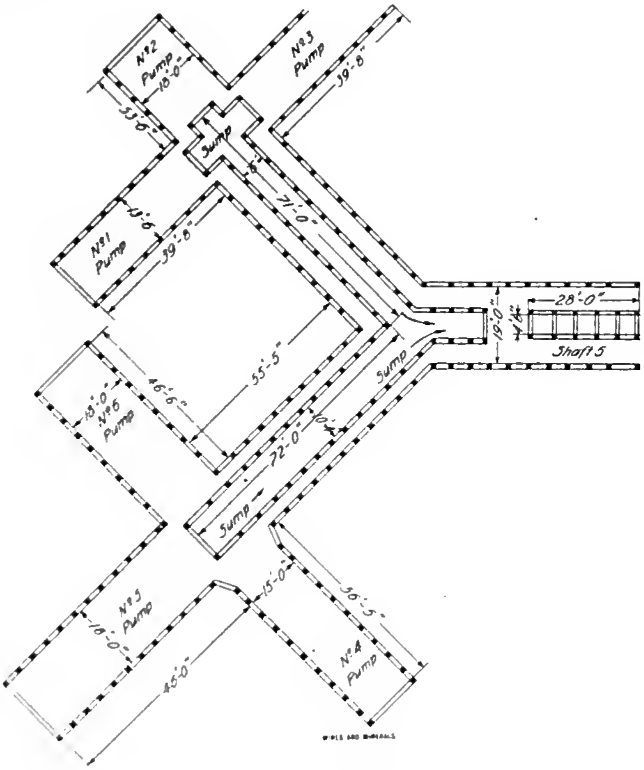

Fig. 1. Plan of Pumping Station, Junction Shaft

The plant was designed to pump the water from the Briggs, Hoatson, and Junction mines. The lower head against which this water may be pumped at the Junction and the economy in the operation of one large station instead of several small ones led to the construction of the large Junction station. From the Briggs and Hoatson, the water runs by gravity in a flume through the drifts to the Junction, where it is pumped to the surface. The collar of the Junction shaft is 124 feet below that of the Briggs and 150 feet below that of the Hoatson; thus the economy of this common station can be readily seen.

Fig. 1 shows the plan of the station, the peculiar arrangement of the pumps being used because it facilitates the superintendence of their operation. Pumps Nos. 1, 2, and 3 are direct-acting pumps which have been working since April, 1907, while Nos. 4 and 6 are crank and flywheel pumps which were erected in September, 1907. No. 5 will be installed when needed, furnishing the additional 2,160,000 gallons capacity mentioned before. The drifts lead from the main entry at 45 degrees in order to minimize the loss resulting from right-angled turns in the water columns. The sump extends from a point 10½ feet from the shaft to where it divides, one branch going to each set of pumps. It is 7 feet deep and holds 65,000 gallons.

Pumps Nos. 1, 2, and 3 are triple expansion and direct acting, with 15-, 23-, and 39-inch steam cylinders, 10-inch water cylinders, and a 24-inch stroke. Pumps Nos. 4 and 6 are of the crank and flywheel, cross-compound, Corliss-engine type with 20- and 38-inch steam cylinders, 6½-inch water cylinders and a 36-inch stroke. The duty of the direct-acting pumps is 80,000,000 foot-pounds, while 100,000,000 foot-pounds duty is obtained from the crank and flywheel pumps. Pumps Nos. 1, 2, and 3 are jacketed on the intermediate and low-pressure cylinders, but the low-pressure cylinders of the crank and flywheel pumps have jacketed heads only, because with jacketed cylinders, they could not be taken down the shaft. Each unit has a capacity of 1,000 gallons per minute, the direct-acting pumps running at 31 revolutions per minute and the crank and flywheel pumps at 48½ revolutions per minute. Each pump has a 25-per-cent. overload capacity, making a total available capacity of 6,250 gallons per minute, and for a short time, these pumps could all be run at 50-per-cent. overload. This heavy overload capacity is necessary in mining work as a heavy flow of water may be encountered at any time.

The steam piping of this station differs from that ordinarily used. In general practice the steam pipes are placed in the shaft and along the roof of the levels to the pumps; with this arrangement at the Junction, however, the large number of steam pipes required would make the station almost unbearably hot. To avoid this the steam pipe was placed in the shaft to a point 50 feet above the station. Drifts were then driven from here to points directly over pumps Nos. 1, 2, 3, and 4, and duplicate steam lines were run down to each throttle valve. Besides disposing of the heat on the station, which it does admirably, this plan creates a circulation of air through these drifts and raises, and keeps the air fresh.

On all the pumps jet condensers are used. The crank and flywheel pumps run their own condensers, which are 11 in. × 36 in. while the other condensers are independent of the pumps. The independent condensers are 12" and 20" by 18" and run at about 25 revolutions per minute, providing a vacuum of 20 to 22 inches when the barometer on the station stands at 25 inches. The condenser injection pipes are made about 18 inches shorter than the pump suction pipes. Then, if for any reason, the water in the sump should get low, the condensers will take air and the added back pressure on the exhaust will stop or slow down the pumps before any damage is done.

The system of steam piping used on these condensers is unusual. Instead of exhausting into the vacuum they exhaust into the low-pressure steam chests. This is not done to increase the economy of the pump, although it does so slightly, but to prevent excessive wear on the water valves and springs of the condenser. The pump cylinder never fills completely with water, and with steam pressure on one side of the piston and a vacuum on the other, the water piston moves back very quickly and strikes the water with sufficient force to wear out the water valves and springs rapidly. When exhausting into the low-pressure steam chests, however, the back pressure on the steam piston prevents this shock and considerably lengthens the life of the springs and valves.

Some features of the water columns are unique. Before installing the new pumps, two 8-inch pipe lines reached from an abandoned pump station on the 770-foot level to the surface. It was decided to extend them down to the new 1,000-foot level, join them at the bottom, and use them as one of the three necessary water columns. This junction was made by means

*629 N. Russell St., W. Lafayette, Ind.

of a peculiarly shaped special fitting which joins the columns, supports them, and receives the flow from a 12-inch pipe coming directly from one of the pumps. Twelve-inch pipe lines were then laid from pumps Nos. 1, 2, and 3 to the shaft, one emptying into the fitting mentioned above, as shown in Fig. 2, the other two extending to the surface. Each of these 12-inch column pipes had to receive the discharge from one other pump as there is not room in the shaft for a separate column from each. These lines had to join the first without tees to avoid the loss of head resulting from right-angled turns. Forty-five-degree **Y**'s with the branches turned down at 65 degrees and 32 minutes, shown in sectional view, in Fig. 2, and a 45-degree fitting bolted to each branch was put into each line. This arrangement allowed the pipes to be laid to Nos. 4, 5, and 6, and avoid sharp turns. The complete system of water columns and valves, shown in Fig. 2, will make plain how any column can be cut out and drained for repairs while the discharge continues through the other two. Check-valves are put into the discharge of each pump to obviate the necessity of opening and closing the 12-inch hydraulic valves near the roof.

No arrangement of valves or piping needs to be made on pumps Nos. 1, 2, and 3 for expansion, as the water ends of the pumps are anchored and the steam ends are on rollers. Owing to the shape of the crank and flywheel pumps, the steam ends are anchored and the provision for expansion, which is about ⅜ of an inch, is made at the water end. When pump No. 5 is installed, the valves and fittings for pumps Nos. 4, 5, and 6 will be arranged the same as for the direct-acting pumps in order to avoid the use of a cross at the junction with the water columns.

Hydraulic fittings tested to 2,000 pounds pressure are used throughout, while the extra heavy pipe is used from the pumps to a point 550 feet up the shaft, and standard pipe for the remaining 450 feet.

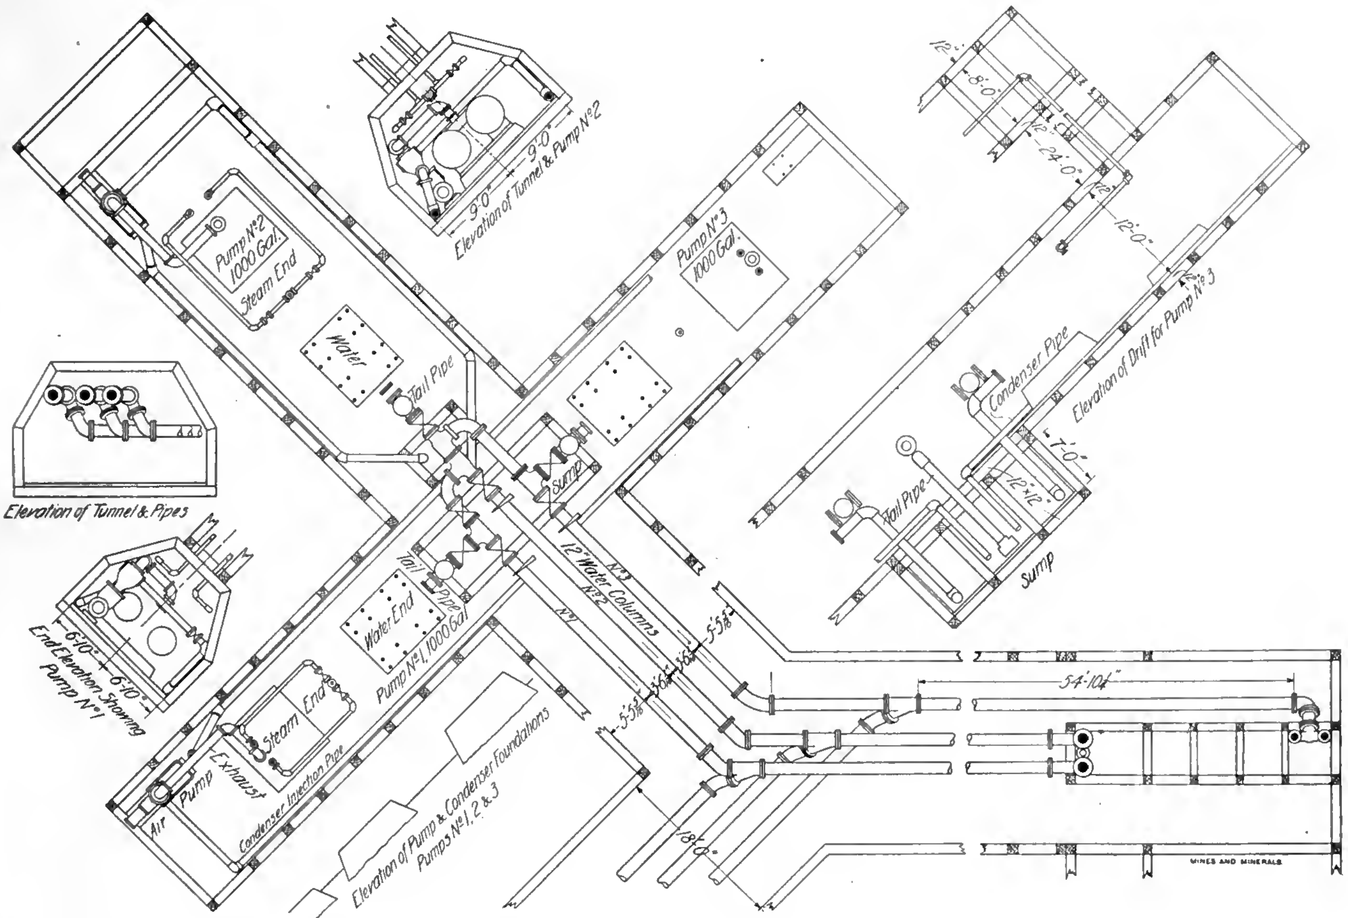

Fig. 2. Plan of Piping, Junction Shaft

While no unusual arrangement is used for supporting the water-column pipes in the shaft, the expansion and contraction of the steam pipes has required the installation of expansion joints. The latter are similar to those in use at the properties of the Oliver Iron Mining Co., of Duluth, Minn., and manufactured by the Imperial Iron Works, of Duluth. Fig. 3 shows the detail of the joint and the method of supporting it from the shaft timbers. We are indebted to Mr. H. J. Wessinger, chief engineer of the Oliver company for following data and illustration: "A joint is placed with the fixed end up so that each expansion joint supports and takes care of the expansion for the 200 feet of pipe above it. The first joint is placed 10 feet from the shaft collar to reduce the distance to the horizontal line leading to the boiler house. This arrangement is the fruit of experience in several bad breakdowns caused by omitting this joint and making the second joint do the work. The pipe expands 4 inches to 6 inches, causing the horizontal pipe to leave its supports. If blocking is then put under the pipe while it is hot there is no chance for the pipe to contract when steam is shut off, and

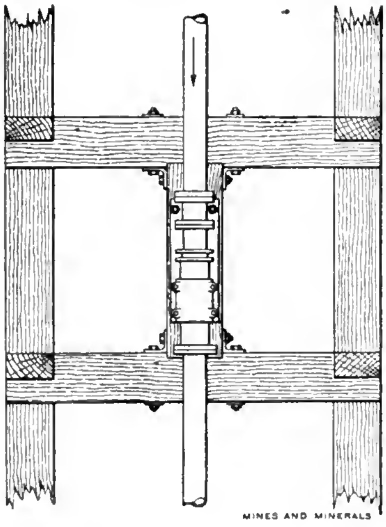

Fig. 3. Expansion Joint

it breaks usually causing the pumps to drown. By placing the top joint near the collar, the expansion to the horizontal line is reduced to less than ½ inch, making it impossible to block the pipe so that it will break when steam is shut off."

The station has been in complete operation since about the first of January, 1908, and is being watched with interest by all mining men who are confronted with the problem of handling large quantities of water.

OIL NOTES

State Mineralogist Lewis E. Aubury has, through the Mining Bureau of California, commenced to use the "Big Stick" on illegitimate oil companies, or those who strike oil by selling stock. Concerning this matter, he says: "We are determined that investors in California mines and oil wells shall be protected from the parasites which attach themselves to the industry. With this end in view, we propose to give the fakers all the publicity possible, and to cooperate with persons who have purchased stock in these companies, and to punish the offenders."

Mr. Aubury wishes to remind the purchasers of stock in these fake companies that he will not permit the State Mining Bureau to be made a collection agency—after they become aware that they have been "fleeced." The average person who has been duped is interested in only one phase of the question—the return of his money—not in the criminal prosecution of the faker.

"There is not one chance in a million," said Mr. Aubury, "of recovering a cent from these fakers, and there is only the satisfaction of placing them behind the bars, but this course remains for the person who has been swindled, and is one which is hardly ever adopted."

He calls attention to the Illinois Oil Bond Co., Chicago, the Paxton Gold Bond Co., Paxton, Ill., and the Wisconsin Gold Bond Oil Co. These were Arizona corporations, and were advertised as non-assessable, though it is well known that in California any corporation, foreign or domestic, may be assessed, and as a matter of fact, these, as well as the later corporations, were assessed out of existence. The Gold Bond part of the name refers to 3-per-cent. 30-year guarantee bonds which were offered to stockholders, but whether any of these bonds were called for, and if so what has become of them, cannot be determined. One of the companies supposed to issue these bonds cannot now be located; the other refuses any information.

"The Illinois Oil Bond Co. drilled a shallow hole said to be less than 300 feet deep and abandoned operations in this state."

"The Wisconsin drilled a hole to a depth of 1,335 feet and got a little heavy oil. This well was abandoned."

"The Paxton drilled a hole 1,500 feet, getting a trace of oil at 500 feet, but nothing below. This well was able to produce a few barrels of oil at considerable intervals."

Oil mining is about as uncertain as any other kind of mining, but like gold mining there are possibilities if one is fortunate. Where a person's investment is employed to develop the venture there is nothing to be said against promotion, but where there is intentional fraud and grafting they should be dealt with severely.

Trinidad Oil Fields.—Consul Franklin D. Hale furnishes the following information concerning oil seeking in the West Indian island of Trinidad:

"Oil men from England and the United States are working in the interest of their respective employers. The southern half of the island is being investigated, and all reports therefrom are favorable for a field of from 500 to 800 square miles of oil-bearing territory, some of the oil experts say that the field in all probability will extend all the way under the Gulf of Paria and westward to the region of the 1,200-acre pitch lake at Guanaco, which is operated by an American company, and still further westward to the Gulf of Maracaibo Should these surmises prove true, this is undoubtedly one of the largest oil fields in the world.

"A $1,500,000 company, floated in London, has taken over the Canadian company's 25,000-acre oil property in the southwestern section of the island, and a dozen wells, 800 to 1,400 feet in depth, have been bored with satisfactory results, some being excellent producers, although efforts are being made to check their flow until facilities for exportation are completed.

"An American company, which has long operated the pitch lake, has been exploring for oil for some time, and is constantly extending its operations. It has a number of wells at depths of 900 to 1,400 feet, and although it has two steel tanks of 84,000 gallons capacity each and land reservoirs of great storage proportions, many thousands of gallons of crude oil have run into the sea, which is only a few hundred feet from the field of operation.

"Many other companies are organized and being organized to develop the oil fields, and private capitalists are securing concessions and buying property and mining rights for prospective development or on speculation. A company located near the city of San Fernando has not only fair oil prospects, but has discovered coal of excellent quality in unknown quantity outcropping in its property, samples of which have been sent to England for examination and test.

"Exploration work is in prospect everywhere in the island; wells are being bored in new districts, while in the old districts everything is being rapidly enlarged. Under such circumstances reports of all sorts are in circulation, such as oil being struck a few feet from the surface in many places, etc. Regulations for acquiring rights in the oil fields and governing the prospecting for oil, transmitted by Consul Hale, are on file in the Bureau of Manufactures."

It is estimated that $210,000,000 are invested in productive oil properties in California, and to date $31,500,000 have been paid in dividends. The greatest oil well probably in the world is in the Midway field and is known as the Lake View. Its first day's production was 47,000 barrels, and it is thought to have attained a maximum flow of 90,000 barrels subsequently for a few days; at the end of 4 months it flowed 25,000 barrels per day. It was drilled to a depth of 2,265 feet. It is estimated that the output of California oil will be 80,000,000 barrels in 1910, making that state the largest producer of oil. At present the production is about 80,000 barrels more than the demand.

The steamboats Yale and Harvard, running between New York and Boston, are using oil as fuel. It is thought that the change from coal to oil, with the corresponding decrease in labor, will save $5,000 monthly.

Petroleum in New York State.—The oil district in the southwestern part of the state continues to afford a fairly large yield, though it has long since passed the high mark of productivity. The pools of Cattaraugus County were first tapped in 1865, and those in Allegany County about 1878, since which times they have been actively exploited. Many of the original wells that were drilled over 25 years ago still give a profitable return for pumping. No important discoveries have been reported in ecent years, yet by redrilling of territory once abandoned as worthless and by gradually extending the bounds of the known pools the natural decline has been checked, so that a long career of activity may be confidently expected for the future.

The productive area in Cattaraugus County is situated principally in Olean, Allegany, and Carrolton townships, embracing about 40 square miles. The oil is found at depths ranging from 600 to 1,800 feet. The larger pools are the Ricebrook, Chipmunk, Allegany, and Flagstone. They occur in the Chemung formation of the Upper Devonian.

In Allegany County are the Bolivar, Richburg, Andover, and Wirt pools, which extend across the southern townships and are tapped by wells averaging from 1,400 to 1,800 feet deep. The Andover pool lies partly in the town of West Union, Steuben County. A recent estimate placed the number of productive wells in Allegany County at 6,000.—*New York Museum Bulletin 142.*

TUNNELING ON LOS ANGELES AQUEDUCT

Written for Mines and Minerals, by R. L. Herrick

Conditions Found and Methods Used in Breaking All American Tunneling Records

In recording the great engineering feats of the twentieth century, the historian will certainly mention the Los Angeles aqueduct. Its claim to greatness will be based not so much upon the complexity of the engineering problems as upon the magnitude of the work and upon the speed and economy with which it was conducted. For a proper conception of its magnitude, nothing short of a trip over its 217 miles of length will suffice; but a fair idea may be obtained by reference to the map, Fig. 1. Other great enterprises of the future may be as successfully terminated, but thus far in the history of American engineering, the Los Angeles aqueduct stands without a peer among the various enterprises of similar character. This holds true, not only of those portions of the work involving mining problems, but also of the greater portion of the aqueduct involving civil engineering.

In pushing the work on more than 100 tunnels, aggregating a total length of about 28 miles, the best previous world's record for driving in soft rock has been exceeded, while the hard-rock record for the United States has been six times exceeded, and a new record established on each occasion.

The aqueduct when finished will deliver an ample water supply to the city of Los Angeles sufficient for the future, even should it attain to more than a million population; the surplus water will be used for irrigation and the proceeds will go to the city treasury. The water will generate hydroelectric power at three separate plants for transmission to the city and surrounding territory. The proceeds from the sale of this power will likewise go to the city treasury, so that with the income from the sale of water and power, the aqueduct is expected, not only to pay for itself within a few years, but to pay all expenses of the city government thereafter, thus relieving its inhabitants of all except nominal taxation.

The difference in elevation of the aqueduct line from the ntake at the Owens River to the city at approximately sea level, is 3,800 feet.

While the total length of the aqueduct as first surveyed was 238 miles, this original location has been several times changed in order to shorten the line and cheapen construction. The third annual report of the Bureau of the Los Angeles aqueduct gives the aggregate length as follows:

	Feet	Miles
Unlined canal	111,200	21.06
Lined canal	803,711	152.25
Tunnels in rock	91,019	17.24
Tunnels in earth	58,508	11.08
Siphons crossing cañon	74,847	14.19
Flumes	9,050	1.72
Total	1,148,335	217.56

Minor changes have been made in the line since this report, but the above may be taken as approximately correct.

Those familiar with the region traversed by the aqueduct know that the country to the east of the Coast Range is a desert; however, to others the accompanying views will doubtless prove interesting. In approximately level stretches there is sandy desert, where the heat is excessive, the alkali and dust-laden winds almost intolerable, good water scarce, and transportation very difficult. The same things may be said in general of those mountainous portions of the line traversed by the tunnels, with the addition that such portions are doubly inaccessible, so that road building has been no small item chargeable to the expense of tunnel driving.

West of the Coast Range, however, the character of the country traversed is the direct antithesis, much of it being under cultivation and favored by a plentiful rainfall.

The work has been divided into 11 divisions, each with its conveniently located construction camp, in charge of a division

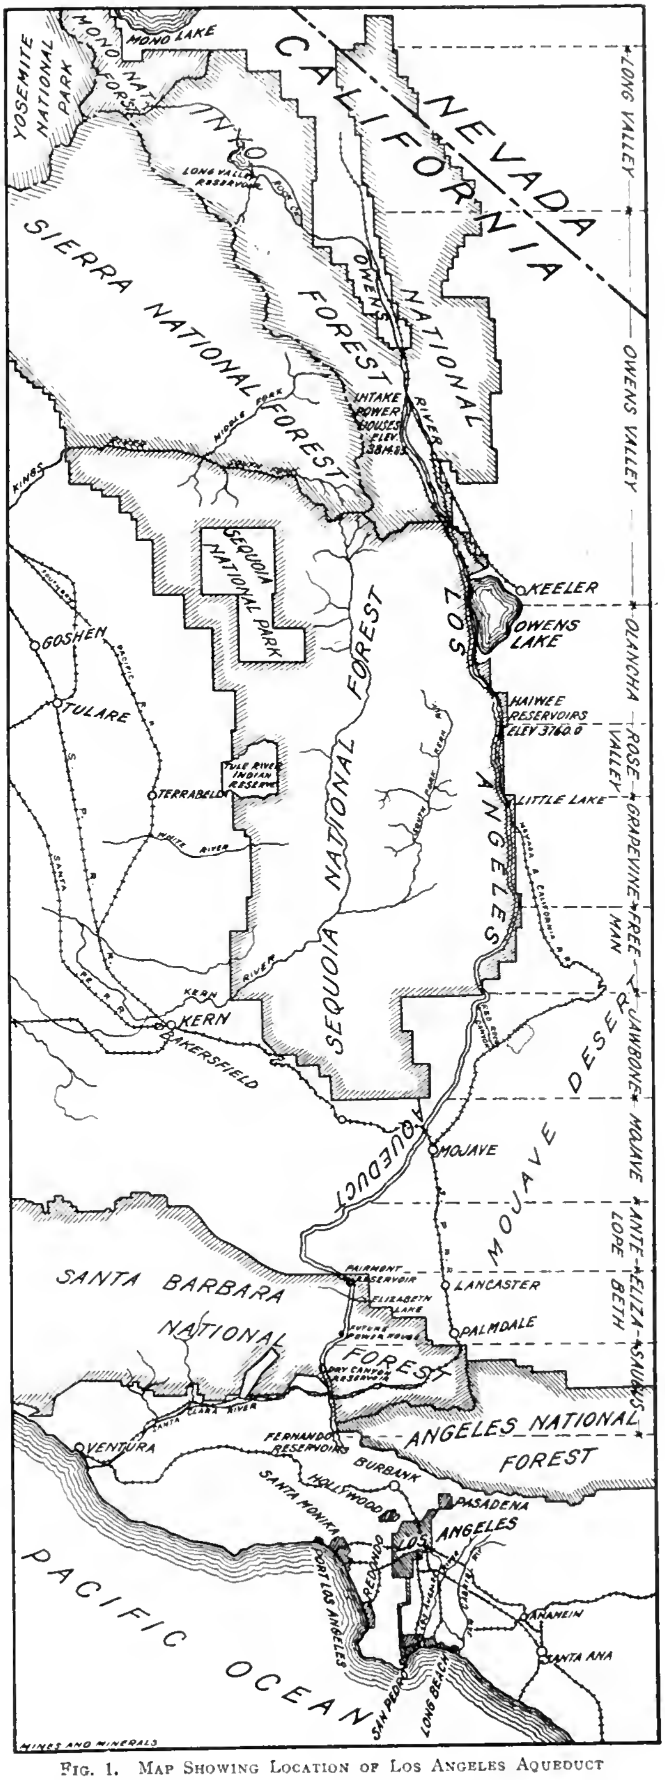

Fig. 1. Map Showing Location of Los Angeles Aqueduct

engineer. A railway has been built to parallel the aqueduct as closely as allowed by the contour of the country, and a complete telephone system connects all the camps and the main city office. Electric power transmission lines have also been built in to many of the camps, furnishing power for lighting and machinery. A pipe-line system likewise parallels the aqueduct, supplying water for the concrete work and domestic purposes. The cement for the concrete is supplied by three cement plants,

Fig. 2. Interior of Jawbone Tunnel

likewise constructed by the aqueduct commission, and they are sintering and grinding tuffs which outcrop at points adjacent to the plants. Four divisions of the aqueduct contain the majority of the tunnels. These, commencing with the most western, are the Saugus, the Elizabeth, the Jawbone, and the Grapevine.

Table 1 furnishes an idea of the magnitude of tunnel work.

Table 1

Division	Number Tunnels	Aggregate Length of Tunnels Feet	Longest Single Tunnel Feet	Kinds of Formation Penetrated	Boring Equipment	Status to Date
Saugus	30	54,040	San Fernando, 9,100	Compact sand and gravel formation free from water; also soft shale	Hand augers and hard drills	Completed
Elizabeth	2	26,860	Elizabeth Lakes, 26,860	Granite, schist, and gneiss	Machine drills	19,492 feet up to April, 1910, inclusive
Jawbone		59,448		Sand and gravel; cement; some granite largely decomposed	Hand work	Completed
Grapevine		40,350		Hard granite	Machine drills	

The tunnels were driven in hard rock only in the Elizabeth and the Grapevine divisions; in the others the formation penetrated was for the most part a sand and gravel cement with comparatively small extents of soft decomposed granite and soft black oil shales.

In soft-rock tunnels the world's best previous record for speedy driving, namely, 842 feet in 31 days, established at the Gunnison tunnel, has been exceeded.

The new record is 1,061.6 feet, established in the north portal of tunnel No. 17, Jawbone division, for the month of August, 1909, T. J. Flanigan, superintendent, and A. C. Hansen, division engineer in charge. An abstract of the official report in regard to this work shows there were 91 shifts with 9 men on a shift, and that these advanced the excavation 11.7 feet per shift through dry cemented sand and sandstone. The work was done by hand, using 4,450 pounds of 40-per-cent. dynamite and 2,372 pounds of black powder. The cost in dollars of the operation is given in Table 2.

Table 2

Classification	Labor	Animals	Supplies	Freight	Cost Per Linear Foot
Excavation.....	5,338.80	259.2	989.27	197.85	6.39
Timbering......			6.53*	1.30*	
Engineering	90.33				.06
Totals........	5,429.13	259.2	995.80	199.15	6.45

* Timbers under air shaft

This is ideal material in which to break records, for the ground can be rapidly drilled by hand augers, shoots fine, can be rapidly shoveled, and the walls stand without timbering for weeks, provided the roof is carefully arched. Fig. 7 gives a typical section of the tunnel driven in this division; Fig. 3 shows the kind of material excavated; Fig. 2 is a flashlight of the completed concrete-lined section; while Fig. 4 is a completed portal of the Saugus tunnel.

From this greatest speed record made in the most favorable material, we turn to examine into the records made in the next most favorable material—the black shale. Perhaps the best records in this material have been made in the second longest tunnel of the work, the San Fernando of the Saugus division, of which D. L. Reaburn is division engineer, and J. W. Henderson is superintendent. This tunnel, No. 104, has a total length of about 10,000 feet and was driven from the two opposite sides of the last barrier ridge of the Coast Range.

The first creditable record was made at the south portal under the charge of Foreman H. E. Warden, during the month of April, 1909. The arched section excavated had a width of 13 feet, and a height of 12 feet 3 inches. Using hand augers for drilling, and working 11 men per shift, 3 shifts per day, a total

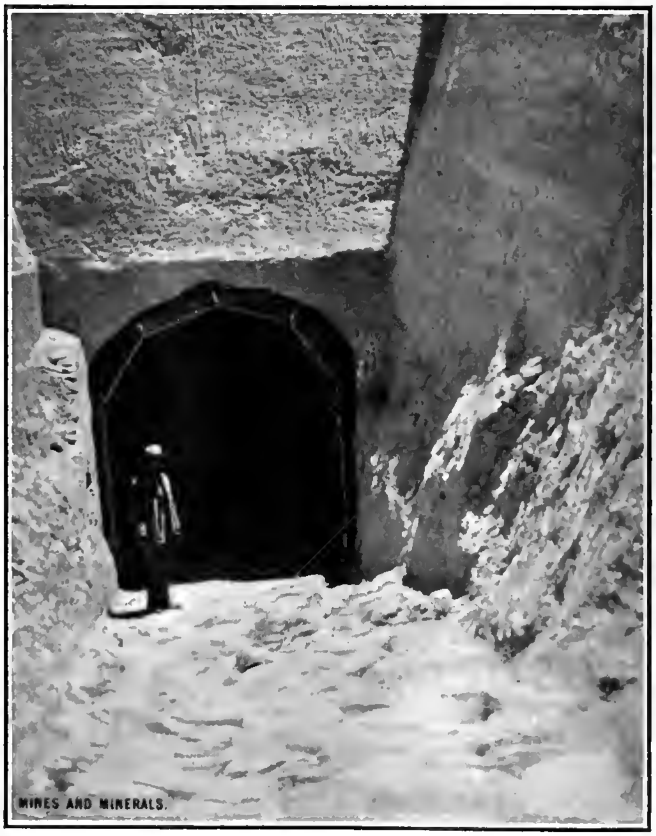

Fig. 3. South Portal, Tunnel No. 18, Jawbone Division

length of but 29 days, the progress made was 586.5 feet. The ground stood so well that the breast could be kept about 12 feet ahead of the timbers. The following were the total official costs per foot of advance, exclusive of concreting: Excavation, \$10.37; timbering, \$3.86; total, \$14.23.

In the following month of May, a record was made at north portal of this same tunnel, in charge of Foreman Sidney Dean, which everything considered is also very creditable. The ground at this end, however, was heavy and necessitated considerable retimbering as the breast was advanced. With other conditions similar to those already detailed at the south portal, the north portal heading was driven 579 feet in 31 days.

The effect of the heavy ground in increasing the costs over those of the south portal is seen in the following average costs per foot, exclusive of concreting: Excavation, \$14.11; timbering, \$5.45; total, \$19.56.

At both of these portals 40-per-cent. gelatin powder was used, of which about 10 pounds per foot of advance was the average consumption.

The crew at the faces on each shift consisted of a boss, 5 miners, and 5 shovelers.

Of the two aqueduct divisions containing hard-rock tunnels, namely, the Elizabeth and the Grapevine, the former has been the scene of all the record runs Up to October, 1908, the best previous American hard-rock record was held by the Gunnison tunnel—449 feet in granite for the month of January, 1908.

Table 3. Elizabeth Tunnel Records

No.	Month	Portal	Superintendent	Distance
1	October, 1908	South	Aston	466
2	March, 1909	South	Aston	474
3	September, 1909	North	Gray	488
4	October, 1909	North	Gray	547
5	April, 1910	North	Gray	561
6	April, 1910	South	Aston	604

Fig. 4. Portal of Finished Tunnel, Saugus Division

In October, 1908, however, the south portal of the Elizabeth tunnel established the new one month's record of 466 feet, and since that time this record as shown in Table 3 has been five times exceeded, till at the end of April, 1910, the record stood at 604 feet. It is noteworthy that this record now ranks fourth in the list of world's records, those ranking above it, all foreign records, being as follows:* Simplon tunnel, 755 feet; Arlberg tunnel, 641 feet; Albula tunnel, 607 feet.

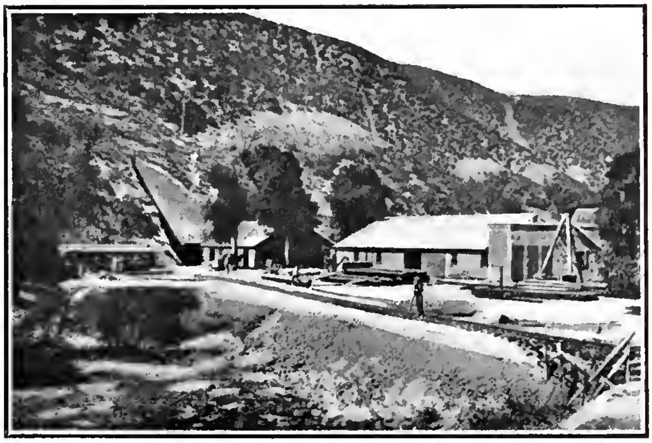

Fig. 5. South Portal, Elizabeth Tunnel

Construction work started on the tunnels of the Grapevine division early in 1909, and, everything considered, progress to date has been satisfactory. No records have as yet been established on this division, probably because the majority of the tunnels penetrate the hardest and toughest rock encountered on the aqueduct. This rock is very largely a tough seamless granite, very similar to the toughest of that encountered in the Cripple Creek drainage tunnel.

Fig. 9 gives a typical section of the excavation. Table 4 gives the costs in dollars of the best month's run up to the time of the writer's visit. In this tunnel the two shifts of 11 men

Table 4. Grapevine Tunnel. South Heading

Classification	Labor	Animals	Supplies	Power	Freight	Cost Per Linear Foot
Excavation	3,199.54	54.00	1,269.22	293.73	253.84	18.37
Engineering	43.64					.16
Timbering						
Totals	3,244.18	54.00	1,269.22	293.73	253.84	18.53

each succeeded in driving 9 feet per day, thus obtaining a bonus on 3 feet per day. There was 28.1 pounds of powder used per foot driven. While 270.5 feet is small progress as compared with the spectacular achievements on other portions of the line, everything considered, it is a very fair record for two shifts per day; besides, next to the Jawbone division, the Grapevine division work presents more difficulties than any other, due to its rugged contour, inaccessibility, etc. In the effort to ascertain ways of increasing progress on these tunnels, the division engineer, C. H. Richards, made the only carefully detailed study on the work which has yet been made on the aqueduct tunnels. The following is the report made by Mr. Richards on the work at the north portal of Tunnel No. 7.

As this is the only compilation of such detailed costs the writer has been able to secure, the report is published entire in the hope that, aside from the data given on aqueduct costs, it may serve as a model for other tunnel men:

*See "Tunnel Driving Records," Mines and Minerals, April, 1909 page 422.

Report on Tunnel Cost

The appended study covers unit costs of driving a timbered tunnel (North Portal, Tunnel No. 7) in the Little Lake subdivision of the Grapevine division of the Los Angeles aqueduct, Edward Comerer, foreman in charge; and the writer, C. H. Richards, engineer in charge of the division.

Ninety feet were driven in 15 eight-hour shifts, the period covered by detailed cost keeping.

The tunnel is approximately 10 ft. × 10 ft. in section; 3½ cubic yards in place per linear foot to pay line; overbreakage about 17 per cent., making a total of 6½ cubic yards of broken material per foot of tunnel.

The heading is in 800 feet, lighted by electricity at 110 volts, ventilated by a No. 3 Champion blower through 12-inch pipe, the heading being cleared in 15 minutes after shooting.

Drilling is done by one No. 7 Leyner drill, water being forced through hollow steel; drill uses approximately 66 cubic feet free air per minute at 83 pounds pressure per square inch, drilling holes to 10 feet in depth.

Mucking is accomplished by use of steel sheets laid down before shooting; No. 3 D-handle, square-point, shovels, and 32-cubic-feet rocker dump cars pulled by a 3½-ton locomotive, running on a 24-inch gauge single track laid with 25-pound steel.

The rock is a close-grained, hard, gray granite with numerous seams, causing the drill to run from alinement, but breaks well. The seams and water combined make it necessary to timber all this ground. The ground carries enough water to make disagreeable mucking, and has to be pumped out.

Timbers are of 6″ × 8″ Oregon pine, spaced 5 to 8 feet apart, as ground permits, lagged with 2″ × 6″ plank. Sets of timbers consist of two vertical posts and a four-segment arch.

Table 5. Labor Costs

Class of Work	Total Hours Labor	Total Labor Costs	Cost Per Foot of Tunnel
Inside Labor:			
Squaring heading	23.50	$ 9.03	$ .100
Setting up and tearing down machine	36.00	16.59	.184
Drilling, one No. 7 Leyner; including shift boss' time	55.33	43.21	.480
Number of holes drilled 150			
Total footage of holes 1,202.30			
Feet drilled per hour, including lost time 15.84			
Feet drilled per hour, actual drilling time 21 74			
Average depth of holes, feet .. 8.00			
Cost per foot of hole, cents ... 3.60			
Fastest hole 9′ 6″ in 10 minutes			
Slowest hole 8′ 6″ in 1 hour 18 minutes			
Average hole 8′ in 22 minutes			
Blowing out holes	5 75	4.15	.046
Loading and shooting	56 25	22.31	.248
Mucking, 412 cars	835.00	268.44	2.980
Trimming, stulling, caves, etc.	102.00	39.24	.436
Timbering (cost per M′ = $11.32)	107.25	40.82	.453
Lost time	40.75	15 66	.174
Bonus, 30 cents per man per foot in excess of 2.3 feet per shift		112.08	1.240
Repairs, to trolley, pump, etc	3.25	1.20	.013
Totals, inside labor	1,265.08	572.73	6 354
Outside Labor:			
Sharpening steel, with Leyner No 2 machine	44 00	17.83	.198
Repairing drill	7.50	2.88	.032
Framing timbers, at shop, pr. M′ = 2.42		8.75	.097
Light and power	90 00	33.75	.375
Totals, outside labor	141.50	63.21	.702
Auxiliary Labor:			
Laying track, 90 feet	31.50	12.75	.141
Drainage line, 90 feet	43.50	14 33	.160
Ventilation line, 72 feet	11.00	3.41	.048
Trolley line, 95 feet	18.00	6.35	.067
Air line, 80 feet	2.50	.80	.010
Water line, 80 feet	2.50	.79	.010
Lights line, 90 feet	8 00	2.86	.032
Totals, auxiliary labor	117 00	41 32	.468
Local Administration and Engineering:			
Proportion of division engineer and assistant's time		50 40	.560
Total labor costs	1,523.58	$727 66	$8 094

The crew consisted of 1 shift boss at $3.50 per day; 4 miners at $3.50; 5 muckers at $2.50, and 1 trammer at $2.50. The blacksmith doing repair work was paid $4 per day.

The four miners worked on day shift drilling the ground, timbering and shooting, the muckers following on night shift, resulting in a clean heading for the drill crews, and nothing interfering with the mucking crew.

Tables 5, 6 and 7 give the amounts and costs of the different items used.

Table 6. Costs of Materials and Supplies

	Total Material Costs	Cost Per Foot of Tunnel
Construction Materials and Supplies:		
Drill repairs, 2 side rods, $1.40; 1 chuck, $15; 2 rings, $2.02; 1 oil can, .15; 1 belt, .16; 20 per cent. freight, $3.74	$ 22.47	$ .250
Cost per foot of hole = .018		
Drill supplies, machine oil, .58; drill steel, 45 inches, $4.12; 412 lb. blacksmith coal, $3.14; 20 per cent. freight, $1.57	9.41	.104
Cost per foot of hole = .008.		
Mucking supplies, car oil, .20; pick handle, .26; hammer handle, .15; 20 per cent. freight, .12	.73	.008
Power, machine, 2,052 K. W. H.; blower and lights, 355 K. W. H.; locomotive, 1,800 K. W. H. = 4,207 K. W. hours. at 1.7c.	71.52	.795
Explosives, tamping stick, .40; 2,700 feet fuse, $11.54; 306 15 gr. Lion caps, $2.08; 650 lb. 1¼ inch, 40-per-cent. gelatin powder, $69.88; 250 lb. 1 inch, 40-per-cent. gelatin powder, $26.88; 150 lb. 1 inch, 60-per-cent. gelatin powder, $20.63; 20 per cent. freight, $26.28	157.69	1.752
1,050 lb. powder = 11.66 lb. per foot of tunnel.		
1,050 lb. powder = 3.3 lb. per cubic yard in place.		
Explosive cost = $.050 per cubic yard in place.		
Explosive cost = $.27 per cubic yard broken.		
Timbers, 3,597 feet B. M. lumber, $59.24; freight on same $55.01; 775 wedges, $5.43; 50 dowel pins, .42; nails, .73; freight, $1.33	122.16	1.360
Timber per foot of tunnel, B. M. = 40.		
Lighting, candles, $7.15; 14, 16, and 32 candle-power globes, $2.58; 20 per cent. freight, $1.94	11.67	.130
Totals for construction materials	395.65	4.399
Auxiliary Material:		
Trackage, 180 feet, 25 lb. rail, $15; splices and bolts, .83; spikes, .18; ties, $1.42; 20 per cent. freight, $3.68	21.11	.235
Drainage 90 feet, 250 feet wire, $2.13; knobs, .07; 2-inch pipe, $4.36; 20 per cent. freight, $1.31	7.87	.087
Ventilation 72 feet, 12-inch pipe, $24.34; 20 per cent. freight, $4.87	29.21	.405
Trolley 95 feet, wire, $6.32; lumber, .37; fittings, $1.42; 20 per cent. freight, $1.62	9.73	.102
Air line 80 feet, pipe, $5.28; fittings, .76; 20 per cent. freight, $1.21	7.25	.090
Water line, 80 feet, pipe, $5.28; fittings, .76; 20 per cent. freight, $1.21	7.25	.090
Light line, 90 feet, wire, $1.48; fittings, .37; 20 per cent. freight, .37	2.22	.025
Total auxiliary materials	84.64	1.034
Total material costs	480.29	5.433
Live Stock:		
Mule 15 days at 90 cents $13.50		.150
Total direct and auxiliary field charges $1,523.58 $727.61	$480.29	$13.667

ELIZABETH DIVISION TUNNEL

The greatest obstacle to the success of the aqueduct as a whole was believed at the start of work to be the highest barrier ridge of the Coast Range which is penetrated by the Elizabeth tunnel whose length when completed will be 26,860 feet. The rock composing the ridge is mainly granite, which in places shades into both gneiss and schist. The granite is composed mainly of feldspars and biotite with only a small amount of quartz usually present. Its texture varies at different points along the tunnel, the finely crystalline rock usually being without joints or seams and the coarsely crystalline rock usually being full of seams. The finer crystalline rock, therefore, allows much the slower progress in tunnel driving, while the blocky ground gives about as near ideal conditions for record-breaking drives as one is apt to find.

Powder 16.8 pounds per foot. Estimated cost $763,420. Cost for 9,754 feet, $475,472.—E. J. Sharpe, Superintendent.

While originally the rocks composing both sides of the ridge were doubtless similar, today they are widely dissimilar in physical character, which necessitates two widely differing methods of mining attack.

The rock so far penetrated by the south heading is hard, unaltered, and in general blocky enough to afford fine breaking qualities. It requires no timbering except one or two sets at long intervals where the roof is heavy, and there is comparatively little water encountered.

In the north heading, the rock has been shattered by scores of fissures, and in general is so kaolinized by percolating

Fig. 6. Interior of North Portal, Elizabeth Tunnel

waters that it is for the most part soft, friable and frequently pasty. Considerable water enters the tunnel, and the ground is so heavy it requires timbering. except at one or two places in the tunnel of small extent where hard unaltered rock was penetrated. Long extents of heavy, treacherous ground are continually encountered, so that the timbering must be kept well up to the face.

As a result of these widely varying conditions neither the costs, nor the record performances of work at one heading may be fairly taken as a criterion of the work at the other heading of this same tunnel, a fact the aqueduct supervisors would do well to recognize.

In spite of this diversity of work, however, the progress made at each heading has been surprisingly uniform as shown in Table 8, until at the end of April, 1910, 30 months after starting work, the north heading has penetrated 9,754 feet and the south heading 9,738 feet, totaling 19,492 feet, or nearly 72 per cent. of the entire length. At this rate of progress the tunnel will be finished by April, 1911, or 18 months before it was estimated at the start of work that the tunnel could be completed.

For the accomplishment of this work, destined long to mark the top notch of the American tunnel driving art, two former Colorado men have earned a large part of the credit. They are C. W. Aston, superintendent of the south portal, and John Gray, superintendent of the north portal. Between these two and their crews has sprung up a friendly rivalry resulting in the shifting of the championship of America from one side to the other as each in turn has exceeded the record month's progress of the other, as shown in Table 8.

North Portal Tunnel Driving Methods.—The north portal of the Elizabeth tunnel is located on the desert side of ridge and the effect of the radically different climate upon the vegetation and surroundings is made clearly apparent by contrasting Figs. 5 and 10.

Tunnel driving on the north side of the ridge is an entirely different proposition from that on the south side. For almost the entire half of the tunnel the rock is shattered by hundreds of faults which have rendered the ground both blocky, and usually very heavy, necessitating the timbering of all but 300 odd feet up to the time of the writer's visit. As this side of the tunnel has a down grade, the water which accumulates in considerable quantity, Fig. 6; has to be pumped to the outside. Owing to the soft, blocky ground, which is easily shattered by comparatively small amounts of explosive, the average round at this end includes only 16 holes instead of 25, and they are drilled by two Leyner machines instead of three as at the south heading.

The heading crew, exclusive of the shift boss on each shift, is as follows: Two machine men and helpers (4), 6 shovelers, 2 trammers, 8 timbermen, and from 6 to 8 trackmen, making a maximum total of say 28. To this must be added the train motorman and outside dump man. Instead of hauling the loaded cars from the heading back to the switch where the

Powder 19.15 pounds per foot. Feet to be driven, 13,430. Estimated cost, $750,570. Feet so far driven, 11,693. Actual cost so far, $343,114. —W. C. Aston, Superintendent.

trains are made up by a mule, the adverse grade is overcome by rope haulage, a small compressed-air hoist located a short distance back from the face being employed in the work. Of the two trammers mentioned, one runs this hoist and the other manipulates the rope. In this heading from 6 to 8 timbermen find steady employment and the work they perform is one of the main features of interest.

A reference to Fig. 8 will show the section of the finished tunnel and its dimensions, while a careful study of Fig. 11 will make clear the steps by which that condition is arrived at.

For convenience, assume the time of inspection to be at the end of a shift when the drills have been cleared away from the breast preparatory to shooting the round. Arrived at a point 100 feet back from the breast the transition of method in roof support is found similar to that shown in Fig. 11 (*a*). The finished sets are best seen in the end sectional view through $E\ F$, in front of which stand the temporary supports or "false sets." These false sets support the heavy roof by longitudinal timbers resting upon them after the manner of the ordinary forepoling method, the roof being carefully supported on blocks, timber ends, etc., all carefully and tightly wedged. The situation at the breast just before shooting is shown in Fig. 11 (*b*). It will be noted that the last false set has been placed within 3 or 4 feet of the face about to be blasted, carefully braced with timbers and the roof wedged up as tightly as possible.

Shortly following the blasting the timbermen go into the heading as quickly as possible and shore up the roof temporarily from the top of the broken material, as shown in Fig. 11 (*c*).

The posts of the permanent sets are 8″×8″ squared timber, spaced irregularly from 2 to 8 feet apart depending on the weight of the roof; those shown in the illustration are spaced on 8-foot centers. The sets are ordinarily spread by lengths of 2″×6″ plank whose ends are supported for convenience on either wedges or timber ends spiked to the posts. The posts are 8 feet 6 inches in length and set 10 feet 2 inches in the clear while the heading is broken as nearly as possible to a width of about 12 feet. Over both sides and top arch timbers is placed 3-inch timber lagging.

In ground that stands fairly well for a day or two, this full width of 12 feet is blasted by the rounds and the placing of false sets is, of course, an unnecessary preliminary. In the heavy ground, the width of the heading first blasted varies from 6 to 8 feet, or whatever it happens to break, and the rock is so often be crushed. For this reason the timbering in the heavy ground is of vital importance to avoid delays, which mean a loss of bonus to the crews. The only time when the roof is not kept constantly supported, therefore, is the interval of from

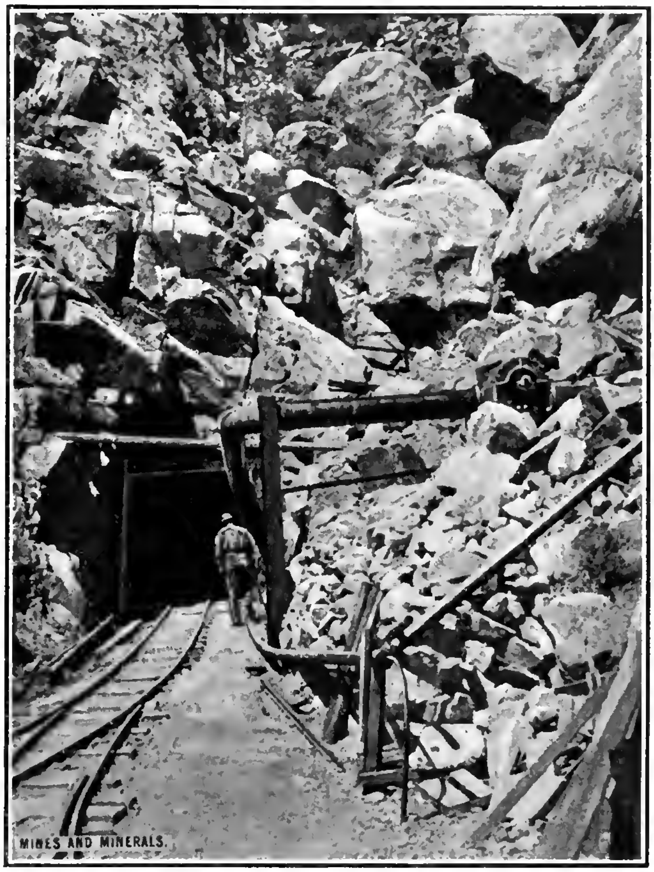

FIG. 10. TUNNEL ADIT IN BOULDER PEAK REGION

15 to 20 minutes following the blasting during which the gases are being cleared out. The first work of the timbermen on the new shift is to shore up the roof temporarily from the top of the rock pile. By placing two longitudinal timbers, Fig. 11 (*c*)

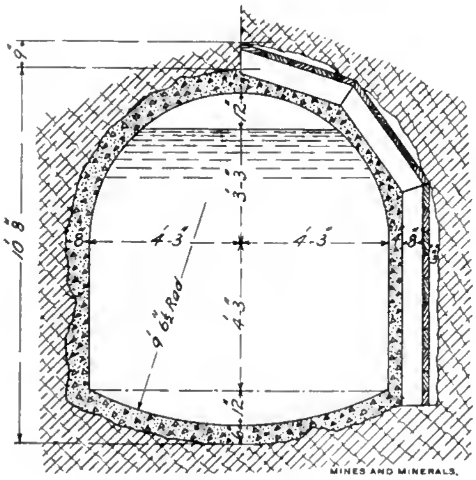

FIG. 7. SECTION OF TUNNEL NO. 17, JAWBONE DIVISION

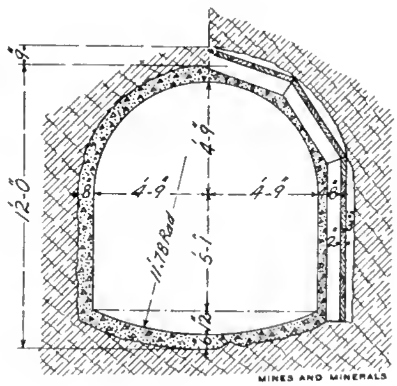

FIG. 8

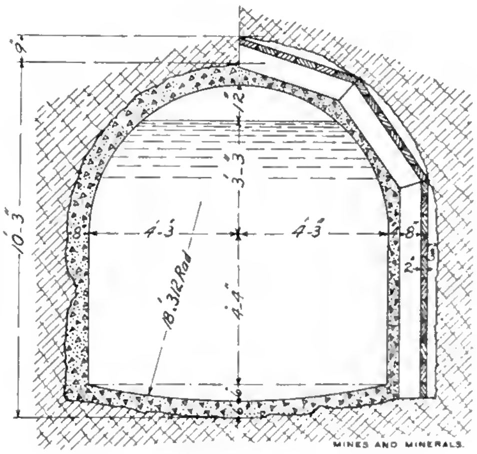

FIG. 9. SECTION OF TUNNEL, GRAPEVINE DIVISION

badly shattered that the subsequent enlarging to the full section is only a matter of judicious pick work. Experience has proved that if the roof is at all times kept well supported on the timbers, so that it does not start to fall, little retimbering will be necessary, while if it once breaks loose, heavy close-set timbering will supported from the broken rock close to the side walls, and shoring up the shattered roof by means of transverse timbers and blocking resting upon them, the timbermen interfere but little with the shoveling back from the face to allow the placing of the drills. This done, the broken rock is thrown aside to allow

placing a false post on solid bottom, which post from here on takes the weight of the roof, while the simultaneous shoveling and drilling for the next round go on. The false posts used in this work are later used as permanent posts, and as their upper ends are beveled to support the roof arch, these beveled ends are placed next the floor, as shown in sectional views *AB* and *CD*, while their squared ends support the caps which consist likewise of the timbers already cut to length, which are later used as permanent posts. In this way there is no handling of heavy timbers not intended for permanent use. With the false sets to the number of six or more, placed for a distance of about 50 feet back of the breast, plenty of leeway is allowed for the ground to work and settle for several days before the permanent sets replace them. The posts of these false sets are placed no fixed distance apart as the width of section first broken varies considerably.

The section *A B*, Fig. 11, contrasted with that of *C D*, shows the situation before and after widening out the tunnel to its proper dimensions by means of pick work. This widening-out process starts next the permanent set and proceeds toward the face, the permanent posts *p*, shown in (*a*), being placed as fast as the section is widened. Transverse spreader timbers shown in section *C D*, are now supported with their bottoms 14 inches below the top of the posts, resting on timber ends spiked to the posts. Across these spreaders are laid two layers of 2-inch plank forming a flooring 4 inches thick. This floor is some 2 or 3 inches below the bottom of the caps resting on the posts of the false sets, so that it is easily laid while the false sets continue to hold the weight of the roof. Working now from the end of this floor, the wedges and blocking transmitting the roof weight to the false sets are carefully knocked out and the shattered roof rock picked down on to the floor. Later on, cars are run beneath this floor, a hole is made in it by pulling out some planks, and muck is allowed to run or is shoveled into the cars.

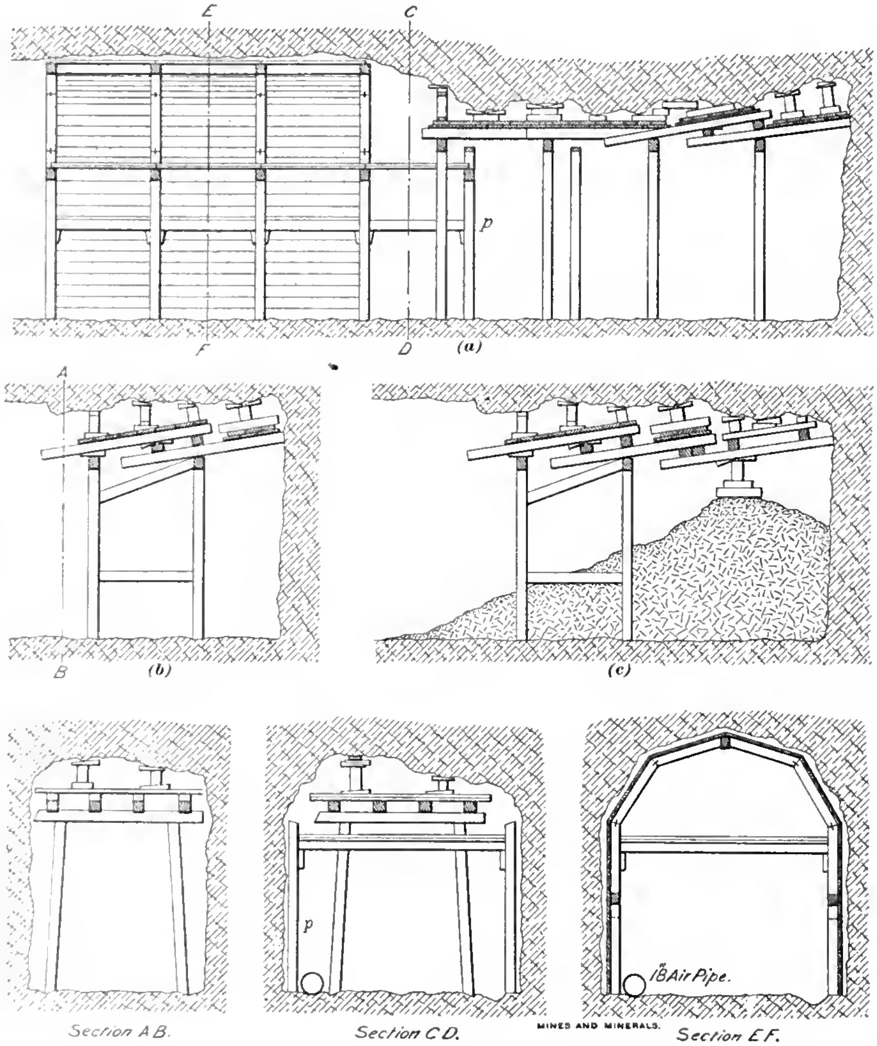

Fig. 11

By advancing the permanent posts *p*, a foot or more forward from the false set posts as in (*a*), the arch timbers of the permanent sets may be placed as fast as the removal of the roof rock exposes their upper beveled ends. Lagging and wedging quickly follow so that the roof weight is taken up by the permanent sets shortly after it is removed from the false sets, after which the posts of the latter are knocked out and carried forward for reuse or are placed as permanent posts.

As the heading is advanced at the rate of 16 to 18 feet per day, 3 shifts, the timbering must be placed and removed by each shift, which keeps every one busy, although system reduces disorder in the heading to a minimum. It is complimentary to the methods adopted by Superintendent Gray that in spite of the hurry with which everything is pushed by the timber crew, up to this writing there has been no fatality in the heading attributable to a roof fall.

To those interested in the rivalry between the crews of the north and south Elizabeth tunnel headings, the accompanying Tables 9 and 10, will be replete with interest as well as with valuable data. These give the official costs for both headings during the month of April, 1910, when the south portal advanced the American record to 604 feet, while the north portal progressed 561 feet in spite of exceptionally heavy ground. It will be noted that, as might be expected, the cost of explosives was the heavier for the south heading, while the cost of timbering is mainly responsible for increasing the cost per foot of the north heading to $4.36 more than the $25.25 of the south heading. It is also significant that the cost of mucking in the two headings is very nearly the same.

And now why is it that in spite of widely diversified methods of attack, of different hardness of rock and many other conditions, the average progress of one heading is about the same as the other? This is surely a fair question whose solution may throw considerable light upon the reason for continued supremacy of foreign records, if indeed they can long continue supreme.

As regards the matter of drills and drilling the writer hazards the opinion that for speedy work the water Leyner has no peer. The fact that both headings maintain about the same speed simply shows that the actual hardness and toughness of rock has but little to do with the problem, at least in this case. It does show that the Leyner drill, owing to its rapidity of stroke, is capable of holing in the soft seamy ground of the north heading, where some drills would be continually fitchering, as rapidly as in the hard fine-cutting granite of the south heading.

Another fact worthy of note is that continuous timbering can no longer be regarded as a bar against speedy work, except where quicksand is encountered, for what time is lost in timbering is balanced by the easier breaking of ground.

The writer is now inclined to the belief that the breaking of records has proceeded to the point where it is a shoveling

problem rather than a ground breaking one. Given an American loading system capable of offsetting the cheap labor handicap of foreign record breakers, the results may soon read differently.

The visitor to the various camps along the line of the aqueduct has only words of praise for every department save one, and that is the commissary department. In spite of the determined and persistent efforts of the men to secure wholesome food they have so far been unsuccessful. If the commissioners would unexpectedly visit the camps under an alias we believe they would quickly change conditions from what at the time of the writer's visit he can only compare to the fertilizer department of a glue factory.

In conclusion the writer extends his hearty thanks to the many executives of the aqueduct work who have furnished data and extended asistance to him, an enumeration of which would read like a directory of the force. May the above remarks on the commissary department result in action that will prove some return for the many courtesies extended. Special acknowledgment, however, is due to Mr. J. B. Lippincott, assistant chief engineer, to whose courtesy the writer is indebted for an automobile trip over the line and to whose kindness he is indebted for much of the tabulated cost data and many of the accompanying illustrations.

KENNETT SMELTER FUME ABATEMENT

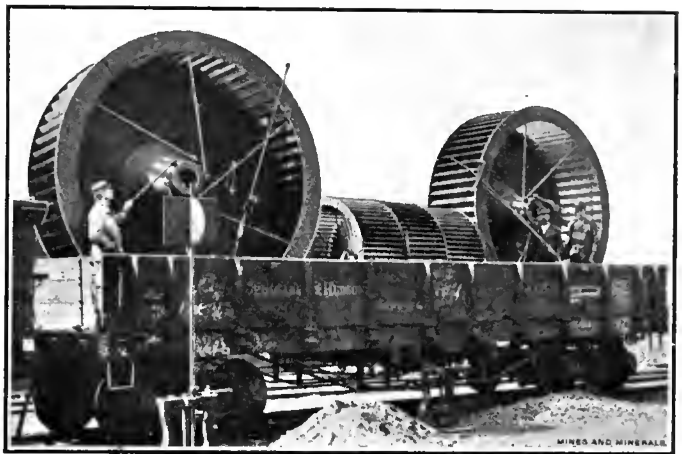
Written for Mines and Minerals, by E. B. W.

The Mammoth Copper Mining Co., controlled, through the ownership of the entire stock issue, by the United States Smelting, Refining and Mining Co., is located 3½ miles from Kennett, on Little Backbone Creek, in Big Backbone district, Cal. The smelter, ½ mile from Kennett, 2½ miles from the mines and 2,200 feet lower, is the largest in California.

The Kennett smelter, which originally had a capacity of 1,000 tons daily, was enlarged in 1907 and the capacity increased to more than 1,500 tons daily. The buildings are of steel, and all material is handled by gravity. Both the mine and the smelter machinery is operated by electric power obtained from the Northern California Power Co. at a reasonable rate.

The smelter plant occupies 80 acres and is equipped as follows: Sampling mill; ore bin house 214 feet long; blast furnace building 72 ft. × 222 ft., which houses three 42″ × 180″, and two 56″ × 180″ furnaces; converter building 92 ft. × 204 ft. with 2 hydraulic stands, 8 converter shells, and 50-ton electric crane; power house 250 feet long, containing seven 15,000 cubic feet per minute blowers, driven by three 200-horsepower and four 250-horsepower motors; boiler house 43 ft. × 176 ft., out of commission, but held in reserve for emergencies; shop building 41 ft. × 432 ft., divided into machine shop; blacksmith shop; shed; warehouse; boiler shop and locomotive stable; office and laboratory buildings complete the plant, so far as buildings are concerned. The equipment in the buildings would read like a stock inventory and in any case could only be appreciated by the experienced, who know that the cost of furnaces is merely a drop in the bucket, to the cost of machinery, apparatus, etc. needed to run them.

When the furnaces were in full blast, about 5 tons of arsenic, 7 tons of lead, and many tons of sulphur escaped from the furnace stack as fume. The farmers in the vicinity declared the fume killed their crops and served an injunction that prevented the company using this plant. The method adopted for overcoming the fume difficulty at the United States Smelting Co.'s Midvale smelter, in Utah, was described in the March, 1910, issue of Mines and Minerals, while the arsenic plant was described in the June, 1910, issue. The United States Smelting Co. is now installing their patented system of neutralizing the noxious fume in the Kennett plant, after which the injunction will be removed in California, the same as it was in Utah in the case of the Midvale furnace. The blast furnaee gases which have a temperature of approximately 700° F. are cooled down to nearly 200° F. and filtered through bags in the bag house. For this purpose powerful fans which will create a partial vacuum equivalent to from 1.5 to 2 inches of water gauge are needed, owing to the friction involved in passing the gases through cooling pipes, flues, chambers, and eventually delivering the smoke to the stack. The two single-inlet Sirocco fans, each 132 inches in diameter shown at the ends of the car in Fig. 1, are destined for the Kennett plant. Each fan is to circulate



Sirocco Fans for Circulating Gas

245,000 cubic feet of gas per minute that has a temperature of 450° F; owing to this temperature and to the altitude, which is 1,000 feet above sea level, the fan must make 235 revolutions per minute and absorb not over 335 horsepower for 5-ineh water gauge.

WET ASSAY FOR GOLD

Written for Mines and Minerals

Dr. F. Jerome Davis, of Raymond, Cal., furnishes the following method of making a wet assay for gold:

The material is pulverized to pass through a 100-mesh screen. It is then soaked in a solution composed of two parts of potassium, four parts of potassium iodide, and 100 parts of water. From 40 to 50 cubic centimeters of this solution is taken to each assay ton of ore. If the solution fades, more solution is to be taken, as there is a reducing. element in the ore. Grind the pulp wet with solution in a Wedgewood mortar at intervals for 2 hours, giving a few rubs each time, then filter off and wash the ore, putting filtrate in a flask or large test tube. Next add from 40 to 60 grams of zinc amalgam, agitate freely, add nitric acid, and boil until a porous button of gold is present. It is necessary to boil slowly or the button will be broken apart. Weigh as in the case of fire assay. In the case of silver, ½ assay ton may be used, the silver precipitated from the silver nitrate solution with hydrochloric acid, and then weighed as silver chloride. In some cases pure mercury is used instead of zinc amalgam with as favorable results.

Another method which is advanced by W. H. Seaman in his recent book on "Manual for Assayers and Chemists," is as follows: A suitable quantity from 10 to 1,000 grams of finely powdered mineral is placed in a large bottle thoroughly wetted with water and then treated with 500 cubic centimeters of bromine water for a period of several days. The bromine forms tribromide of gold $AuBr_3$. With portions of other metals the solution is filtered off, the residue washed thoroughly, and sodium peroxide added to the solution, which precipitates the gold according to the following equation:

$$2AuBr_3 + 3Na_2O_2 = 2Au + 6NaBr + 6O.$$

The precipitates are then taken up with hydrochloric acid, and after the gold is settled the liquid is decanted off and the fine gold caught on a small filter, after which it is dried, ignited, and weighed as a metallic gold.

TIMBERING IN THE JOPLIN DISTRICT

Written for Mines and Minerals, by Lucius L. Wittich

To support the drifts in the soft-ground zinc and lead mines, of the Missouri-Kansas-Oklahoma district, heavy timbering is required. The process is expensive, but failure to timber a drift properly may mean a cave-in entailing damage to property, possibly loss of life.

Conditions that Require Large Quantities of Timber. Method of Placing. Costs

That disastrous cave-ins are not impossible is shown by Fig. 1, this view having been taken when the roof of the Morning Hour Mine, west of Joplin, Mo., dropped without an instant's warning, the track of the St. Louis & San Francisco Railroad being left suspended like a sagging string across the chasm. Other cave-ins have occurred since in this immediate vicinity that stopped traffic on the railroad on several occasions.

Owing to the pockety formations of the zinc and lead ore deposits the drifts of a necessity must conform to the dimensions of the ore bodies if mining is to be conducted at a profit, for which reason it is necessary to make some excavations wide and high while others may be low and narrow. In Fig. 2 is seen a diagram of the typical pocket formation and the method of working it by underhand stoping which is followed in the majority of the mines. In this system the ore is taken up from below, a face about 6 or 8 feet in height being worked first, then, if ore still exists in the floor, a stope is taken up. This process is carried deeper and deeper until the bottom of the mineral has been reached. In some of the mines of the Joplin district stopes 80 feet in height are worked, but such instances are found only in substantial ground where the placing of little or no timbering is required.

Fig. 1. Cave In at Morning Hour Mine

Timber suitable for mine purposes is plentiful throughout the district, but the supply is diminishing rapidly; especially since operators have displayed a tendency to return to the development of the shallower ore deposits. Many of the deep, hard ground operations in sheet ore have been suspended temporarily on this account.

In following an ore body a drift will twist and curve, but soft-ground deposits as a rule are sufficiently irregular to permit of pillars of barren rock being left as supports for the roof. Occasionally, though, it becomes necessary to leave pillars of ore that contain enough mineral to warrant the operators returning to them eventually and removing them at the risk of a cave-in. It is a common practice to work out an ore deposit, then return to the outlying pillars first and take them down one at a time until the roof of the mine is ready to drop without warning. Timbers seldom are employed as permanent supports, as no tree trunk is sufficiently massive and strong to withstand the weight of earth and rock above it; pillars of rock are a necessity, timbers being employed only to support the walls of the excavation temporarily. In some of the softer mines it is necessary to place large timbers side by side as close as it is possible to get them, and even these cannot hold up the roof when it commences to crush. Heedless, apparently, of impending danger, the Joplin miner will labor day in and day out beneath the splintered timbers, for it is common for massive supports to fracture and yet keep the overhanging tons of rock from crushing down. Even when the strain becomes so great that the timbers creak and groan and crack like rifles the miners realize that the collapse will be slow and with a watchful eye they continue at work. New and even heavier timbers are installed if occasion demands and thus the strain is removed from the ones already broken.

Without timbering the development of a soft-ground mine would be almost impossible. By diverging the advancing timbering the size of the drift may be varied; however, it rarely exceeds 18 feet in width by 30 feet in height, while much smaller drifts are the rule. The cover above the excavations is so heavy that long timbers cannot withstand the strain; therefore, they are seldom used.

In Fig. 3 is shown the common method of timbering soft ground. Where cavities occur back of the timbers, lagging is installed, and by the aid of wedges is forced up against the roof. Behind the lagging, nailed to the legs, short pieces of wood varying in length from a few inches to several feet, are thrown in a conglomerate mass to prevent loose dirt from the sides falling into the drift.

Drifting is accomplished by starting a tunnel from a shaft toward the ore, as it is poor policy in this kind of ground to sink a shaft directly into the mineral deposit. Therefore it sometimes occurs that the bottom of the shaft may be some distance from the ore deposit, necessitating the driving of tunnels through barren ground.

When the drift has reached a length hinting of possible disaster unless precautions are observed, two posts, and possibly a mud-sill and a cap are installed. As the tunnel is lengthened, additional sets of timbers are put in place. Stakes, or poling boards, consisting of split green poles about 5 inches in diameter and known as "spiles" are driven forward over the cap of the set farthest in advance. The softness of the ground will determine how many stakes will be required. In extremely soft ground it will be found necessary to observe extra precaution. The dirt is removed from beneath the stakes, temporary props being employed if necessary until the drift has been advanced to a point warranting the installation of another set of timbers.

An excellent plan is to bevel the "spiles," then drive them forward with the bevel downward. This has a tendency to cause the stake to take an upward course, which is desirable. As the earth is removed from beneath, the pressure from above will cause the spiles to settle. Without proper elevation, on being driven into the face the weight would cause the spiles to settle so that it would be impossible to maintain the regular size of the timber sets and the drift gradually would become smaller and smaller. In addition to the rise resulting from the bevel, the spile should be pointed upward at an angle of about 6 degrees. Where the roof is soft the angle should be increased. As the timber sets are placed the spiles settle down on the cap and form part of the timbered set.

In the oozy ground sometimes encountered, extra precautions are needed when the roof spiling will not hold the mass of earth and rock. It then becomes necessary to advance a cap timber by excavating near the roof of the drift and pushing steadily into the face. Small cuts at either side of the drift are then extended until it is possible to support the cap with posts. This accomplished, the earth in the center of the drift can be removed in comparative safety.

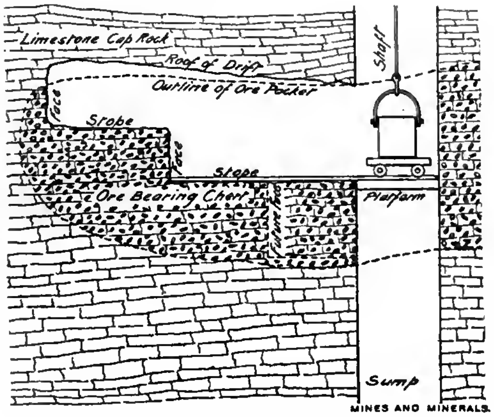


Fig. 2. Method of Mining

Where the ground is fairly substantial it is possible to do away with the lengthwise timbering. the main sets being able to hold the roofs and sides. The principal danger in these mines lies not in the possibility of a falling boulder or two, but in the probability of a disastrous cave-in that will extend to the surface and carry with it loss of life and great property damage.

Where the ore is richest, timbering almost invariably is required. The money-making mines have not all been located in soft ground, but where the percentage of ore is exceptionally high it is found as a rule in ground that is easily worked. Frequently nature has done the work for the operators, by leaving a cap rock of solid limestone over the ore deposit. Where this is the case no timbering is needed. Soft-ore deposits occurring between beds of solid lime have been discovered and such conditions are ideal for mining in the Joplin district, because mining requires small amounts of money for explosives or timbering.

In the Joplin district round sticks are used for timbering purposes, as timbers in this form are more substantial than if dressed.

The life of the average soft-ground mine is short; seldom does the typical pocket producer prove a bonanza for more than 2 or 3 years, although there are examples where such mines have steadily produced for 10 years. Occasionally the ore pockets are closely connected, being joined with thin runs of "shines" that lead the operators to extend prospect drifts into fresh deposits. Some of the Joplin district mines have succeeded in developing pocket after pocket, the deposits sometimes occurring in circular form, while at others they are found in runs.

Where it is necessary to stope in soft ground the operators will save themselves future trouble by using mud-sills in the original drifts, as eventually the floor of the first drift must be taken up. How to accomplish this when roofs and sides are braced and supported, and are none too secure at the best, is a problem. To go beneath these timbers, hold them in place by equally heavy or even heavier timbers, is a necessity if the ore is to be handled. The advisability of employing the mud-sills in the original drift therefore can be appreciated. Unless the mud-sills have been used, the space of the first drift must be cribbed and retimbered, comparatively light timbering from 4 to 8 inches in diameter being sufficiently heavy to answer the purpose. Securely wedged at the top, the cribbing is ready to rest upon the caps of the sets in the drifts to be driven underneath. The method of advancing the stope beneath the old drift is much the same as that employed in driving the original drift. Care is taken to prevent the timbers from above coming down. Overhead stoping sometimes is adopted, the ore deposit where unusually thick being worked from the bottom after the initial drift has been driven. In this type of development the caps of the first drift act as supporters for the platform of the second drift to be driven above the former workings.

An enormous amount of timber also is employed in lining shafts. While the size of this material is less than that used in the drifts, the amount used possibly is as great as that employed underground. Unless sunk through absolutely solid ground, practically all the shafts are lined from top to bottom.

The cost of timbers is regulated by length and diameter, the smaller end always being used in the latter measurement. A log 10 feet in length costs 8 cents per inch of the diameter at the smaller end, unless the log be 10 inches or more in diameter, in which case the cost is 10 cents per inch.

The following gives a fair idea of the cost of timbers in the Joplin district:

Twelve-foot logs, 9 cents per inch up to a 9-inch diameter; above 9 inches, 12 cents per inch; 14-foot logs, 11 cents per inch up to 11 inches in diameter; above 11 inches, 14 cents per inch; 16-foot logs, 12 cents per inch up to 12 inches in diameter; above 12 inches, 16 cents per inch; 20-foot logs, 20 cents per inch, regardless of diameter

The price charged for lagging is about as follows: 3 to 4 inches in diameter, 10 or 12 feet long, 15 cents each; 4 to 5 inches in diameter, 20 cents each; 5 to 6 inches in diameter, 30 cents each. Cord wood, delivered at the mine, $5 per cord; spiles, 40 cents each; collar braces, 10 to 15 cents each.

The cost of setting timbers in the drifts is about equal to the cost of the timbers, although this is only an approximate deduction arrived at by half a dozen of the larger operators in the soft-ground districts. The cost of excavation varies. In an extremely soft sheet ground mine in West Joplin the cost of excavating a drift 12 feet wide, 12 feet high, and 12 feet long was only $25. No powder was required.

The average cost of lining a $4' \times 5'$ shaft with $2'' \times 4''$ plank, at $15 per 1,000, ranges from 95 to 99 cents; a $5' \times 7'$ shaft will cost about $1.25. Rough timber of scrub oak costs from ½ cent to 1½ cents per foot, making a 10-foot length cost about 8 cents

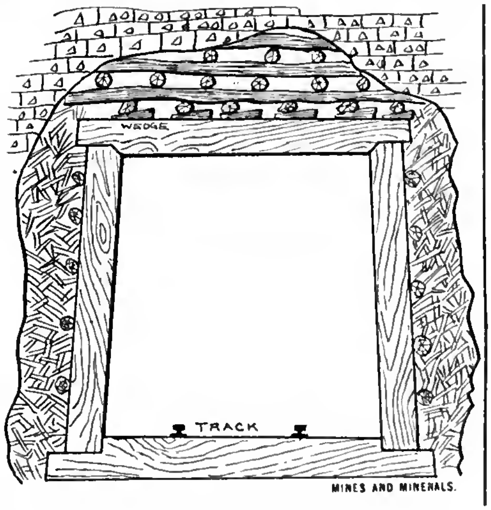

Fig. 3. Timbering in Soft Ground

on an average. These timbers are sawed in two lengthwise, and thus two cribbing timbers are secured from each pole.

Concrete, made partly from the tailing of the Joplin mines, is proving successful as cribbing, while there is much talk of experimenting with this material in bracing the roofs of drifts. On the Granby land at Joplin, and at the Eureka Mine, north of Galena, Kans., concrete has been found effective in walling in the shafts. It is superior to timber in that it prevents the leakage of surface waters.

OXYGEN PROCESS FOR MELTING OF IRON

Written for Mines and Minerals, by Dr. Alfred Gradenwitz

Method by Which Large Masses of Iron or Steel May be Quickly Burued Through

The melting process invented by Dr. E. Menn, engineer to the Koln-Muesener Bergwerks-Aktien-Verein, at Creuzthal, Westphalia, enables iron and steel blocks of considerable thickness to be pierced rapidly in a horizontal or vertical direction, and has been found especially suitable for removing of blast and smelting furnace obstructions. The process is as follows:

The iron or steel masses having been heated by some means or other, preferably with an oxy-hydrogen flame, up to the ignition temperature of their combustible components, oxygen is forced against them at a high pressure (upwards of 30 atmospheres). Though this stream of oxygen exerts some cooling effect, or even puts out the flame entirely, the heat of combustion of the iron causes the metal masses to melt, while the high pressure throws the oxidized and molten material out of the hole thus formed, so that the oxygen always finds renewed points of attack in the combustible material, and cannot exert any cooling effect. Oxygen, in virtue of the well-known law of expanding gases, will cool down considerably below the freezing point of water, and the fact that this gas allows effects to be obtained which are impossible in the case of the hottest of all flames, the oxy-hydrogen flame, at first sight seems paradoxical. The apparent contradiction is accounted for when it is considered that each volume unit of burning iron develops about 5,000 times more heat than an equal volume unit of hydrogen.

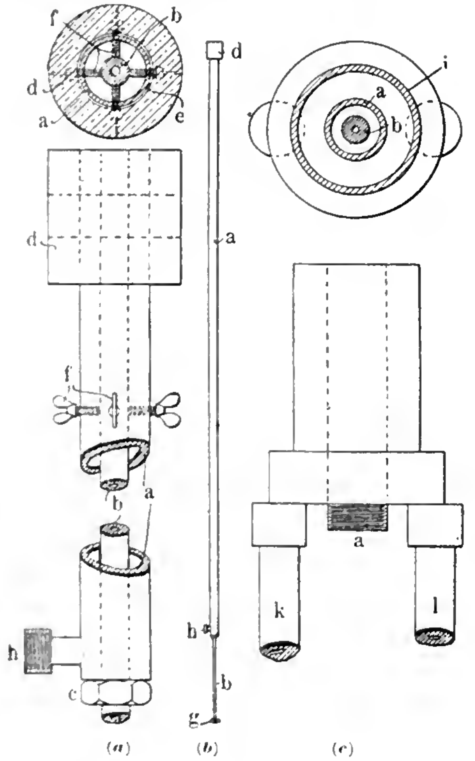

Fig. 1

It is true that the hottest parts of the oxy-hydrogen flame are heated above 2,000° C., so that an ordinary Bunsen burner fed with air will melt thin platinum wires. Any thicker wires will at most become red hot, as the heat losses in this more extensive mass exceed the heat supply. In a similar manner, an oxy-hydrogen flame allows thin sheets to be pierced; as soon, however, as the mass considerably exceeds the flame volume, the heat supply is distributed over the mass of the block, and only exerts far more moderate effects.

The oxygen process, however, is quite independent of heat losses, and allows the largest blocks to be pierced with the smallest flames, owing to the extraordinarily high pressure which throws away the molten molecules more rapidly than heat dispersion is allowed to come into play.

The apparatus is simple and inexpensive. It consists of two steel flasks, each with a reducing valve, and of a few yards of iron tubes and armored hose.

The design of a suitable burner at first offered some difficulty. As this burner, on being introduced into deepening holes, is surrounded by the recoiling flames and the oxygen, its point must, in fact, be protected efficiently lest it become melted more quickly than the block to be pierced. All the usual burner safeguards (platinum, soapstone, etc.), proved ineffective in this connection, whereas heads made of compressed coal, coke, graphite, retort carbon, magnesite, and especially carborundum, were found sufficiently resisting.

Fig. 1 (*b*) represents the burner with its head and sleeve, and the connection tubes for supplying combustion gas and oxygen, and (*a*) details of the burner itself.

The tube *a*, supplying the combustion gas, is arranged outside the tube *b* supplying the oxygen, and which, at its rear end, is tightened by a stuffingbox *c*. The sleeve surrounding the burner head, made of compressed carbon or the like, is shown at *d*. Between *a* and *d* there is provided an interval *e* filled with yielding material, such as asbestos paper, for preventing the sleeve *d* from breaking as the tube *a* is expanded by heat. The setscrews *f* are holding the tube *b* in position while *g* and *h* are fittings for connecting the hose. The sleeve can be made of several rings so that in case of rupture of the foremost ring the burner point only can melt down to the next.

Beside these sleeves of refractory material, water-cooled burner heads, as represented in Fig. 1 (*c*), have likewise given good results. The hollow burner head *i* is made of metal, and provided with a water cooler *k l*. Burner heads have been made of copper provided at the outside with grooves 3 to 4 millimeters in depth which are smeared with loam so as to damp the heat of the flame and the projected iron by a bad conductor of heat. This arrangement prevents the cooling water from being heated to any considerable degree. The burner is preferably some yards in length.

This simple appliance is worked as follows:

The hydrogen is allowed to escape first from one of the two tanks shown in Fig. 2, and is lighted, after which the stream of oxygen from the other tank is turned on. The pressure of both gases is first kept low, but gradually raised and regulated in such a way as to give a very hot flame, which heats the spot upon which it impinges to a white heat, as in Fig. 3. The pressure of the oxygen is then raised to such an extent that the iron commences to burn, which is shown by sparks being thrown about, as in Fig. 4, taken half minute after Fig. 3.

The pressure of the oxygen is now further raised to 30 atmospheres and above, whilst the supply of hydrogen is entirely stopped. It is now the iron alone which burns, thus replacing the hydrogen as a combustible, whereby a degree of heat is developed which far surpasses that produced by means of oxy-hydrogen gas. The high pressure of the escaping oxygen serves to force out all the molten iron, thus keeping the hole perfectly clean throughout the operation. In this way a solid block of cold iron or steel, say 16 inches thick, can be pierced within 1 or 2 minutes.

The heating effect of the oxy-hydrogen flame alone is far too low to serve the purpose of opening closed-up tap holes or tuyeres. This is principally due to the fact that (on account of the comparatively great volume taken up by hydrogen) the loss of heat of formation is much too large, as compared with iron, taking both as combustible matters into account.

The oxygen process, however, has been successfully applied for opening tap holes closed up by solid iron or steel. It is of great importance that no delay should occur in tapping an open-

hearth furnace as soon as the liquid metal has reached the desired degree of decarbonization, as otherwise its composition might change to such an extent as to render it useless. The new process is extremely rapid in working, a few minutes being sufficient to perform the operation. Fig. 5 was taken half minute later than Fig. 4: the tap hole is being opened, the iron pouring out.

The same process is also used for improving steel ingots by removing the "pipe" caused in the upper portion owing to the shrinkage during cooling. The crust of solid steel or iron above the pipe is burnt through by means of the outfit above described within less than a minute, and superheated liquid metal of the same quality as the rest of the ingot poured in so as to thoroughly fill up the pipe.

Another successful application has been made for removing dead heads or runners on steel castings, which is of special value in cases where the hardness of the steel casting is such as to resist the action of the cutting tool.

The oxygen process can be employed also in rolling mills, where work can be discontinued only at considerable expense, for melting through and quickly removing any broken shaft or axletree from couplings, flywheels, and the like. It has also been advantageously used for piercing armor plates for war ships, and armored turrets, which is of special importance in case such plates are of hard metal. A hole through such a plate of say 9-inch thickness would require 2 or 3 hours if drilled in the ordinary way, whereas the same work can be done with compressed oxygen within 15 or 20 seconds. In this case the electric current has been found more convenient than oxy-hydrogen flames for producing the necessary initial heat, a current of from 4 to 6 volts, and about 200 amperes, being quite sufficient.

FIG. 2. OPENING A TAP HOLE

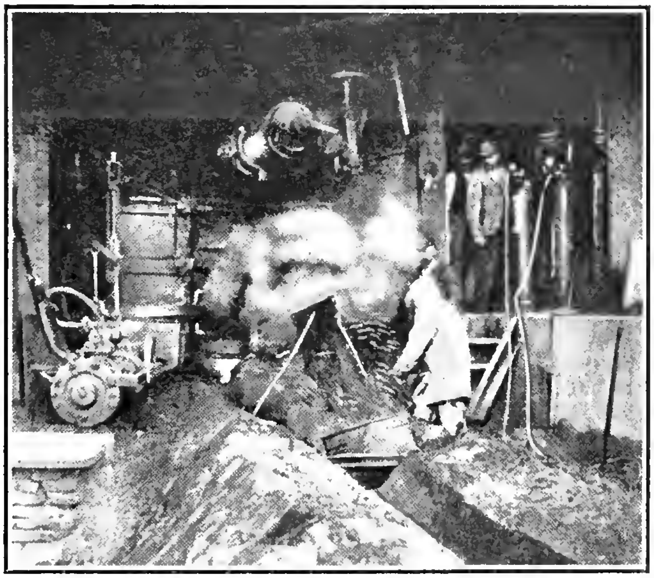

FIG. 3. PREHEATING

FIG. 4. ONE-HALF MINUTE AFTER FIG. 3

FIG. 5. IRON POURING OUT ONE-HALF MINUTE AFTER FIG. 4

The principal outlay is for the oxygen gas, which costs about 75 cents for 35 cubic feet, so that the working expenses are far from being prohibitory.

The Yukon placers yielded their largest annual output in 1909. Practically all the Yukon camps have increased production, those of the Tanana Valley leading with about $10,150,000. Of this amount the Fairbanks district produced $9,650,000. A further increase of production is recorded for the Koyukuk district and an important feature of the year's mining was the continued success of dredging in the Fortymile district.

HISTORY OF THE WATER LEYNER DRILL

Written for Mines and Minerals, by Chas. A. Hirschberg

The Development of Hammer Type of Rock Drill Delivering Air and Water at Point of Steel

Any "History of the Rock Drill" would be incomplete without mention of the Water Leyner drill, which is in general use wherever mining or tunneling is in progress, and marks a stage of advancement in rock drilling, the same as the electrified street railways of today have superseded the old cable tram lines.

Mr. J. Geo. Leyner is of German descent and was born in Boulder County, on August 26, 1860, being the second white male child born in what is now the state of Colorado. His father was a ranchman, but Mr. Leyner very early developed a genius for things mechanical and was not content to stay and take up the work upon his father's ranch.

He spent a number of years in active mining, both in the mechanical and in the underground departments. In 1893 he located in Denver, opening a shop for the repair of mining machinery. In 1895 he brought out his first rock drill, which was of the reciprocating piston type; 1897 saw his first hammer drill and 1898 the first Water Leyner drill.

There is no questioning the debt the mining industry owes to the invention of the reciprocating or piston type of rock drill. It has been the means of increasing the world's mineral production, more than any one thing, through placing the operator in a position to work the low-grade ores that previous to the advent of power drilling were in the prohibited class, due to the cost of hand drilling absorbing the full value of the mineral contained in the rock.

But, from the advent of the first reciprocating piston drill up to the present day, there has been but little material improvement made upon them along the lines of greater drilling efficiency or tending to abate the very serious dust nuisance, which has been the bane of the rock-drill operator.

It remained for a western man, born and raised among the hills of Colorado, to raise the standard of efficiency in rock drilling machines and also bring about a healthier underground condition, by the invention of a water device which allays the dust and prevents that dread disease, miners' phthisis, which has always been associated with drilling, except where this device is used.

The first drill brought out by Mr. Leyner, in 1895, was of the reciprocating piston type, similar to those on the market at the present time. Being, however, of a progressive and inventive turn of mind, he was not satisfied with this type of drill, which had then been in use practically 40 years. He began experimenting with drills involving the principle of the hand hammer blow and soon became convinced that this was the ideal one for rock drilling, due to the fact that the whole energy of the blow would be imparted to and through the drill steel to cut the rock and would not be wasted in overcoming inertia and friction. This is the case with piston drills in which the steel is rigidly fastened to the piston and both move back and forth in the drill hole several inches, whereas, in the Leyner drill the only moving part is the hammer. This construction also gives a weight that is light and constant at all times, permitting lighter construction and greater drilling speed.

The correctness of this principle is generally admitted by the mining fraternity and by manufacturers, who, until recently, advocated the reciprocating piston type of drill, exclusively.

Other inventors had previously experimented with drills of the hammer type, none of which, however, proved successful commercially. Mr. Leyner is, therefore, the pioneer in the advocacy, invention, manufacture and sale of drills constructed on this principle, which has proved successful.

The first hammer drill which he produced did not embody the water feature, but, realizing the value of cleaning the holes of the rock cuttings while drilling, and, as the dust created by passing air alone through hollow drill steel to the cutting point prohibited the use of the drill as then constructed, he conceived the idea of passing air and water combined through the drill steel to the cutting point.

Passing air and water through the drill and the drill steel is very important to the mine manager, for the reason that it ejects the rock cuttings from the hole during the process of drilling so that the steel is cutting virgin rock with every blow. Further, the fact that the dust is allayed at the same time, improving underground sanitary conditions, is receiving the attention of governments, notably that of the British government, particularly in South Africa and in Australia.

The first model of the Water Leyner drill was brought out in 1898 and demonstrated the value of the hammer principle as well as the water feature. The attention of Mr. Leyner has since been devoted to simplifying and strengthening the means of utilizing these two features, with the result that now the Leyner rock drill consists of the fewest possible number of parts, each of ample strength to constitute a rock-drilling machine of the highest efficiency and economy yet attained. In late models, new appliances of utility and convenience have been added, one of which is an automatic oiling device which consists of a pocket or oil chamber cast on the side of the drill cylinder, from which ports lead into the cylinder and are covered by the hammer, which at every movement, wipes a light film of oil sufficient to oil the machine throughout. The importance of this is at once apparent, for rock drills, more than any other class of machinery, are subjected, not only to abuse, but to passive inattention and neglect as well. This device insures proper, automatic, continuous lubrication of the drill without any attention from the operator.

The air throttle, unlike that of other drills, is located in a taper seat formed in the drill cylinder casting. This is automatically pressure packed and consists of two parts, a handle and valve, while its location is both convenient and safe.

Another important feature of the Water Leyner drill is that it permits of the use of an improved system of pointing drill holes, which, when charged with explosives and fired, break the ground more effectually than by other systems. The term "Leyner cut"* as applied to a round of holes has come into general use on account of the many upper or dry holes involved which can be drilled to advantage only with Water Leyner drills. From the fact that the drill holes can be pointed exactly as they should be, without regard to angle, direction, or condition of the face and are not limited in position by the unwieldiness of the machine, as is the case with piston drills, much less powder is required and the same breaking effect can be obtained with fewer drill holes of smaller diameter.

It is possible with Leyner drills to carry out accurately every time, any system of holes that may be devised for breaking the rock to the best advantage. In other words, a hole can be started wherever desired and bottomed accurately at a predetermined point, which is an advantage especially valuable in tunnel driving. In fact, the Leyner drill has reached such a point of efficiency that today it holds the three best American tunnel-driving records, not alone for drilling speed, but on a basis of cost per foot of advance, for maintenance, power, and labor.

Owing to the rapid growth of Mr. Leyner's business it was necessary to move to larger quarters, but in 1902 it was found that still larger quarters would have to be provided, and, consequently, in September, 1902, he formed a stock company, incorporating under the name of the J. Geo. Leyner Engineering Works Co. Twenty-six acres of land were arranged for just north of Littleton, Colo., a suburb of Denver; new shops were erected and October, 1905, found the company occupying its present home.

The shops contain 107,350 square feet of floor space and are equipped with the most modern machine tools, all operated

* See Mines and Minerals, June, 1910, page 652.

by electric motor, current being generated by their own plant, making the combination one of the most compact modern manufacturing plants west of the Mississippi River. Although when built it was expected to be ample for the company's requirements for many years to come, the need for more room is becoming very apparent.

LAKE SUPERIOR COPPER ORES

The persistent rumors that the Calumet & Hecla Mining Co. is planning to curtail still further its production of copper are not borne out by indications at various shafts and mines controlled by the big company. The Allouez is increasing its ore reserves and doing much development work underground on the Kearsarge lode. No indication that the rock shipments are to be cut are to be seen. At the Red Jacket shaft it is said that the rock shipments are to be kept as large as possible and at the same time allow for the repairs that have been planned and are considered absolutely necessary there. The repair work at this shaft started the first of August and probably will continue a month and a half. At none of the other shafts are there any indications that the product is to be further curtailed at the present or any time during the summer. This leads local investors to believe that the mining company officials see more than a mere gleam of hope for a betterment of the copper metal situation in the near future. Buying of copper shares is a little stronger and the tone of the market of late has been much better than for some time past.

More encouragement is being met at the Seneca as the work of development continues. Nothing but disappointment was experienced for a long time but now some copper is being cut in the south drift at the third level. The shaft is down 920 feet and the station is being cut, preparatory to cross-cutting. The shaft is in the foot-wall of the Kearsarge lode.

At the New Arcadian the pit is down 16 feet in the overburden. This is being sunk to uncover the copper bearing amygdaloid cut some time ago during the diamond-drill operations.

By utilizing exhaust steam to drive a turbine electric generator, the Quincy Mining Co. hopes to secure 50 per cent. more power for the amount of fuel consumed, thereby reducing the operating costs. Waste steam from the No. 2 hoist will be employed and from one turbine the company hopes to secure about 500 additional horsepower, all without extra expense. The first turbine has been placed in operation and attracted considerable attention from mine superintendents from all parts of the district. Other turbines will be placed in operation at other parts of the mine, and also at the stamp mill. The power generated by the one turbine is believed to be sufficient to operate all underground electric locomotives, rock-house machinery, shops, and all places where electricity can now be used. The coal used in mining and stamping 1 ton of Lake Superior rock is estimated to cost from 14 to 24 cents, according to the hardness of the rock, the depth and haulage, and it is hoped to reduce the cost of coal from one-third to one-half by utilizing the exhaust steam. The idea is that of General Manager Lawton of the Quincy Mining Co., who braved the skepticism of mining men for about two years while he was planning the details. There is no doubt that the arrangement, which so far has worked all right, will help the mines of this district to economize.

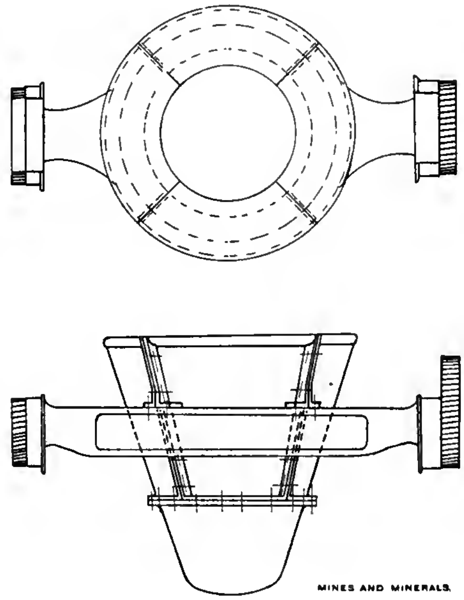
A notable change in policy is to be put into effect at the property of the Lake Copper Co. by the new management, which recently assumed control. Rock shipments will soon be stopped, it is said, and the entire attention of the management centered on development work, the opening up of large ground reserves, and proving up of the property so as to leave no doubt as to its future. The new management believes it will save money by preparing the property for operation on a large scale, and will inaugurate a systematic and broad-gauge plan of development work in every department of the mine's operations. The company's new compressor and its 50 drills will be in operation next month. No attention will be paid to production, but all efforts aimed at making the property one of the big and profitable producers of this region when sufficiently opened up.

SECTIONAL SLAG POT

Written for Mines and Minerals, by E. C. Reeder

Among all smelters handling furnace slag from the furnaces to the dump in large pots drawn by locomotives, there is always more or less trouble with the bowls of the pots from cracking of the material, which, of course, leads to breaks which destroy the usefulness of the pot. These breaks are usually patched up to prolong the life of the pot, but a new bowl is the final solution.

At the works of the Canadian Copper Co., at Copper Cliff, Ont., they use large pots which run on standard-gauge trucks and hold about 20 tons of slag. Originally these pots were made of cast iron in one piece, but after comparatively short service they went to pieces. Cast steel was then tried without much



better results. Finally a scheme to make the pot sectional was hit upon and it was worked out very successfully.

The bowl is made in five pieces, as shown in the sketch, the various sections being held together by bolts which pass through flanges on the edges of the sections. Asbestos gaskets are used to take up the inequalities of the castings which are not machined. All bolt holes are cored. In actual use the top sections crack first, but it is a very simple matter to take out the broken section and replace it with a new one.

With this form of construction the evils of pouring hot slag over a joint are done away with and the expansion of the bowl automatically adjusts itself without strain.

This device has been in use at the Canadian Copper Co.'s smelter for some 4 years or more, and all their slag cars are so equipped.

PROOF ASSAY FOR COPPER

In the proof assay for copper, instead of adding hydrochloric acid and filtering, it is possible to allow for the silver present, and subtract this amount from the result of titration. For every 100 ounces of silver present, subtract .10 per cent. copper. Thus for 600 ounces of silver per ton, subtract .6 per cent. copper. This simplifies the operation.

UTAH CONSOLIDATED AERIAL TRAMWAY

Written for Mines and Minerals, by Leroy A. Palmer

Method of Cheaply Transporting a Large Tonnage of Ore in a Rough Region

When the International Smelting and Refining Co. located its plant at the mouth of Pine cañon, at Tooele, 6 miles from the nearest railroad, the question of ore transportation became one of importance. In order to get supplies, the company built the Tooele Valley Railroad which serves very well the shippers from the south and west, but a large part of the ore supply is to come from Bingham, and this called for some special provision. While the plant is only a few miles over the mountain from Bingham, the country between the two places is impractical for railroad construction, and in order to ship by rail the ore must be hauled out of Bingham around the mountains to Garfield, over the Denver and Rio Grande, thence by the Salt Lake route to Tooele, and by the Tooele Valley to the smelter, a distance of 48 miles from the loading stations at Bingham, which are 1½ to 3 miles from the largest shippers. To overcome this roundabout and costly way of transportation two enterprises were projected, both of them to serve individual corporations, but one of which will doubtless serve other of the Bingham companies than that for which it is being constructed. One of these is the aerial tramway of the Utah Consolidated and the other is the tunnel of the Utah Metals Co. The Tooele Valley Railroad does not present any features which are not found in many ore roads but the other two projects are worthy of some consideration.

The new aerial tramway of the Utah Consolidated starts from a loading station near the mouth of the mine tunnel and ends about 500 feet from the sampler of the International

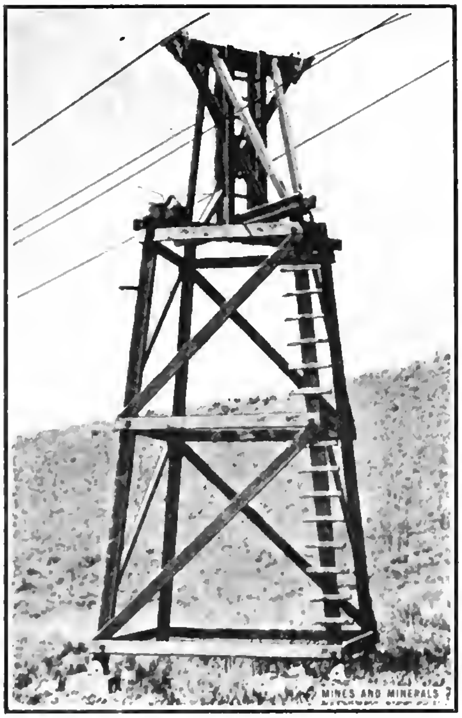


Fig. 1. Tramway Tower

smelter, a horizontal distance of 21,040 feet, slightly less than 4 miles. It is the Bleichert wire-rope tramway system of the Trenton Iron Co., and erected by the Utah Consolidated under the supervision of the Trenton Iron Co.'s engineers. The capacity is 100 tons per hour with a rope speed of 600 feet per minute. Leaving the loading station at an altitude of 6,824 feet the line goes directly up the side of a mountain to a tension station from which it crosses a gulch with its longest span, 1,145 feet, to control station No. 1 at an altitude of 8,250 feet, the highest point on the line, where the first traction rope ends. Thence down the side of a mountain to control station No. 2 in a gulch, where the second traction rope ends. From control station No. 2 it goes up a second mountain side, then down the opposite side and across a flat to the smelter, the ter-

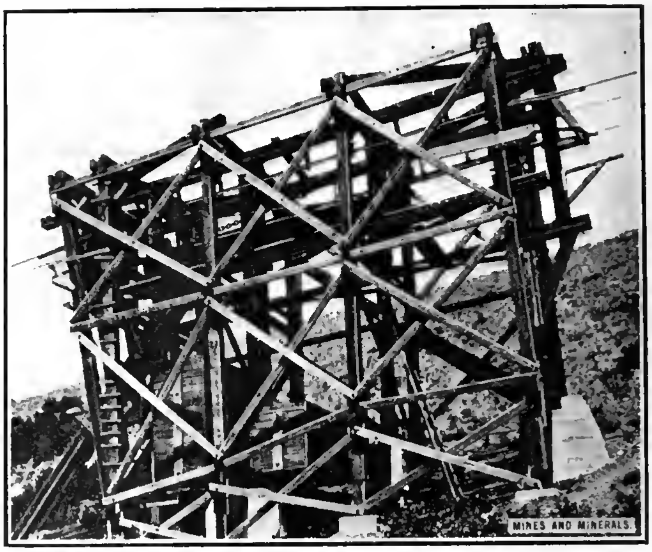

Fig. 2. Tension Station

minal at this point having an altitude of 5,507 feet. The rise to the summit is 1,426 feet in 4,400 and the drop is 2,743 feet in 16,600 so that the line beyond the summit not only has 1,300 more feet of drop than the portion to the summit but also carries 3¾ times as many loaded buckets which gives an excess of power which is utilized for doing work.

These figures will give some idea of the topography of the country, and when it is considered that the line runs directly over two mountains and through a heavy growth of scrub oak for a considerable portion of the way it will be understood that the construction was attended by considerable difficulty. A wagon road winds back and forth across the line as it goes up the first slope, but even so a considerable amount of packing was required. Over the mountain the only method of transportation by which the materials could be gotten into place was by means of burros, and all timber, cement, sand, gravel, and even water, was hauled in this way. For this reason the company found difficulty in letting a contract for the construction of this tramway and finally undertook the work themselves. Notwithstanding the fact that the cost of construction was high, the tramway was completed at less cost than the tramway company's engineers placed as a minimum.

The ore is hauled from the mine in trains drawn by an electric locomotive and is dumped to the bins from which it is unloaded through hand-operated rack-and-pinion gates to the buckets which have a volume of 8 cubic feet and a capacity of 1,280 pounds. Inside the loading and terminal stations, and all others where the traction rope is led around sheaves, the buckets are detached from the stationary cable and run along a track to the other cable or to the return side of the same cable, as the case may be. The detaching and attaching is done automatically by a board which lies alongside and engages a lug on the grip. The stationary cable on the load side is a 1½-inch patent lock-coil and on the empty side a 1-inch of the same type. In the lock-coil cable the two outer rows of wires are made with flat surfaces and the outer row cut so as to interlock. This gives a perfectly smooth surface which has proved very efficient in withstanding the continual wear to which it is subjected. The moving rope, which is $1\frac{1}{16}$-inch, 6-strand, 19-wire Lang-lay, cast-steel, passes

around an 8-foot terminal sheave mounted on a tension car connected by cable to a box containing 3,000 pounds of scrap iron, the tension at the sheave is 1,500 pounds as the weight is suspended from a pulley.

On the line there is a total of 78 towers, 7 tension stations, and 2 control stations. The towers, which are of the latest model adopted by the manufacturers, as shown in Fig. 1, vary

Fig. 3. Control Station No. 1

in height from 10 to 80 feet. They consist of 4 posts of 8"×8" timbers with a batter of 1 in 10 each way, so that the slant of the post is about 1 in 7. These posts are braced by 3"×8" timbers every 10 feet of height. The cap, which is 10 feet above the tower proper, is of 10"×12" timber substantially supported by posts and side braces, also by floor beams, front and rear braces. The towers are set so that the diagonal coincides with the center line of the system. Each post rests on concrete which has been carried to a firm foundation, at least to 4 feet unless solid rock was encountered at less depth. Bolts are embedded in the concrete of each pier and to these a square cast-iron socket is attached. The post sets in this socket and is securely bolted to it.

The tension stations are built of 10"×10" timbers set on concrete piers as in the case of the towers. The end posts are slanted so as to give stability and rest against buttresses on the piers. There is, perhaps, more timber in these stations than is really necessary, but the line is built for high duty and high speed and it is doubtless that any error in the design of these stations lies on the side of safety. One end of each rope is anchored to a deadman, and the other ends are attached to boxes which contain 42,000 pounds of rock on the loaded rope and 21,000 pounds on the empty rope. The boxes are shown in Fig. 2. The braces of the tension stations are of 3"×8" timbers.

One of the two control stations, Fig. 3, is situated at the highest point of the line and the other is in the bottom of a deep gulch beyond. That portion of the line from the loading station to control station No. 2 works almost in balance. A 100-horsepower General Electric induction motor at control station No. 1 is used to start the line, but once in operation, only 15 horsepower is required to maintain it, this amount being used in overcoming friction. The motor is belted to a pulley which is clutched to a 6-inch shaft. On this shaft is a pinion which drives an 8-foot gear mounted between two grip sheaves carrying the traction ropes. The sheaves are controlled by 10-inch strap brakes which are applied by wheels running on threaded reach rods.

Power is being taken temporarily from a stub line of the Telluride Power Co., but will be supplied by the International smelter when that plant is in operation. It comes from the line at 5,000 volts and is stepped down to 2,200 at control station No. 1 in three 37½ kilowatt General Electric transformers and part sent to control station No. 2 at the lower voltage.

Control station No. 2 is similar to No. 1 but is equipped so that the motor can be used as a generator. This portion of the line requires about 100 horsepower to start, but once in operation, the long drop on the farther side of the mountain develops 100 excess horsepower which is returned to control station No. 1 and to the mine, the only power drawn from the supply line being an amount sufficient to excite the field of the generator.

The lower terminal of the line, shown in Fig. 4, is about 500 feet from the sampler of the smelter. The general arrangement is similar to that of the loading station. The buckets are detached automatically and are dumped by hand to the bins from which the contents are unloaded to standard-gauge railroad cars and hauled to the sampler.

According to the annual reports of the company, shipment to the Garfield smelter by means of the old tramway and the Denver & Rio Grande Railroad cost in round numbers, 50 cents per ton, 8 to 10 cents on the tram and 40 cents on the railroad. The old line was something over 2 miles long, so, while it is too early to make any definite statements, it would seem that transportation by the new line should be accomplished for 15 cents per ton and perhaps less in time. The contract with the International smelter allows a maximum of 1,200 tons per day but it is probable that the Utah Consolidated, for the time being at least, will maintain its present output of 800 tons per day. They had a 40-cent per ton rate from Tooele to Garfield, and shipped that way, while trying out the tram, a sufficient amount of ore to close the contract with the Garfield smelter, which was on a tonnage basis. To ship from Bingham to Tooele by rail would require transfers at Garfield and Tooele, so that it is unlikely that a rail freight rate of less than 80 cents per ton could be obtained, to which must be added the 8 to 10 cents cost over the old tram. The tramway should thus effect a saving in freight of 75 cents per ton or $600 a day, practically $220,000 per year, and will thus return the cost of construction within a very short time.

The writer wishes to acknowledge the courtesy of J. B. Risque, general manager of the Utah Consolidated, and S. S. Webber, chief engineer of the Trenton Iron Co., who have assisted in the preparation of this article.

The farmers in Shasta County, Cal., have been so aggressive in their fight against smelter smoke that the different smelters have been compelled to meet the smoke problem in various ways.

The Mammoth Copper Co. has added a bag house to the Kennett smelter and will neutralize the gases by the process so successfully adopted at the Midvale smelter, Utah.

The Mountain Copper Co., an English corporation whose furnaces are at Keswick, have added an acid plant and entered into the manufacture of fertilizers.

Fig. 4. Tramway Terminal at Smelter

The Balaklala Co., at Coram, Cal., is installing the Cottrell process of smoke abatement, $ZnO+SO_3=ZnSO_4$, which was introduced at the Selby Smelting and Lead Co.

The Cottrell process of smoke abatement consists in precipitating solid particles in the smoke by electrical discharges.

LAKE SUPERIOR IRON ORE

A document filed for record in the mining region is a mortgage for $2,500,000, given by the Shenango Furnace Co. to the Pittsburg Trust Co., Pittsburg, Pa. The property covered by the transaction is the Webb Mine, near Hibbing, Mesabi range, and the mortgage is executed to secure the issuance of $2,500,000 in 5-per-cent. 20-year gold bonds, redeemable on any interest day after June 1, 1911. The bonds are dated June 1, 1910.

The purpose in giving the mortgage and issuing the bonds is to provide funds for the development of the Webb property. The Webb has been closed since the fall of 1908, although some ore was shipped during the season of 1908. The mine has been operated as an underground proposition, and it is now the intention to transform it into an open pit. The stripping will require a number of years and will cost, it is estimated, about $2,000,000. The Webb contains a large body of excellent ore, and once opened for steam-shovel mining the deposit can be taken out much more cheaply than under the present system.

The Syracuse Mine has been abandoned by Pickands, Mather & Co. While $6,000,000 worth of iron ore is contained in the property, it is impossible to mine it, and it rests securely under a deep, treacherous and shifting overburden, half water and half ground. The Syracuse is in the Lake Embarrass district of the Mesabi. A large sum of money was spent in a fruitless endeavor to open the deposit by the usual methods.

Pickands, Mather & Co.'s Hemlock Mine in Amasa, Menominee range, which has been closed down during the erection of a new shaft house and the installation of a new hoisting plant, has resumed operations. The shaft house has a total height of 85 feet and is built of Washington fir. The hoisting plant is of the Wellman-Seaver-Morgan Co. pattern. The duty is 5 tons from a depth of 2,000 feet.

The Jones furnace interests of Iron Mountain, who some time ago took over the old Kloman Mine, in the Republic district of the Marquette range, have decided to erect a large engine and boiler house and install a plant of machinery forthwith.

The Jones & Laughlin Steel Co., Pittsburg, has started the exploration of additional tracts of its Marquette range lands. Diamond drills are to be used. The tracts to be tested are in the Ishpeming district. The company's Lake Angeline Mine in Ishpeming, which is still a valuable property, is not the producer of high-grade ore that it once was, and it is hoped to supplement it with the development of new deposits

The Rolling Mill Mine, at Negaunee, was discovered by the company as a result of deep drilling operations some years ago, and is now becoming an important producer.

The Republic Iron and Steel Co. is restoring the Hartford Mine in Negaunee to the list of Marquette range producers. The new operators acquired the property in June, when a 10-year lease held by the United States Steel corporation expired. The ore in stock, and which is owned by the steel corporation, is being shipped at the rate of 10,000 tons a week.

Some notable improvement work is being carried on at the Zimmerman Mine, in the Spring Valley district of the Menominee range. The Spring Valley Iron Co., besides erecting two new engine and boiler houses, has under construction a commodious office building, two stories high. An entirely new plant of machinery has recently been installed. A new spur track to the property is being built by the Chicago and North-Western Railroad. The mine is controlled by Eugene Zimmermann, of Cincinnati, and his associates.

The Section Thirty Mining Co. is proceeding rapidly with the development of its property on the Vermilion range. The deposit, apparently, is extensive, and the ore is of the finest quality. The property is being given an excellent equipment. Ore is being hoisted from two shafts. The product is being mined almost entirely as a feature incidental to the development work, notwithstanding which, fully 50,000 tons will be shipped the present season. The ore is going to the docks at Two Harbors over the Steel corporation's Duluth and Iron Range road. It has cost upward of $500,000 to demonstrate the existence of high-grade ore in quantity in the Section Thirty, and this only after various operators had made a failure of the effort. The mine is being developed now by George A. St. Clair, mining engineer and geologist, associated with Alfred Merritt, of Duluth. The developments at Section Thirty have greatly stimulated exploratory operations on the Vermilion. Various properties are being drilled or test pitted, and in some cases shafts are being sunk. It is the claim that new ore bodies are being found.

Among other properties, the conditions at the North American, Vermilion Steel and Iron, and Vermilion Steel Extension, are reported satisfactory.

The Vermilion Iron Development Co. is sinking a shaft on Pine Island. The formation here is about 200 feet in width and on the surface contains a fair grade of ore mixed with jasper. The shaft will be sunk 500 feet.

SLAGS

The furnace man aims to make a mixture of ore and fluxes which will form a fluid slag, as thick or pasty slags prevent a thorough separation of the metal and much will be lost in such slags. Since acid ores are in excess in the precious metal mines, the slags are made silicates by the addition of lime or iron oxides in sufficient quantities to make the silica run easily.

Slags are classified when they are silicates according to the ratio of oxygen in the base R to the oxygen in the silica (R stands for any basic oxide).

The fusibility of a slag depends upon the character of the bases and upon the percentage of silica it contains. The silicates of lime and alumina are the least fusible. Slags of the composition $CaO \cdot SiO_2$ and $4CaO \cdot 3SiO_2$ are fusible, but the latter is not as readily fusible as the former. It requires a little over 1.6568 times as much limestone, $CaCO_3$, as silica to produce a slag of the composition $CaO \cdot SiO_2$.

Name	Slag	Oxygen Ratio
Subsilicate	$4R_2O \cdot SiO_2$	2 : 1
Singulosilicate	$2R_2O \cdot SiO_2$	1 : 1
Bisilicate	$R_2O \cdot SiO_2$	1 : 2
Trisilicate	$2R_2O \cdot 3SiO_2$	1 : 3
Sesquisilicate	$4R_2O \cdot 3SiO_2$	2 : 3

2. Another system of naming slags is according to the ratio of FeO to CaO. Thus, a slag containing 36 per cent. FeO and 24 per cent. CaO would be termed 1½ : 1 slag.

Slags, Typical Lead

	Per Cent. in Slag			
	SiO_2	FeO	CaO	ZnO
A	35	28	28	
B	34	34	24	
C	34	34	17	7
D	30	40	20	
E	30	48	12	
F	28 to 30	54	6	

A, is adapted to ores carrying Al_2O_3.
B, one of the best fusible slags.
C, favorite with high Zn in charge.
D, an excellent slag known as the one-half slag.
E, an excellent slag, known as the one-fourth slag.
F, not as good as the others.

The sum of the SiO_2, FeO, and CaO is considered as making up 90 per cent. of the slag constituents, except when the ores contain much ZnO and Al_2O_3.

THE EVOLUTION OF HOISTING

Written for Mines and Minerals, by E. B. W.

Raising mineral products is a problem, old as mining, which has been solved in many ways by succeeding generations according to the exigency of the case. Naturally in semibarbarous times the demand for coal and ore was not so great as to require the engineers of those times to devise means for hoisting from great depths; but the engineers of today must take off their hats and acknowledge that the engineers of the past solved their problems properly.

Some Ancient Methods Showing the Ideas from Which Modern Machines Have Been Derived

If it were possible to avoid hoisting by driving adits they did so, even in barren rock, without powder, using fire and water and their rude tools to make the advance. It could be understood readily from present-day practice had not Agricola, who wrote in 1550, stated, that hoisting was one of the greatest obstacles to economic mining.

Near Guanecevi Durango, Mexico, there is an ancient mine opening with stone steps leading to a subterranean excavation, which tradition states was worked in the seventeenth century by Spaniards who used Aztecs as miners. The opening is inclined, and up this inclination the "carilleros" brought baskets of ore.

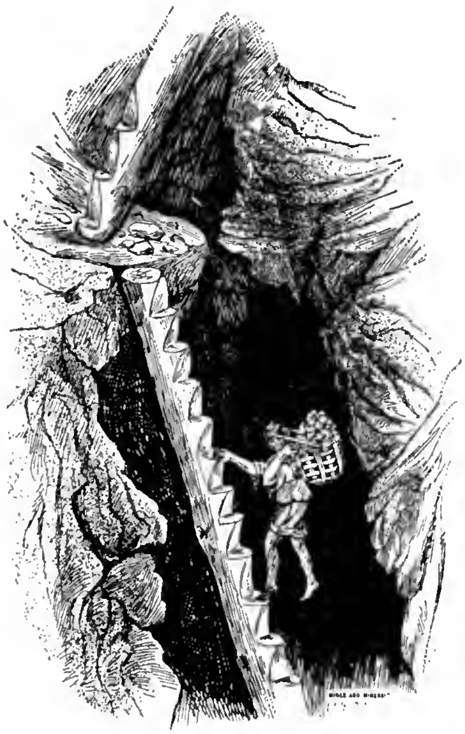

FIG. 1. NOTCHED POLE LADDER

Near the Ojuela Mine, at Mapimi, Mexico, mining is carried on in a small way, and the hoisting is done by carrying baskets of ore up steps cut in the limestone. The contrast between the old and the new way is here made impressive, because of the excellent hoisting apparatus of the Ojuela Mine.

In a number of places in Mexico where mining is carried on in a small way, the shafts are supplied with logs in which alternate notches have been cut for the feet. Ore is carried up these poles, which the English-speaking scoffers term "chicken ladders," in bags or baskets. One of these poles was to be seen protruding from the shaft in the illustration of the Mexican ore carriers mentioned in the "Evolution of Mine Haulage."* The illustration, Fig. 1, of this article is no exaggeration, besides this method of hoisting is not uncommon in other countries as well as Mexico, hence the past and present can be linked without fear of contradiction in this cameraean age.

Until the middle of the eighteenth century, in Great Britain men and women were worked under laws which practically made them slaves. Children, as soon as able, were sent into the mine to help their parents, in fact were born miners, whose bodies belonged to the operators. In 1373 Bishop Hatfield constituted John de Belgrave and Nicholas Cook commissioners to seize workmen and coal bearers for the mines of Whickham and Gateshead, wherever they could be found within his royal liberty, with full power to imprison and otherwise punish them should they prove rebellious and obstinate.† Fuller states in his "Worthies of England," that in 1296, 360 miners were impressed out of the Peak of Derby and Wales for the King's silver mines in Devon. Again in 1526 it was proposed to Henry VIII to levy men for the same mine. Queen Elizabeth gave power to impress workmen, wagons and horses to carry on mining in 1580. In the following century Lord Bacon advocated the employment of felons in recovering and working abandoned metalliferous mines; thus holding out a prospect of great treasures being obtained from "a promiscuous chaos of drowned minerals and condemned men." The Tennessee Coal and Iron Co. employs convicts in coal mines of Alabama, so that at present the states of Tennessee and Alabama are about in the position of enlightenment that England was in 1600, or the middle ages. The services of bondmen being available, the bulk of all kinds of work was no doubt performed by manual labor, and the "bearing system" continued well into the eighteenth century. From 1706 to 1842 mine workers hired out for a whole year under conditions and laws which practically made them slaves. Able-bodied men were paid 20 cents per day for mining and the women who carried the coal out of the mine received 6 cents per day. Lord Ashley made such a stir over the living and working conditions of miners that a Royal Commission was appointed to examine into the truth of his statements that boys and girls had to work 16 and 18 hours and never saw daylight except Sunday. The commissioners evidently found Lord Ashley's statements conservative for their report changed the complexion of coal mining in England, and from it Fig. 2 has been copied. One of the claims made by Lord Ashley was that men, women, and children who worked in the coal mines were subjected to unnecessary dangers and hardships, besides the remuneration they received was not enough to supply their demand for food. This illustration and several others appeared in the Royal Commissioners report and is therefore authentic.

FIG. 2. WOMEN CARRYING COAL IN 1842

Jonathan Bartley, of Trenton, N. J., in writing on "Graphite Mining in Ceylon," in 1909, uses Fig. 3 as an illustration of the method of hoisting in that country. He says: "The method of mining is the simple hand process with pick and shovel. Steam or air drills are unknown. As a rule shafts are sunk to water level, which usually is about 60 feet below the surface. The method of entering or leaving a mine is by means of one of two kinds of ladders. In soft soil where it is necessary to 'crib,' strong vines are cut and woven into a ladder such as shown in Fig. 3. The natives go up these ladders with alacrity

* June, 1910, MINES AND MINERALS, page 683, Fig. 2.

† Annals of Coal Mining, R. L. Galloway, page 48.

carrying bags or baskets of graphite on their shoulders. Where the rock is firm and hard, holes are drilled in the walls of the shaft into which are driven round sticks of wood. These are placed about 12 inches apart and extend about 14 inches from the wall into the shaft."

Mining machinery with men to set it up was sent to these mines in Ceylon, but nothing could be accomplished as the natives broke the machinery as fast as it was put in place. The objection to machinery seems to be an inherent quality of miners, whatever their nationality, yet the growth and development of the machine system in mining has been sure, and no attempt to resist it will be successful. The machine is a labor-saving device which lightens the miner's work, increases the output of the mines, and does not decrease wages. At some of the graphite mines in Ceylon a rope and windlass are used for hoisting, this, however, is no innovation, since it was used from time immemorial. Agricola speaks of the windlass being used in Ger-

Fig. 3. Shaft Mining in Ceylon

many. Owens "History of Pembrokeshire," which is supposed to have been written in 1602, states: "They used not engines for lifting up the coles out of the pitt, but made theire entrance slope, soe as the people carried the coals uppon theire backes along stayers, which they call landwayes; whereas nowe they sinke theire pittes downe right foure square, about 6 or 7 foote square, and with a wyndles turned by foure men, they drawe up the coles a barrel full at once by a rope."* Pits were sunk from 70 to 120 feet deep, and were drained wherever possible by water levels or adits which Owens remarks are "very chargeable."

While the windlass is the oldest mechanical hoisting apparatus known, it is still in use and will continue to be until prospecting ceases. Frequently it may be found in out-of-the-way places, constructed entirely of wood, yet nevertheless portable. Fig. 8 shows a strong-arm hoister constructed in the twentieth century. The barrel on which the rope coils is about 10 inches in diameter and is supplied with a strap brake, shown to the left of the barrel. With one man on each handle the capacity of a strong-arm hoister is 4 tons per day of 10 hours from a depth of 100 feet. In sinking winzes in ore mines, the windlass is almost invariably adopted and there are few ore-mining men who have not had the pleasure of being hoisted in a strong-arm hoister bucket which would insist on turning completely around a few times to permit of their being scratched before they reached the top.

The crab winch is an improvement, in that one man can safely handle as heavy a load as two with a windlass, but the fixed principle in mechanics that what is gained in power is lost in time prevents increased output over the windlass. The hand winch, Fig. 4, will find many uses about a mine where heavy bodies are to be lifted from time to time, and the purchase of one will not be regretted. It is probable that when animals were first used for hoisting they were attached to a rope passed over a pulley, and by means of their dead weight pulled the load up the shaft. The ancients probably found as many objectionable features to this way of hoisting from a shaft as the present generation of miners, for it seems to have been entirely overlooked in early reports, which again makes us respect our progenitors. It is presumed that the equivalent of the horse whim with several sweeps was introduced by the Egyptians; however, instead of horses, slaves were used on the sweeps.

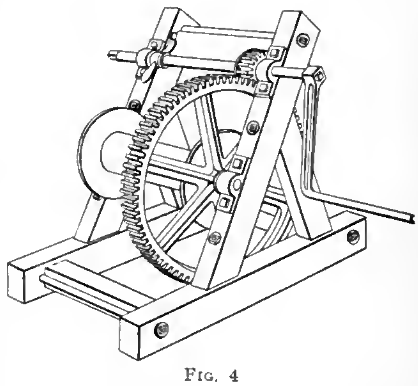

Fig. 4

From Court Records,* dated 1667, the style of horse whim, known as horse-gin,† is described, and Galloway has it illustrated, as shown in Fig. 5. It was termed a "cog-and-rung gin," and is the earliest known form of horse engine used in drawing coals.‡ The drum was placed horizontally over the shaft, as the windlass had been, but was more elaborate and of better construction, besides, as may be seen from the cut, it had a horizontal rung wheel at one end. The cog wheel, which was arranged horizontally on a vertical shaft meshed with the rung wheel and when revolved by the lever or sweep drawn by horses caused the drum to wind or unwind. It will be noted that the hoisting

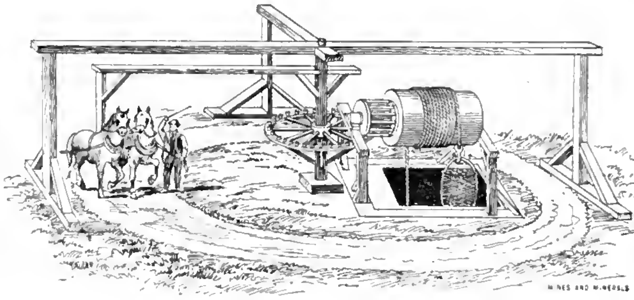

Fig. 5. Cog-and-Rung Gin, 17th Century

is done in balance and that as one bucket is drawn from the pit the other bucket descends, thus practically leaving only the weight of the coal to be raised by the horses. If one looks at the details in this engine of the seventeenth century he will find various mechanical devices which now, even if elaborated and improved, are still the same old sixpence. Galloway says that "on account of the position of the drums directly over the shafts they were frequently wrecked by colliery explosions."

*Annals of Coal Mining, R. L. Galloway, page 120.

* Transactions North of England Institute, Vol. XV, page 269.

† Contraction for engine.

‡ Annals of Coal Mining, R. L. Galloway, London, 1898, page 168.

It is possible that on this account the "cog-and-rung" gin was soon replaced by the vertical gin shown in Fig. 9, although there are other advantages in favor of the latter which the ancients learned from experience. It is interesting in following up the work of ancient Spanish miners, and the work of native miners six generations ago, to notice that their ideas of mining and the general fitness of things were equal to the miners of the present; in other words, our generation of miners are merely elaborating on the experience of their predecessors.

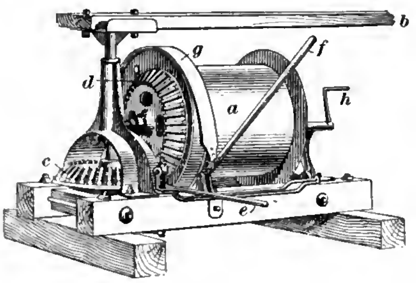

Fig. 6. Geared Horse Whim

The advantages of the "whim gin" in Fig. 7 are that the barrel is not placed directly over the shaft to interfere with the handling of the buckets, and it is not badly injured in case of an explosion. The "whim gin" shown can be fitted to hoist in balance, although this particular product of the twentieth century was not, while that shown in Fig. 7, which belonged to the seventeenth century and was used at a coal mine in England, was so arranged. It has been stated that two men working with a windlass could raise 4 tons from a depth of 100 feet. With an animal pulling over a loose wheel about 10 tons can be raised 100 feet in a day. With the horse whim in Fig. 9, 200 pounds can be raised 175 feet in 4 minutes; however, to this must be added the time for delays, so that it is not probable that more than 20 tons daily can be hoisted by this affair. With the "whim gin" in Fig. 7 a good day's work was about 90 tons of coal from a depth of 360 feet. It will be noticed that the drum is large, and the records from which it was taken state that eight horses were required to work the gin in four relays of two at a time, or, if it were necessary, four at a time. The hoisting ropes were of hemp; the drum large; while the sweeps were attached directly to the axle of the drum where the horses could pull naturally from a whiffletree, and their number was increased as required. In lowering a bucket it was necessary to reverse the direction in which the horses traveled. With proper arrangements this could be quickly accomplished, although later some one with less mechanical skill than the ancients used a swiveled whiffletree that was suspended from the ends of a

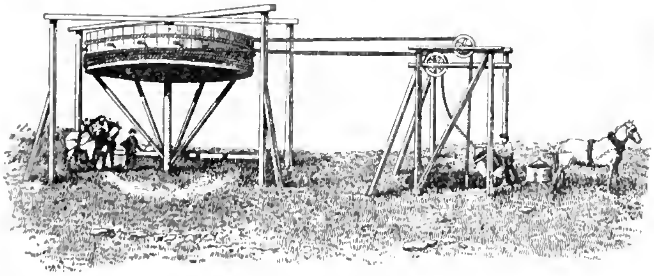

Fig. 7. Whim Gin of 17th Century

sweep above the horse. This latter arrangement greatly reduced the tractive effort of the animal, and the size of the drum, and was not adopted generally. At some mines the drums for the horse gins were housed; at other places the drum protruded above the roof of the shed which covered the teams and drivers in inclement weather. When the friction due to the rigidity of the rope and that of the axle and other sources are considered, a strong horse cannot raise more than 2,500 pounds 1 foot high in 1 minute with a whim and keep it up for any length of time. If this work be taken as the basis of foot-pounds, the power of any similar machine can be readily calculated.

In recent years the geared horse whim and horsepower have been introduced for hoisting purposes. These machines are great improvements over the old style whim gins so far mentioned; for instance, sometimes a horsepower similar to that shown in Fig. 6 has two gears, one which acts slowly for heavy lifts, and a faster one for lighter lifts.

These hoisters are well known owing to their being used so extensively by railroad contractors. They are very serviceable in prospecting and at small mines, for they are capable of raising 100 tons from a depth of 200 feet with one horse in 10 hours. The working parts of Fig. 6, with the exception of the bedplate *e* and the sweep *b*, are of iron. The machine shown has but one set of gears *c* and *d*, which are thrown in by the lever *e*

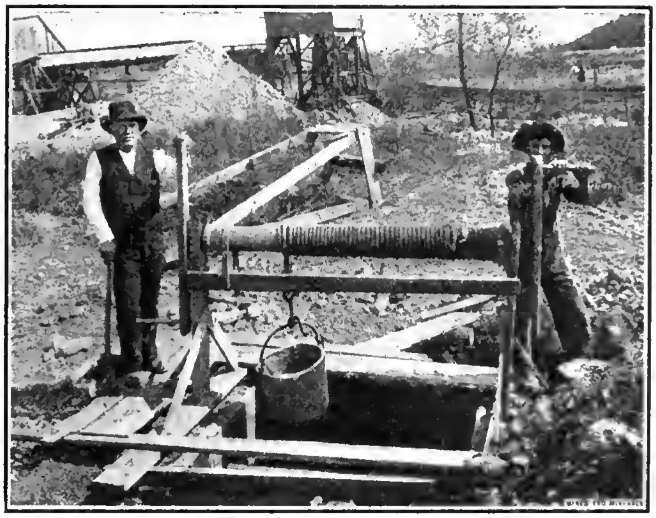

Fig. 8. The Strong-Arm Hoister

Fig. 9. Modern Vertical Whim Gin

when hoisting is to be done, or out when it is desired to lower the load. Wire rope of $\frac{1}{2}$- or $\frac{5}{8}$-inch diameter is generally used on the drum *a*, and in a pinch $\frac{3}{4}$-inch rope may be used although the rope winds stiffly. When lowering a load by gravity the brake lever *f* is used to draw the brake band *g* tight on the brake shoe of the drum. In case it is necessary the rope can be coiled on the drum by the handle *h* independent of the gears. The crank is also supplied with a dog and ratchet to prevent the rope running back when power is removed from the handle. Small loads can also be raised by the use of the crank *h*. It is possible to hoist 2,000 pounds 26 feet per minute with the slow speed, or 800 pounds 55 feet per minute with high gear. Horsepower hoisters may be used to advantage in places where prospecting, shaft sinking, and mill building, is going on, also in mining districts where fuel, water, or both, are scarce.

For some years the horse whim, shown in Fig. 10, was a favorite in the West on account of its portability and other good points. The driving gear of this machine is connected by a shaft which turns a drum, not shown, but located below ground at one side of the shaft. On the drum, a hemp or wire rope is wound, one end of which passes over the pulley on the head, frame. In this case the head-frame is more elaborate than usual, a tripod answering in most cases; however, this is not a prospect hole but a small zinc-ore mine being worked by a farmer in Missouri, between crops. It will be noticed that the bucket is landed on a small truck, which is on the platform that is the continuation of a trestle. In many cases zinc mining in Missouri is a side issue to farming that keeps the hired men busy, exercises the horses; besides "every little bit helps."

As early as 1550, at which time Georgius Agricola wrote his excellent treatise, "De Re Metallica," waterwheels were in use at German ore mines to raise buckets fastened on an endless belt which turned about a shaft and went down in the mine. The illustration, Fig. 12, is taken from Agricola, and one similar in arrangement, was erected early in 1700 for raising coal from Alloa collieries in Scotland. In 1774 a similar waterwheel hoist was constructed in Newcastle, and at the same date Smeaton erected a waterwheel for hoisting both coal and water at Griff colliery in Warwickshire.* In 1777 Smeaton designed a single bucket "water coal gin" for the Long Benton colliery. The drum motion was accomplished by means of gearing. This waterwheel gin was found to be a great improvement over the horse gin of that time, for it hoisted a basket containing 6.5 hundredweight of coal from a depth of 492 feet in 2 minutes. It is said to have accomplished the work of 16 horses and 4 men with a "whim gin."

Fig. 10. Horse Whim for Hoisting

When water was available for hoisting it was carried in flumes to the pit mouth, where of course the wheel must be situated. Such conditions necessarily limited the number of waterwheels for hoisting, nevertheless, improvements were made so that they could be quickly reversed, without the use of the gearing required in Smeaton's Griff colliery waterwheel. The simplicity of the double waterwheel, shown in Fig. 11, where it was merely necessary for the operator to move a lever attached to a gate to regulate and make the waterwheel move to the right or left, led to its general adoption wherever conditions were favorable. Those erected in 1782 in the Tyne district were abandoned in 1808, although one was in use at the Leafield colliery in the Wear district, till 1812. Even if the rise of the waterwheel gin to prominence was slow, its fall was speedy, owing to the introduction of the steam engine for hoisting purposes, in about the year 1780, when the crank was first added to furnish a rotary motion. Some of these antiquated and interesting old engines are still said to be at work in South Staffordshire.

Mr. Curr* writes in 1797 that the most ancient hoisting machine he has knowledge of was invented by Menzey, "but there are few situations that afford the requisites necessary to that invention. A stream of water with a fall of about half the depth of the pit is necessary, if any business of consequence is to be done. Its construction consists of two rope wheels fixed on one horizontal axis, which are so proportional to the depths of the water pit and coal pit as to reach separate depths of the pits by the same revolutions; and the power applied is a tub of water large enough to overbalance the weight to be drawn."

In 1891 there was a somewhat similar arrangement at Sterling Furnace, Rockland County, New York. The construction of the apparatus is shown in Fig. 13. The drum *a* is assumed to be 10 feet in diameter, the drum *b* 1½ feet in diameter, therefore, with one revolution of *b* the circumference of drum *a* will have traveled 31.416 feet. The drum *a* had cage and load to lift; from the drum *b*, which was on the same shaft *c*, a large iron tank *d* was suspended at such a height that water from a sluice *e* could quickly fill it. Assuming that the tank *d* descended to *d'*, a distance of 16 feet, or 3.44 turns of the drum *b*, then the drum *a* would raise its load 108 feet. When the tank *d* arrived at *d'* the valves *f* in the bottom were lifted and the water load discharged. The weight of the cage and empty barrow, acting on the long arm of the lever or the circumference of the drum *a*, would raise the empty tank to the position at *d* when it would be again filled with water. This machine worked satisfactorily many years at Sterling furnace. In the book termed "Fossil Fuels," a somewhat similar machine is described as follows: "The vicinity of a pit nearby sunk for working, happening to include an old shaft heavily watered from near the top, an axle with drums was placed across; to one of these was suspended by a rope a large tub, and from the other a rope was carried over the head-wheels at the adjacent pit, the tub being at the top of one pit while the basket of coal was at the bottom of the other and vice versa. The tub thus suspended near the spring is filled with water, and on the ringing of a bell, the signal for hoisting, a catch is let go by the banksman, who, pressing upon

* Farey's Steam Engine, page 297.

* The Story of American Coals, W. J. Nicolls, page 202.

a brake to regulate the velocity of the machinery, allows the tub to descend to the bottom, where a valve is opened and the water flows out. The empty corfe or basket is so much heavier than the empty tub that the former descends while the latter is brought up and secured in the situation first described."

(*To be continued*)

A SIMPLE HYDRAULIC HOIST

Written for Mines and Minerals

The auriferous gravels near Fairplay, Colo., are apparently of glacial origin, with some evidences of secondary river sorting. About 10 per cent. of the mass of material to be removed consists of boulders varying between 100 and 1,000 pounds in weight, and cannot readily be handled by ordinary means.

To rapidly and cheaply dispose of this large amount of bulky material, Mr. Jas. McChotka, Superintendent of the Platte River Placer Co., at Fairplay, makes use of a simple and efficient hydraulicly operated hoist.

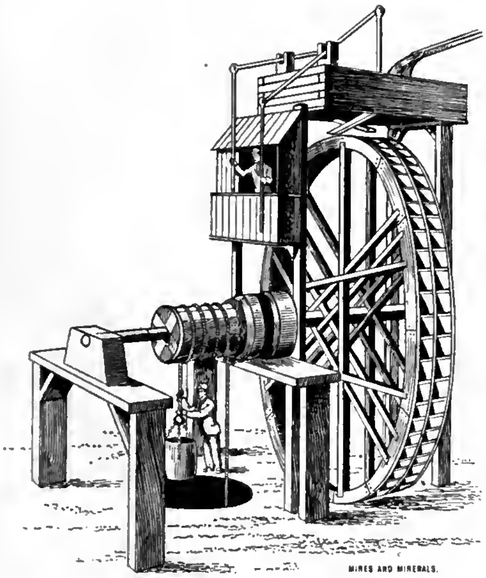

Fig. 11. Double Waterwheel Hoist

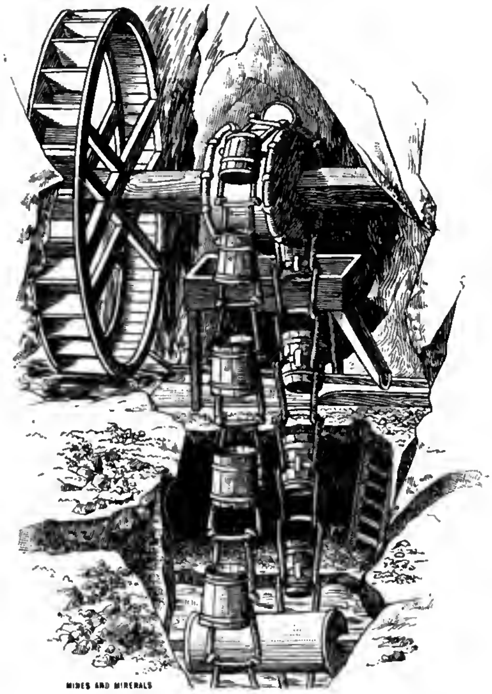

Fig. 12. Ancient Bucket Hoist

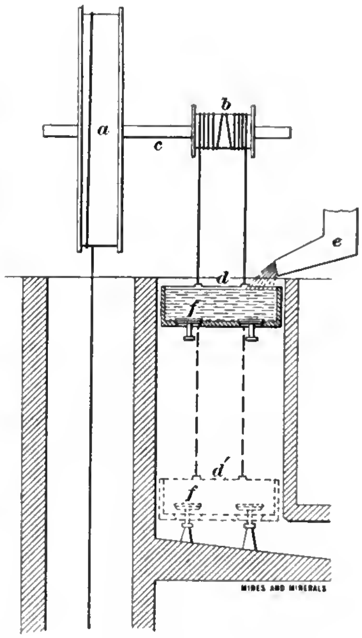

Fig. 13. Water Tank Hoist

The derrick is of the ordinary boom type provided with a detaching hook, etc. The hoisting rope leads from the foot of the mast to a spindle or drum mounted on one end of a horizontal axle, on the other end of which is fixed an impulse wheel 24 inches in diameter.

The main supply pipe line is tapped at some convenient point and the water conveyed to the hoist where it discharges through a giant, the nozzle of which has been reduced to 2 inches diameter. When not in operation the water is allowed to discharge through a wooden box beneath the wheel. After the rock to be moved is slung in chains, the operator depresses a pedal with his left foot raising the nozzle so that the water impinges upon the blades of the wheel, the drum being then brought into gear by means of a horizontal lever, actuating a pinion wheel having a ratio of 1 to 10. When the rock reaches the required height, raising the foot from the pedal allows the nozzle to drop by its own weight, the water then discharging through the box as noted above. After the water is shut off from the wheel, the drum is controlled by a brake brought into play by a pedal depressed by the right foot of the operator.

Water is supplied under a 280-foot head, or at a pressure of about 120 pounds to the square inch. Four men are required to run the hoist, one at the drum, one to release the detaching hook, and two to sling in chains the rocks to be removed. As the hoist is in use but two or three hours daily, a valve to entirely shut off the water supply is inserted in the pipe between the main supply line and the nozzle. This hoist is capable of handling eight to ten rocks of average size in 10 minutes and can be built by any blacksmith or millwright.

MINERALS OF GREECE

The mines of Greece are found chiefly on the eastern shores of the peninsula and in the islands of the Ægean, as these parts of the country are the oldest geologically, and of volcanic origin. Notwithstanding this mineral wealth, the industrial development of the country has been slow, on account of the lack of fuel, which is nowhere found in sufficient quantity. For this reason most of the minerals are exported in a crude state after the simplest possible preparation, and the exploiting only of those minerals has been found to be profitable which are valuable without being bulky and are easily mined and transported.

The following table gives the mineral exports from Greece for 1907:

Classification	Tons	Value
Iron ore	664,071	$744,529
Manganese iron	94,685	147,705
Lead ore	5,538	23,480
Argentiferous lead	9,235	623,824
Zinc ore	25,470	46,360
Manganese	9,788	58,170
Chromium	12,430	92,582
Coal	4,525	17,244
Lead	1,987	7,593

But for the lack of coal Greece would have been an important steel and iron producing country. Studies are being made as to the possibility of using lignite for smelting purposes, of which considerable quantities are found.

The iron ores are hematite, generally of high grade, and manganese in veins piercing limestone or volcanic layers. Often, as at Laurium, they appear as coverings for beds of lead, zinc, and copper.—*United States Consular Report.*

PETROLEUM INDUSTRY, VENEZUELA

Consul Ralph J. Totten, of Maracaibo, submits the following on petroleum deposits in Venezuela, the development of which will have great influence on the import trade:

There are five known petroleum deposits in this consular district. Oozings of petroleum, covering a considerable territory, are found in the district of Mara, near the Limon River asphalt lake. Oil has been located at Bella Vista, near the city of Maracaibo, and wells are to be sunk by the owners in the near future. Their object is to refine the product and to supply the local demand for illuminating and lubricating oils. Evidence of the existence of petroleum is found over a large area in the district of Sucre in conjunction with asphalt deposits. An oil field on the Sardinate River in Colombia, near the Venezuelan frontier, is being worked at the present time. The oil is refined at the wells and is sold in the near-by Colombian cities. The fifth field, and the one that seems to be the largest and most conveniently situated, is south of Lake Maracaibo in the district of Colon, state of Zulia.

A company of Maracaibo business men, who have control of these fields, is preparing to make an active campaign to interest foreign or domestic capital in the exploitation of its property. It has an advantageous contract with the Venezuelan government, which grants it free entrance for its drills, machinery, and supplies.

These oil fields can be reached by light-draft lake and river steamers. Passing up the Catumba River to its junction with the Tarra River, about 30 miles beyond Encontrados, the capital of the district, then about 50 miles through the latter river, brings one to the village of La Paloma. The oil-bearing land commences at this point and continues nearly to the Colombian frontier, including an immense area.

Abundant evidence of the presence of petroleum is to be found close at hand on some rugged hills 40 to 50 meters above the level of the river. From sources on these hills run some 20 small streams, the waters of which are constantly covered with a thick coating of petroleum. Some of the oil comes from the springs with the water and some from fissures along the banks of the streams. In one of these fissures an excavation was made 3 feet deep by 2 feet square which in almost 6 hours filled with crude oil. In this locality were found places where the surface of the earth was covered with a deposit of tar from oil that had been evaporated by the heat of the sun, sufficiently thick to destroy vegetation of all kinds.

Crude oil of two classes is found. One kind is thin enough to flow readily, having a specific gravity of .8837 at 15° C.; the other is very thick and of the color and consistency of coal tar. Both varieties show an asphaltic base, in this resembling the Texas crude oils as distinguished from oils having a paraffin base. A distillation test of the thin oil gave the following results: Between 0° C. and 120° C., .5 per cent.; between 120 degrees and 170 degrees, .5 per cent.; between 170 degrees and 235 degrees, 14 per cent. (illuminating); between 235 degrees and 271 degrees, 28 per cent. (illuminating); between 270 degrees and 370 degrees, 51 per cent. (lubricating); coke, 6 per cent. The product between 170 degrees and 235 degrees flashes at 62° C., and that between 235 degrees and 270 degrees at 83° C. The viscosity of the lubricating oil is twice that of water.

The thick oil gave the following results: Water, 28 per cent.; between 0° C. and 310° C., none; between 310 degrees and 370 degrees, 61 per cent. (lubricating); coke, 11 per cent.

The forests in this region contain great quantities of construction wood of all kinds, and, although the contract with the government permits the free introduction of all materials and machinery for the exploitation of the property, they would be of great utility in the construction of buildings, derricks, tanks, and casks. The land is sufficiently sloping for the laying of pipe lines to the river port La Paloma, where it is intended to place the refinery and tanks. Abundant wood can be had for fuel and there are coal deposits close at hand.

Venezuela alone consumes annually about 1,000,000 gallons of kerosene. The price here is seldom lower than 42 cents per gallon and often reaches 50 cents.

The location of these fields is especially favorable, having all-water connection with the city of Maracaibo and the other lake ports, as well as with the city of Encontrados, on the Catumba River. Encontrados is a city of 25,000 inhabitants and is the terminus of the Tachira Railway, which connects it with the Province of Santanner, of the Republic of Colombia. Oil could thus be shipped to all of the Venezuelan and Colombian seaports and to the interior of both republics by rail and water combined.

CALCULATING THE TONNAGE OF ORE PILES

Written for Mines and Minerals, by R. T. Hancock

The following tables are intended for calculating the weight of ore in a pile or bin whose contents in cubic yards or meters has been measured, and are based on the assumption that broken ore occupies 75 per cent. more space than it did in the solid, which is approximately true for run-of-mine, though screened large may occupy only 60 per cent., and small free from lump, up to 80 per cent. and over.

Specific Gravity	Weight Per Cubic Yard		Weight Per Cubic Meter	
	Long Ton 2,240 Pounds	Short Ton 2,000 Pounds	Long Ton 2,240 Pounds	Metric Tons 2,204 Pounds
1	.42984	.48143	.56223	.57143
2	.85968	.96286	1.12446	1.14286
3	1.28952	1.44429	1.68669	1.71429
4	1.71936	1.92572	2.24892	2.28572
5	2.14920	2.40715	2.81115	2.85715
6	2.57906	2.88858	3.37338	3.42858
7	3.00888	3.37001	3.93561	4.00001
8	3.43872	3.85144	4.49784	4.57144
9	3.86856	4.33287	5.06007	5.14287

The specific gravity used should of course be that of an actual sample of the ore in question, and not that of its principal mineral constituent as given by the textbooks.

In the absence of more elaborate apparatus the specific gravity may be approximately determined in the following way:

A weighed quantity, say 50 grams of the ore, is placed in a dry 100-cubic-centimeter measuring flask, which is then filled up to the mark with water from a burette, pausing half way to shake up and dislodge any air bubbles entangled in the powdered ore. The difference between the quantity delivered by the burette and 100 cubic centimeters, divided into the weight of ore taken, will give the specific gravity.

Example	Grams
Weight of ore taken	50.0
Cubic centimeters delivered	87.3
Cubic centimeters by difference	12.7

50 ÷ 12.7 = 3.937 = specific gravity of ore

Weight Per Cubic Meter of Ore Pile (Long Tons)

	Long Tons
3.000	= 1.68669
.900	.50600
.030	.01687
.007	.00393
3.937	= 2.21349

GASOLINE LOCOMOTIVE

The only gasoline locomotive in the coal mines of the United States is at the Midvalley Coal Co. mines, Wilburton, Columbia County, Pennsylvania. The locomotive's speed is 3 miles per hour for low gear and 6 miles for high gear. On low gear the locomotive pulls eight mine cars, about 32 tons, and has replaced five mules and one steam locomotive. Mr. H. D. Kostenbander, superintendent, writes that it consumes on an average 20 gallons of naptha per day of 10 hours, works very satisfactorily, and that it is considered very cheap haulage.

EXPLOSIVES FOR TUNNEL DRIVING

Written for Mines and Minerals

Importance of Using Explosives That Are Suited to the Conditions

The selection of explosives for tunnel blasting, probably requires a more careful study of conditions than for any other kind of excavating. Maximum speed in driving cannot be attained unless the explosive best adapted to the work is used. When starting a tunnel or drift, it is a good plan to thoroughly try out several explosives, which are distinctly different in action, before finally adopting any one of them. The results, however, from this preliminary trial will be of little or no value, unless each different explosive is used under exactly the same conditions. Care must be taken to see that no change occurs in the character of the rock, number and direction of the bore holes, strength of the detonator, kind and quantity of tamping, amount of water encountered, method of connecting up the bore holes for firing, and that the explosive is always thoroughly thawed. If a material change in any of these conditions occurs as the work progresses, further tests should be made to determine whether a quicker or slower, a stronger or weaker, explosive might not break the ground, or bottom the bore holes better, or make it possible to bring out the cut with fewer holes or deeper ones. The speed at which rock can be drilled, does not indicate how it will break, and not infrequently that which can be easily drilled is very difficult to blast.

High explosives suitable for tunnel blasting, should not give off objectional fumes on detonation, and accordingly gelatin dynamite, blasting gelatin, or ammonia dynamite should always be selected.

Gelatin dynamite is made in various grades of strength, from 25 to 80 per cent., inclusive. It is comparatively slow in action, the higher grades being little, if any, quicker than the lower ones.

Blasting gelatin is manufactured in only one strength, which for comparative purposes may be said to be 100 per cent. It is more powerful and quicker acting than any other blasting explosive. It should be used sparingly, therefore, until the maximum safe charge has been learned from experience. Good results will often be had in hard ground, if a few cartridges of blasting gelatin are used in the point of the bore hole, with gelatin dynamite on top. When this is done, it is best to put the detonator in one of the cartridges of blasting gelatin.

Ammonia dynamite is made from 25 per cent. to 75 per cent. strength. All grades are quicker than gelatin dynamites, and generally speaking the quickness increases with the strength. That is, the stronger grades are quicker, and the lower grades slower, in action.

The various grades of these three high explosives, offer a wide range in strength and quickness to select from, and it is always possible after a few trials to find an explosive exactly suited to the conditions.

Railroad tunnels, mine tunnels and drifts, highway tunnels, and irrigation tunnels, are being driven daily through various kinds of "ground." Often it is a matter of first importance to finish them quickly, and consequently details in regard to methods and equipment are matters of general interest. Within the past few months, a number of speed records in tunnels of different sizes have been made, and descriptions of them have appeared in various technical magazines.

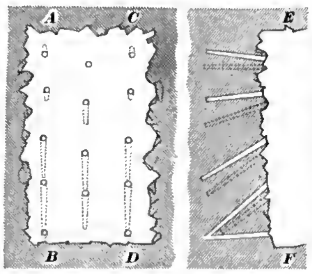
In *Engineering Contracting* of October 20, 1909, Mr. J. B. Lippincott, assistant chief engineer of the Los Angeles aqueduct, gave an interesting account of the driving of the Red Rock tunnel of the Los Angeles aqueduct system. In August, 1909, this tunnel, which is 9 ft. 10 in. $\times$ 10 ft. $8\frac{1}{2}$ in. in section was advanced 1,061.6 feet. Mr. Lippincott states that the explosives used were Du Pont 40-per-cent. ammonia dynamite and blasting powder.

In the *Engineering News* of November 18, 1909, the Red Rock tunnel is again referred to, and details are also given by Mr. C. H. Richards, division engineer, in regard to a tunnel on the Little Lake Division of the Los Angeles aqueduct. The explosives used in this tunnel were Hercules 40-per-cent. and 60-per-cent. gelatin dynamite, the average weight of explosives per cubic yard of rock, place measurement, having been only 3.3 pounds, or about 35 pounds per linear yard of tunnel almost 10 ft. $\times$ 10 ft. in section.

A short time before, accounts were given in several engineering magazines, of a record driving speed made in the Roosevelt drainage tunnel, at Cripple Creek, Col. The explosives used in this tunnel were 40-, 50-, and 60-per-cent. Repauno gelatin dynamite and Du Pont blasting gelatin.

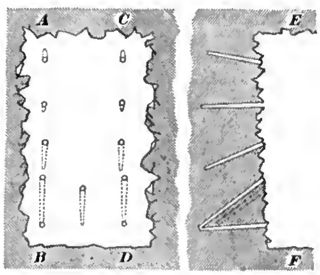
A very interesting description of the Rondout pressure tunnel of the Catskill aqueduct, written by John P. Hogan, assistant engineer of the New York City Board of Water Supply, was published in the January 1, 1910, number of the *Engineering Record*. Very rapid progress was made in this tunnel, and also in the Moodna pressure tunnel of the same system, described in an article in the *Engineering Record* of June 4, 1910. The explosive which gave best results, and which was used exclusively in both of these tunnels, was 60-per-cent. Forcite—a gelatin dynamite.

Reference to a paper by B. H. M. Hewett and W. L. Brown, on the land sections of the Pennsylvania Railroad North River tunnels, published in Vol. XXXVI of the Proceedings of the American Society of Civil Engineers, and reprinted in part in



Section E–F   Section A–B and C–D

Fig. 1



Section E–F   Section A–B and C–D

Fig. 2

Engineering Contracting of May 11, 1910, shows that 40-per-cent. Forcite was used in blasting on the Manhattan section, and 60-per-cent. Forcite on the Weehawken section.

The records of many other tunnels recently constructed, further illustrate how many kinds and strengths of explosives are used for blasting under the different conditions encountered in one class of work.

The specific cases referred to above, were all connected with large and important contracts, where equipment and methods were at the best, and several of these tunnels were driven at record speed. The fact that so many different explosives were used in the several tunnels, goes to show that care was taken to use the explosive which was best adapted to the conditions, and it is not unlikely that the speed of driving these tunnels, was largely due to the attention given to the selection of the explosives.

This point is equally important when driving narrow tunnels and drifts. After a study of the rock in a cross-cut, 3 ft. 6 in. $\times$ 7 ft. in section, recently driven by J. R. Marling in the Callie shaft at Cripple Creek, it was decided that best execution would be given by a 40-per-cent. gelatin dynamite. Repauno-40-per cent. gelatin was accordingly adopted, and it was necessary to drill 14 holes, as shown in Fig. 1, from 3 feet 6 inches to 4 feet 6 inches deep and blast them with about 35 pounds of 40-per-cent. gelatin dynamite, in order to advance the tunnel about 3 feet. In an attempt to increase the speed of driving, and to reduce the cost, the face was drilled with 11 holes, as shown in Fig. 2;

and these holes were loaded with Du Pont blasting gelatin in the points, and Repauno 40-per-cent. gelatin dynamite on top. In this method of loading about 7 pounds of the blasting gelatin, and 17 pounds of the gelatin dynamite were used, making a reduction of about 15 per cent. in the cost of explosives, and 20 per cent. in the amount of drilling, while the tunnel was still advanced full 3 feet each shift. Here the adoption of a more suitable explosive for the work, resulted in a great reduction in cost instead of increase in speed.

No matter what explosive is used in blasting, maximum results can only be attained by always having the explosive in a thoroughly thawed condition when it is used, by tamping firmly with damp clay, or similar material, from the charge of explosives to the mouth of the bore hole, and by using the strongest and highest grade detonator that can be secured.

Ridgway Dynamo and Engine Co., Ridgway, Pa., have combined their various bulletins into an illustrated catalog descriptive of their products. It also contains photographs of various plants which they have installed.

FOREMAN OF MINE RESCUE STATION

The United States Civil Service Commission announces an examination on October 15, 1910, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of foreman in connection with mine-rescue training at the stations of the Bureau of Mines located throughout the United States, at salaries ranging from $1,080 to $1,500 per annum.

The examination will consist of the subjects mentioned below, weighted as indicated: (1) Physical ability, weight, 40; (2) training and experience, weight, 60. Total, 100.

Applicants for this position should have had experience as fire boss, mine foreman, or inspector in coal mining. They should be thoroughly experienced in underground work, capable of finding their way in the darkness of mines with which they have had no previous familiarity, and should have the courage, skill, and physical endurance required in directing rescue operations underground after mine explosions.

Applicants must execute their applications in their own handwriting.

Applicants must have reached their 25th birthday, but not their 50th birthday, on the date of the examination.

Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application and examination Form 1800. No application will be accepted unless properly executed and filed in complete form with the Commission at Washington prior to the hour of closing business on October 15, 1910. In applying for this examination the exact title as given at the head of this announcement should be used in the application.

OXYGEN HELMETS USED AT MINE FIRE

*Written for Mines and Minerals, by T. A. Carraher**

This is written in reply to an article in the July edition of Mines and Minerals entitled "Oxygen Helmets Used at Mine Fire," by Oscar Cartlidge, a mine manager of the Hart-Williams Coal Co. I wish to correct some statements made by Mr. Cartlidge, whom I succeeded on April 1, 1909.

On the night of June 15, 1909, as the result of blasting coal with black powder, a fire started in the face of the fourth southeast entry in the mine of the Hart-Williams Coal Co. It was 9 p. m. when I received the information that there was a fire somewhere in the mine; as quickly as possible the superintendent and I drove to the mine and on arrival found great clouds of smoke coming out of the hoisting shaft, which is the upcast. I went down immediately, but on the bottom found the smoke so dense that it was impossible to reach the fire by this route. On going to the top and being assured that the men were all out I gave orders for the fan to be reversed, but on investigation found that no provision had ever been made for reversing the fan, and this idea had to be abandoned.

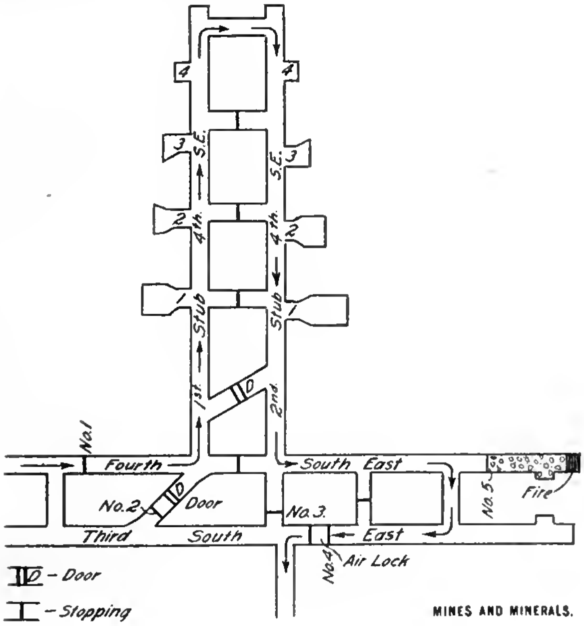

Fig. 1

I again descended, taking with me the night boss and four of his men, with whom I proceeded by way of the intake to the fourth southeast entry where I saw at once that it was useless to attempt to fight the fire, so we began to wall it off immediately, accomplishing this by means of stoppings numbered 1, 2, 3, and 4, as shown by the map, Fig. 1. These stoppings were built of boards nailed to good strong props and plastered with wood fiber instead of walls filled between with fireclay, as stated in the article referred to above, and the last wall was completed at 3:30 a. m., June 16, 1909.

This mine at this time was 3½ years old, but the average output per working day was only 590 tons, therefore, the loss of 12 working places and 1 chain machine was felt so severely we resolved to open the district as soon as possible.

On June 19 we began making the water connections and building an air lock of ship-lap lumber; and a door was cut of sufficient size to admit a man with a helmet; the location of the air lock may be seen from the accompanying plat. Two helmets and two storage-battery electric lights were borrowed from a neighboring mine and at 2 p. m. we had everything ready for entering the walled-off area.

*Mine Manager for Hart-Williams Coal Co., Benton, Ill.

31—3—5

L. T. Putman, a mining engineer, and I, then proceeded to the fire-wall where we put on the helmets and entered through the door in stopping at No. 4; we then cut a door in the second wall and entered the fire district, closing the door after us; we next proceeded to the face of the fourth southeast where we found a fall about 10 feet high and 40 feet long; the fire was, of course, smoldering beneath and the place was very hot. Having previously extended the water line to the outside wall of the air lock we then made the hose connections and dragged the hose inside and up to the top of the fall, where the water was started at 3 p. m. Saturday, and allowed to run continuously until 2 p. m. Sunday, or during the period of 23 hours, the position of the hose being changed every 3 or 4 hours. At the end of this time the face of this entry was submerged in water (it being a dip heading) and we were quite certain that the fire was extinguished, but as a matter of precaution we placed a good canvas brattice at the position shown by 5, the occasion however did not require a plastered stopping, which any one who has had any experience in Draeger helmet work will agree is very difficult to build while wearing a helmet.

We then started the ventilation on its regular course, as shown by the accompanying plat, and in less than 30 minutes the section was entirely free from gas, this being less than 5 days from the date on which the fire was sealed off.

To any one who has seen the actual conditions it would be clearly apparent that it was not a hazardous thing to ventilate this section in this manner, for we had every assurance that the fire was extinguished.

On the following Tuesday, for lack of men to load the fall, I built a plastered stopping just in front of the fall merely as a precaution in case the fire might possibly start up again.

PERSONALS

Frank Koester, of New York, in an important paper presented before the recent convention of the Society for the Promotion of Engineering Education, held at Madison, Wis., discussed in detail the "Educational System of the German Technical Universities." He also analysed the conditions and standing of the German engineer as compared with our own.

Prof. H. P. Boardman, of the Mackay School of Mines, University of Nevada, spent the summer months in teaching the junior class practical metal-mine surveying. Prof. J. C. Jones had charge of the geological work.

Charles Wilke, formerly general manager of sales of the Jeanesville Iron Works Co., has been appointed district manager at Philadelphia for the Wheeler Condenser and Engineering Co. His office is at 318 Commonwealth Building.

Marshall D. Draper and John Gross announce the establishment of the firm of Draper & Gross, mining and metallurgical engineers, with offices at 746 Equitable Building, Denver, Colo. Mr. Draper will be more directly in charge of the mining, and Mr. Gross of the metallurgical work.

Vice-Consul-General Stuart J. Fuller states that ever since Hong Kong was established the industry of vermilion making, entirely in the hands of the Chinese, has been an important one.

The manufacture of this pigment is among the foremost of the colony's industries. There are something like 100 small plants for the manufacture of vermilion in Hong Kong and Kowloon. The raw material comes from Australia, and the vermilion is prepared altogether by what is known as the wet method. The Chinese made artificial cinnabar long before Europe was a civilized country, and to this day there are trade secrets in the vermilion industry which no European has yet been able to fathom. Some of the granite stones here, between which the pulverized ore is ground, are almost prehistoric.

ANNOUNCEMENT

MR. WIN. G. CONLEY has been appointed Eastern Advertising Representative for Mines and Minerals, succeeding Mr. Webster H. Taylor.

THE DIRECTOR OF THE BUREAU OF MINES

IT would be a very strong sign of the near approach of the millennium if President Taft's appointment of Dr. J. A Holmes as Director of the Bureau of Mines had been accepted without adverse criticism.

Doctor Holmes is a geologist, born at Laurens, South Carolina, in 1859; a graduate from Cornell in 1881 with the degree of B. S.; was Professor of Geology and Natural History in the University of North Carolina from 1881 to 1891; was State Geologist of North Carolina from 1891 to 1904. He was in charge of the United States Geological Survey Laboratory for Testing Fuels and Structural Materials in St. Louis, from 1904 to 1907, and since then in charge of the Pittsburg and other similar testing stations of the Survey.

There is no question that Doctor Holmes has given the subject of increased safety in the working of coal mines careful and conscientious study and has acquired a great deal of very valuable experience. As a geologist he is, from an educational point, and from the standpoint of experience, an able man. However, Doctor Holmes is not a practical mining engineer, and most of the adverse criticisms on his appointment come from those who conscientiously believe that the Director of the Bureau of Mines should be a mining engineer of education and broad practical experience.

As this is an age of specialty in mining engineering, as well as in other professions, it would probably be an impossible task to select an educated mining engineer of practical experience in all kinds of mining of sufficient ability to fill the position for the salary the government offers. Such engineers are very scarce at any price.

Mr. John Mitchell, speaking from the standpoint of the miner, accords to Doctor Holmes a due measure of credit for what he has done, but criticises the appointment on the ground that the law provides for the appointment of a mining engineer and makes impossible the appointment of a practical miner, a man whom Mr. Mitchell claims would know more about the actual conditions existing in the mines.

There is no doubt that Doctor Holmes, while not a practical mining engineer, can just as well be classed as a mining engineer as many who claim such a title. The designation, "Mining Engineer," is a very broad one, particularly in this country where there are numerous examples of men who, without a college education or an engineering degree from a college have, by sheer force of natural ability and hard work, won positions in the foremost rank of American mining engineers. Colleges confer the degree of "Mining Engineer" on young men who have simply acquired at college a fundamental education on which a mining engineering

reputation can be built by experience. Statistics show that a comparatively small number of such men remain in the profession after leaving college and, of course, all that do remain do not rise to eminent positions.

Taken all in all, Doctor Holmes secured his education at one of the best universities of the country. He has added to it nearly 30 years of experience and study which has given him knowledge of great value, and as he is a man of exceptionally clean character and much tact, he has probably just as many qualifications for making good as Director of the Bureau of Mines as any man President Taft could select. Had President Taft appointed a coal-mining engineer, no matter how eminent, the ore-mining interests of the country would have criticised him on the ground that the appointee was not familiar with the conditions existing in their mines and would be apt to cause trouble. If, on the other hand, as eminent a mining engineer in the field of metal mining as Mr. John Hays Hammond had been selected, the coal mine owners would have had just as strong a reason to object to him from their standpoint.

Viewing the appointment from all sides, we are inclined to believe that, everything considered, the appointment of Doctor Holmes was as wise a one as could be made, and we express, both for the mining fraternity and for Doctor Holmes, the wish that his record in the difficult position of organizing the Bureau of Mines and of carrying it on in its first crucial years shall be so successful as to meet the approval of all classes connected with the mining industry.

CARBON DIOXIDE AND VEGETATION

Curious surmises originate when contemplating such abstract matters as the final distribution of the millions of tons of carbon dioxide mixed yearly with the atmosphere.

Roughly estimated, there are 3 tons of coal consumed yearly for each inhabitant in the United States, and if the coal contains 90 per cent. of carbon this amount will produce 10 tons of carbon dioxide, thus from the combustion of coal 900,000,000 tons of carbon dioxide go into the atmosphere yearly.

When the exhalations of individuals and animals, the decay of vegetation and other organic substances, the combustion of oil, gas, wood, tobacco, etc., are annexed to the problem, it is probable that the total of carbon dioxide going yearly into the atmosphere will reach 1,600,000,000 tons in the United States alone.

Carbon dioxide, while not poisonous, has, when greatly in excess in the atmosphere, a toxic effect, which suggests such questions as the following: Is the carbon dioxide in our atmosphere increasing? What becomes of the carbon dioxide going into our atmosphere?

In order to answer the first question it is necessary to revert to ancient geological times and take up the formation of limestone, which, as all engineers know, is composed of calcium oxide, an inorganic product, and carbon dioxide, an organic product, in the ratio of $\frac{56}{44}$. There is no inorganic carbon, which makes it necessary to assume that organisms of some kind produced the CO_2 to form limestone. The organic life which produced the limestone came from the sea, in fact the large beds of limestone in the United States, which greatly exceed the coal beds in area and tonnage, were mostly made by shell fish. After their formation the surplus of carbon dioxide was so enormous that it formed the coal beds of the Carboniferous period, and it is probable that owing to the quantity of CO_2 in the atmosphere of that time no land animals other than amphibians, could exist, at least there are no geological records of them.

It therefore is not probable that the quantity of carbon dioxide is increasing in the atmosphere, in fact analysis shows it to contain the approximate normal one-fifth oxgyen and four-fifths nitrogen.

The second question involves a further consideration of vegetation whose structure, largely carbon, derives that element mostly from the carbon dioxide in the atmosphere, at the same time it returns the oxygen to the atmosphere. From the quantity of carbon dioxide going into the atmosphere and the great number of trees that have been cut down it would seem as if the carbon dioxide must increase in the atmosphere, or vegetation grow more luxuriant. As the forests have diminished the grain fields have expanded and kept the atmosphere normal by their absorption of carbon dioxide. Thirty years ago Kansas and Nebraska were included in the Great American Desert, today they are in the agricultural belt. The land was arid and the atmosphere contained little carbon dioxide, while at this time it is receiving considerable from various sources. Given proper soil, the results of cultivation will depend on carbon dioxide and moisture, and if one of these factors is lacking the other is likely to be also.

THE OXYGEN BLOWPIPE

In 1908 the Germans introduced the autogenous method of cutting and welding metals with an oxy-hydrogen blowpipe. This was an application of what had been known previously as the hottest flame obtainable and was produced by the combustion of hydrogen in a properly proportioned mixture of oxygen. The heat of combustion of hydrogen gas is 58,060 calories. The Davis-Bournonville Co. substituted acetylene for hydrogen and by this means obtained a calorific power of 395,420 calories, which probably is the most satisfactory welding combustion, owing to the reducing action of the carbon in the acetylene. They also ascertained that if, after heating the metal with a welding flame, an auxiliary jet of oxygen under higher pressure was added, they could cut 2-inch-thick plates of metal with little difficulty.

The Germans, still clinging to their oxy-hydrogen flame, found that if they increased the oxygen after

heating the metal, they could cut metal just as readily, and that the higher the pressure the oxygen was delivered, the quicker would be the cut. This seems at first paradoxical because the highest calorific power of the highest oxide of iron is 270,800 calories, a heat much below that produced by acetylene. When it is considered that the calorific power or total heat produced depends upon the given weight of a substance consumed in a given time and not on its reduction, the paradox is explained, as neither hydrogen nor acetylene are factors in the combustion after heating the metal to the proper temperature, and either one may be discarded.

The construction and operation of the oxygen blowpipe in opening chilled blast furnaces and plugged-steel furnaces is illustrated on another page of this issue.

IN the article on the Coalinga Oil Field in August MINES AND MINERALS to which "we point with pride" because of its neatness and meatiness, we jumbled up material from various sources. P. W. Prutzman's report furnished material for the first column, while Ralph Arnold and Robert Anderson furnished the remainder of the article with one exception, the illustration of the California Midway oil well. This cut came from the Los Angeles *Mining Review*, to whom felicitations are extended for the courtesy.

BOOK REVIEW

In recent years great advances have been made in the art of printing, not only in color effects, but in artistic typography and improved methods of illustration. The railroads are the quickest to take advantage of the newest and most up-to-date processes in artistic printing. A particularly fine example of the highest class of illustrated pamphlet work is "A Glimpse of Utah," just issued by the Passenger Department of the Denver & Rio Grande Railroad. The text is by the brilliant writer, Judge E. F. Colborn, of Salt Lake City, and the excellent illustrations picture the many unique features of that interesting state, Utah.

ALPHA PORTLAND CEMENT CO., Easton, Pa. A very attractive pamphlet, finely illustrated. The Alpha Portland Cement Co. is the pioneer manufacturer of Portland cement in America and its Alpha brand has stood the test for some 19 years. Some of the subjects included are, the proportioning of cement, sand, and stone; the comparative costs of cement; method of mixing; various forms of concrete construction; the protection of concrete from frost; sidewalks and pavement; curbing and gutters; reinforced concrete; concrete blocks; waterproofing; sea-water construction There is an explanation of cement terms, and Extracts from the Report of the Committee of American Society for Testing Materials on standard specifications. This pamphlet is not only a work of art but will appeal to all users of cement.

"THE NATURAL RESOURCES OF COLORADO, UTAH, AND NEW MEXICO," the 1910 edition of the Denver & Rio Grande folder, is especially valuable because of the large map, which takes in territory from the Rocky Mountains west to the Pacific Coast, is not only brought up to date but shows also the route and stations of the new Western Pacific Railway, the Pacific Coast extension of the Denver & Rio Grande Railroad from Salt Lake City to San Francisco

CORRESPONDENCE

Recollections of William Smurthwaite

Editor Mines and Minerals:

Sir:—I became acquainted with William Smurthwaite in 1874, shortly after the mine inspection law of Ohio was enacted. He was the most intelligent practical miner which I have ever met and I doubt if he had a superior during his lifetime. The large mine at Stubenville, Ohio, which he managed, made copious volumes of firedamp, but he had the gas under perfect control. No miner was permitted to go down the shaft until he had personally examined every working place in the mine, returned to the surface and pronounced the mine safe. He went down the pit every morning at 4 o'clock. He enforced strict discipline and had the unbounded confidence of the miners and his word was law, for the underground employes recognized the fact that he was ever vigilant to keep the mine free of inflammable air.

He surveyed and mapped the mine himself and was the only mine manager I ever knew who carried a column of air through all the ramifications of a mine without losing a perceptible part of the column. He was ever watchful of the stoppings and never permitted the air to leak. He made the rounds of the aircourses every day, or sent a trained assistant to do so. All the entries were double, butt and main, and when a new breakthrough was made at the head of a double entry, the stream of air was so strong that he had to keep the next breakthrough below open until the workmen advanced the entry several yards, for the strong current of air chilled the miners and it was sometimes difficult if not impossible to keep the strong current from blowing out the workmen's lights.

Were all mines ventilated in this manner, explosions by firedamp would be few. When an explosion occurs in a mine, somebody is blamed for carrying a naked light into a column of gas. No standing gas was ever permitted to accumulate in the mines in charge of William Smurthwaite. He regarded an explosion as a crime, asserting that there was no occasion for permitting standing gas in a mine, and took the ground that explosions were never caused by the fault of the workmen, a statement he proved by a period of more than half a century of underground life.

The miners of Stubenville, Ohio, owe it to themselves to erect a fitting monument to his memory. If all mine bosses and mine inspectors were half as earnestly devoted to their duty explosions would be like angels visits, "few and far between."

Girard, Ill. Andrew Roy

Black Powder

Editor Mines and Minerals:

Sir:—I wish to take exception to Mr. Beard's answer to question:

"What powders are best adapted to various conditions of mining?

"Ans.—Black powder."

In the first place black powder is not fit for use in many of our coal mines owing to the smallness and hardness of the bed. Black-powder action is such as to break the coal and bone so fine as to make it almost impossible to separate them, while some of the Du Pont Powder Co.'s permissible explosives in these same beds will produce lump coal and leave it in a condition to be cleaned. The permissible explosive reduces the danger to life and limb; sparks from the miner's lamp do not ignite it, etc. I think there are so many things in favor of the permissible explosive, that black powder should be eliminated from mine use.

West Pittston J. S.

Method of Laying Off a Curve

Editor Mines and Minerals:

Sir:—I enclose you a method of laying off curves which may be of occasional use. It is elaborated more than is necessary for practical purposes, but this was done to make the procedure clearer.

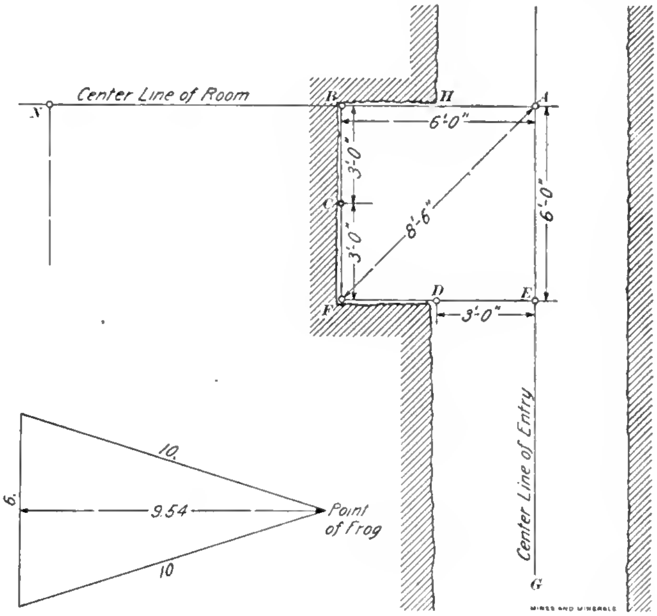

Fig. 1

Note that the two points, *C* and *D*, on the curve are obtained at the start of the operation and that these practically control the work. Also, that the radius of the curve is always $2\frac{1}{2}$ times the side of the square.

To make use of this method:

First. Excavate *H B F D*, Fig. 1. At the center line of the entry and the room make a right angle. *A B F E* is a 6-foot square. *C* and *D* are the middle points of two sides, they are also centers of curves into room. The 6-foot square should be laid off from a long string stretched from *A* to *G*. By the use of an 8-foot 6-inch rod having a 3-foot mark on it and hinged so as to be 6 feet long when folded, *A B F E* may be

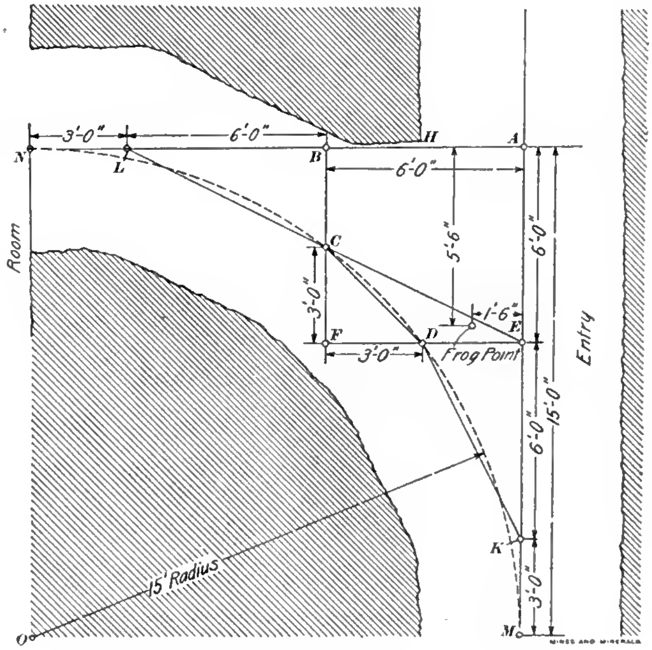

Fig. 2

made exactly square. Good pins are to be driven at the points A, B, C, D, E, and F.

Second. Mark the point K Fig. 2 on center line of entry 6 feet from E, and then use $K\ D$ as a center line for the side cut from K to D.

Third. Use $D\ C$ as a center line for side cut from D to C.

Fourth. Excavate along line $E\ C$ continued as a center line to the point L, making $CL = EC = 6$ feet $8\frac{1}{2}$ inches. L is also on the center line of room 6 feet from B. From L continue along center line of room for 3 feet to N.

Kansas City J. R. Stephens

Surveying

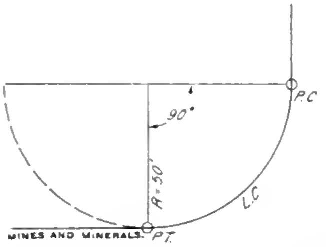
Editor Mines and Minerals:

Sir:—Replying to the question by Gordon S. Cox, Esq., in your issue of July: "What would be the length and degree of a 50-foot radius curve, central angle = 90 degrees?"

$$\text{L. C.} = \frac{(2 \times 50) \times 3.14159265}{4} = 78.539816 \text{ ft.}$$

$$\text{L. C.} = 50 \times 1.5707963 = 78.539815 \text{ ft.}$$

Definition: The degree of curve is an expression identical with the angle at the center of the curve subtended by a chord of 100 feet. When $R = 50$ ft. $D = 180°\ 0'$. It is often found convenient to express D in terms of a chord shorter than 100 feet when by the formula,



$$\text{Sine } \tfrac{1}{2}\, D = \frac{C}{2R}$$

Chord (C) = degree of curve (D); 10 feet = 11° 28′; 20 feet = 23° 04′; 30 feet = 34° 54′; 40 feet = 47° 10′; 50 feet = 60° 00′; 60 feet = 73° 44′; 70 feet = 88° 52′; 80 feet = 106° 16′; 90 feet = 128° 20′; 100 feet = 180° 00′.

Boston Mint Lee Fraser

Lamp Burning in Water

Editor Mines and Minerals:

Sir:—In answer to Student, in the August number of Mines and Minerals, I would give it as my opinion that the burning of his lamp flame in the discharge water of the pump is probably due to the gas, sulphureted hydrogen (H_2S), which has been absorbed by the water in the old lower workings, thence carried to the surface or discharge of the pump I presume the water in the workings is under considerable pressure and if so, gas would be dissolved in the water at a greater density than it would at the ordinary pressure of the atmosphere, so when the water reaches the surface the tendency would be to disengage the gas, together perhaps with some air, which causes the lamp to burn for a short time in the water. This is only an opinion and not intended to be taken as an authoritative statement.

Montcalm, W. Va. E. W Bailey

Thermochemistry of Anthracite

Editor Mines and Minerals:

Sir:—In reply to Mr. R. T. Hancock's communication, page 37, August issue of Mines and Minerals, regarding the apparent heating value of anthracite, would state that in the laboratory we have noted the same discrepancy and have traced it to the incomplete combustion of high-ash coals in the calorimeter. We have after considerable experimentation evolved a slightly modified method by which the British thermal units per pound of combustible, as determined with the Atwater calorimeter vary but slightly, irrespective of ash content, provided this ash content be less than 40 per cent.

Pottsville, Pa. Edwin M. Chance

BUNKER HILL COAL-STORAGE PLANT

Written for Mines and Minerals, by F. Webster Brady

The large anthracite companies in order to work regularly when there is a car shortage or stagnation in the coal market, have places where they stack coal in great heaps. These heaps are drawn on in time, or when for any cause the collieries are unable to supply the market's demand.

Coal-storage plants are arranged usually on level ground with machinery for stacking and reloading from the piles, and provided the company does not possess such ground in the vicinity the coal is transported to a convenient place and there stacked. The Hillside Coal and Iron Co. has taken an unusual course in the matter of coal storage and has made use of the southern exposure of Bunker Hill, in Dunmore, Pa., as shown in Fig. 1. The storage floor is 800 feet long by 230 feet wide and has a capacity for the storage of 80,000 tons of coal. The floor which has a slope of 32 degrees is made of ash concrete 10 inches thick, with gutters lined with stones and suitably arranged for drainage. The coal comes on the trestle, shown in upper part of the floor, in hopper-bottomed gondolas When the hopper doors are opened the coal slides through the trestle and to a small extent over the floor, although the bulk of the storage piles are made by means of a portable belt conveyer, operated by an electric motor. These piles are made as shown in Fig. 2, so that the coal will slide by gravity to the reloading chutes at the lower side of the floor. It will be noticed that the framework of the chutes rests on a retaining wall 10 feet 4 inches high, 5 feet 6 inches thick at the bottom and 3 feet thick at the top, and that the floor of the framework slopes backwards forming a dam. This arrangement prevents the chutes from being pushed out by the coal stacked back of the continuous framework, and permits the chute to act as a blow-off for the dam. Each chute is boarded up on the track side, except where the coal flows through, and this is closed by a swinging apron gate, operated by a lever. The coal shown on the floor is steam fuel, known as anthracite barley. The entire floor is surrounded by a board fence forming a stockade to keep out the public.

ELLIPTICAL VS. RECTANGULAR SHAFTS

*Written for Mines and Minerals, by Wm. Archie Weldin, C. E.**

The article in Mines and Minerals by Mr. Francis Donaldson, on "Modern Shaft Sinking," which was concluded in the May issue, is of great value to mine operators and engineers, as it contributes to the advancement of the art.

Some of the Advantages of Rectangular Over Elliptical Form for Concrete Lined Shafts

This is particularly true of the last chapter, dealing with concrete-lined shafts, as such lining is of comparatively recent development, and is an especially fit subject for discussion.

Most shafts of this type recently constructed have been of circular, elliptical, or other curved form; but Mr. Donaldson's suggestion of a rectangular concrete shaft is deserving perhaps of even more consideration than he seems inclined to give it; for reasons which will be explained.

The matter of comparative cost is important, and Mr. Donaldson's comparative estimates are of especial interest and value. Naturally, the results will vary for different cases, and it would be well to make comparisons for each contemplated shaft, before deciding on the type.

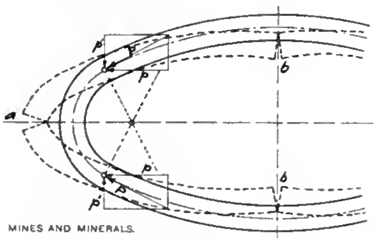

Fig. 1

In designing a shaft lining it is unreasonable to assume (as is done in the article) that the lining must resist the full hydrostatic pressure due to a head of water the entire depth of the shaft.

Water rings, as illustrated in the article referred to, in the February chapter, page 405, and in Mines and Minerals, April, 1910, page 561, should be formed at frequent intervals in the depth; then even if no other precaution were taken, this would effectually prevent the formation of a head of water of greater height than the distance between water rings.

In order to realize the conditions assumed in the article, it would be necessary to have the water completely sealed out of the shaft at the bottom, and backed up clear to the top in an unbroken sheet.

In certain shafts recently sunk, porous drain tile were placed behind the lining; one vertical line at each end, and one at the middle of each side. Of course more lines of tile can be used if desired. They discharge into each water ring, and certainly prevent the formation of a great head. It has also been suggested that bore holes be sunk and lined with tile, just clear of the lining. This would insure thorough draining.

It is recognized that it may be desirable to seal off the water encountered in a porous stratum, particularly if there be an impervious layer below, so that this water may be kept out of the mine entirely. In this case, it will be necessary to proportion the lining for a head of water extending from the impervious stratum up to whatever height the water is likely to accumulate. This height may be limited by the installation of a water ring above the water bearing layer. The thickest portion of the lining will then be at the bottom of the porous material. Below this point it may be reduced again.

The above remarks do not apply to the case of the aqueduct shaft where it is desired to exclude all ground water which might contaminate the water supply.

As explained by Mr. Donaldson, the exact pressure actually exerted on the lining cannot be determined.

It might be a good plan, and is suggested, that water rings be formed at vertical intervals of approximately 75 feet, and that four or more lines of drain tile be installed between and discharge into them; that the lining for the full depth be then proportioned for a static head of 50 feet. This would allow for quite a general stopping up of the drains. That this method is amply safe has been demonstrated by the successful completion of shafts with 12-inch lining of depth and radius such as would necessitate a thickness of 3 or 4 feet to resist the full head.

Before leaving this phase of the subject, it would be interesting to learn more fully Mr. Donaldson's objections to permanent weep holes, which he says are most undesirable. It is hard to see how weep holes would weaken the lining, and if water running down the inside of a timber lining is not objected to, why may it not be tolerated in a concrete-lined shaft?

The unit stresses used by Mr. Donaldson are surprisingly high. He adopts 2,500 pounds per square inch as the ultimate compressive strength of concrete in bending, and 3,000 pounds in direct compression, and uses a factor of safety of 3. This would give a working stress of 833 pounds and 1,000 pounds per square inch, respectively, when most authorities recommend from 350 to 750 pounds. It is unfortunate that the mixture used is not specified, but surely it is not economical to use a richer mixture in the shaft than is advisable in building construction. It is also to be noted that tests show that concrete is stronger in compression due to cross bending, than direct compression. This is indicated in the railroad specifications quoted below.

The uncertainties as to the actual applied loads, and the actual distribution of stresses are at least as great in the case of shaft lining as in other forms of concrete work; and the allowance to be made on account of practical limitations of workmanship and difficulty of inspection must be even greater in shafts than in buildings. Another unfavorable item is the fact that the full load is liable to come on the concrete sooner than in other work.

For unit stresses in general use, the following may be cited:

Specifications for reinforced concrete adopted by the American Railroad Engineering and Maintenance of Way Association, and reported in *Engineering News*, April 14, 1910, page 444. To be used in design; working stress 450 pounds per square inch for direct compression; 750 pounds per square inch for compression due to cross bending.

C. C. Schneider, Paper No. 997, "The Structural Design of Buildings," presented to the American Society of Civil Engineers, October 19, 1904. Working pressure in 1 : 2 : 4 Portland cement concrete walls, 350 pounds per square inch.

New York Bureau of Buildings, according to C. W. Hall in *Engineering Record* of January 22, 1910, 350 pounds per square inch for 1 : 2 : 4 concrete.

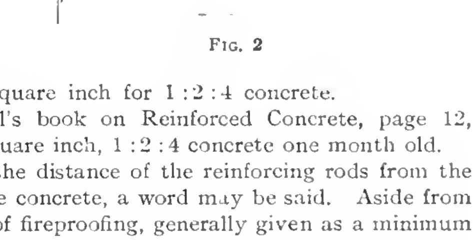

Fig. 2

Buel and Hill's book on Reinforced Concrete, page 12, 500 pounds per square inch, 1 : 2 : 4 concrete one month old.

In regard to the distance of the reinforcing rods from the finished face of the concrete, a word may be said. Aside from the requirements of fireproofing, generally given as a minimum of 2 inches of concrete, and which do not apply here, this dimension need be only sufficient to surround the rods with enough concrete to ensure their being properly gripped. This is frequently taken by the best designers as a fraction of the total depth of the beam, generally $\frac{1}{8}$ to $\frac{1}{10}$. So that for the case cited, assuming the correctness of the calculations, for a lining designed to resist a head of 50 feet, 2 inches would be ample.

Mr. Donaldson's demonstration of the forces acting on the

* 5121 Center Avenue, Pittsburg, Pa.

elliptical lining is very clear and accurate, but it should not be overlooked that this reasoning applies only to sections in solid rock, as clearly explained in the text. The unbalanced thrusts shown require unyielding abutments; otherwise bending stresses are introduced.

The extreme case is sometimes realized when quicksand is to be penetrated. In this case the lining must resist the outside pressure without any assistance from the surrounding material.

In Fig. 1, the unbalanced thrust P produces bending moments about the points a and b. The compression due to

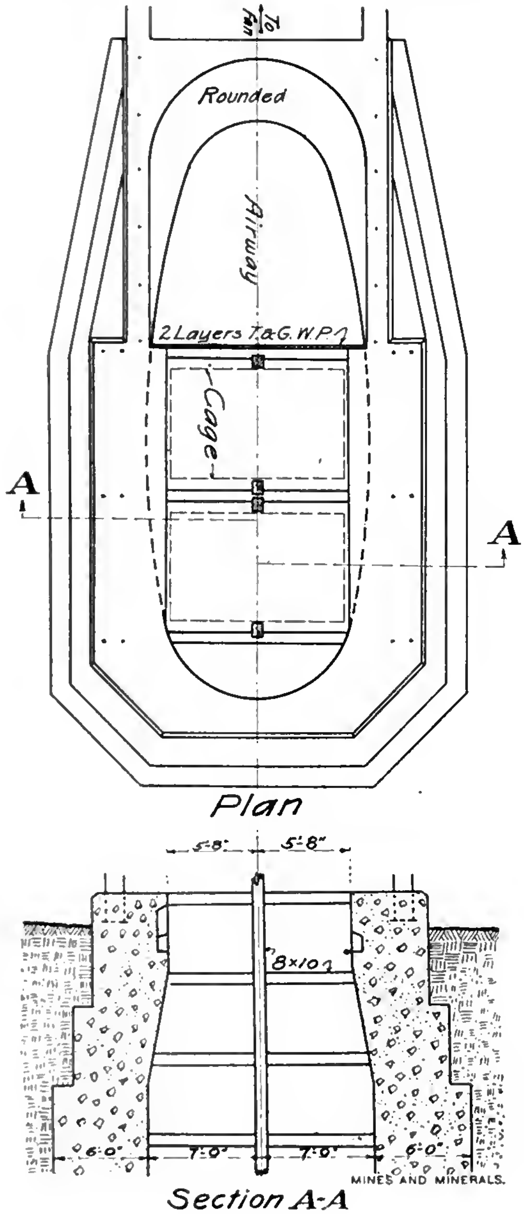

Fig. 3

this bending, combined with the direct compression, gives the maximum compression at these points. The ring of unit length tends to fail in the manner indicated by the dotted lines. The force P may be resolved into its components p and p', respectively, parallel to the longitudinal and transverse axes of the shaft.

It is evident that the effect of the force p' is to cause bending in the end of the shaft. This bending being a maximum at the point a, and producing tension in the outer portion of the lining, and increased compression in the inner.

The components p, may be considered as causing bending in the sides. This will be a maximum at the point b, and will cause tension in the inner portion, and increased compression in the outer.

The lining ring may then be considered in two parts as indicated in Fig. 2. These parts may be treated as explained in "Merriman's Mechanics of Materials" under eccentric loads. By the method there set forth the tension and compressive stresses due to these loads may be found, and added algebraically to the direct compression in the ring acting as an arch. Of course steel will be inserted to care for the resulting tension. It is evident that the relative thickness required at a and b will depend on the ratio of the radii. For a shaft such as is shown in Fig. 3, which is the top of a shaft recently completed, the thickness required at a may be greater than that at b; thus reversing the proportions given by Mr. Donaldson for sections in rock.

The extreme case may be considered to be that in which the long side is of so flat an arc as to be computed as a beam, and the short ends as eccentrically loaded columns whose loads are the reactions of these beams.

Deflections and consequent distortions of the curves will alter the problem and increase the stresses. This may be allowed for by reducing the safe unit stresses used.

The above solution of the problem is only an approximation, and it would be interesting to learn the views of others who have been called upon to meet this case.

A more precise and theoretical treatment may be possible, but in view of the fact that the actual amount of fluid pressure to be resisted is unknown, and on account of other uncertainties, an approximation is all that is required, it being only necessary that we assure ourselves that the proportions are such as to yield stresses on the safe side.

That is to say, on account of the uncertainties inherent in the design, we must add a certain amount of concrete to that obtained by calculations in order to feel safe. So that, in comparing the so-called elliptical with the rectangular design, the former has really less advantage, in point of cost, than is apparent in the comparisons given in the article; particularly if much material other than solid rock is to be penetrated.

Another point in this comparison which is not quite clear: How is Mr. Donaldson justified in reducing the area of the ventilating compartment in the case of the curved form? It is to be doubted if area in the hoistways can be counted as very effective for ventilation, on account of the baffling action of the cages in their rapid travel up and down. They act to some extent as pistons, violently forcing the air, first up, then down; or at least tossing it from one compartment to another.

For an interesting exhibit of the possible effect of hoisting on the air pressure of a mine, see Mines and Minerals of June, 1909, page 489.

Aside from the matter of cost, the rectangular design possesses other advantages over the curved form. Perhaps the most important of these is the fact that it can more easily be made fireproof than can the curved form.

The latter as illustrated in the article contains a considerable amount of wood in the form of guides, buntons, and partitions. Many shafts also contain stairs. A small fire originating at the bottom of the chimney-like shaft, feeding on this fuel, may quickly attain such proportions as to do great damage and cause the mine and the coke plant, which may be tributary to it, to be shut down for a considerable period. The air-way partition is frequently made of reinforced concrete even in shafts of curved outline in order to reduce this danger.

In comparing the relative cost of the two designs in order to place them on an equal basis, this partition should really be included in the curved form. It can be formed after the lining has been completed, by attaching stiffened lath, such as "Hy-rib" or "Trussitt" to suitable grounds, and plastering with cement mortar on both sides.

In the best designs buntons and stairs are made of steel in order to eliminate wood altogether. This is no doubt good

practice, but has its defects. Steel must frequently be cleaned and painted and probably renewed.

The concrete division walls between compartments suggested by Mr. Donaldson form a very desirable step in advance. They should entail no expense and therefore the rectangular design should be credited with the capitalized maintenance of the steel buntons as well as their extra cost over wood.

Another point of advantage of the rectangular form is that it can be made to conform as closely to the outlines of the cages as may be desired. In the curved form, the width of the shaft is not constant for the whole width of the cages, and therefore if the cage platforms be made alike and rectangular, there will be a large open space between the end of one of the cages and the shaft lining This is a source of danger in hoisting men and materials. It has been suggested that the cage platforms be made to conform in outline to the curved lining. There are, however, several serious objections to this. The cages will not be alike and interchangeable, and therefore more spares will be necessary. The landing devices will be complicated and unwieldy. With self-dumping cages it will be found very difficult to arrange chutes at the dumping point so that coal will not be spilled.

The best practice at present seems to be to bring the sides into a straight line at the top, as shown in Fig. 3. This is open to the objections that it complicates the form work, increases the material, and fails to eliminate the danger mentioned. The nature of this danger is well illustrated in the account of the accident at the Ellsworth colliery, in which two mine surveyors lost their lives. A timber being hoisted with the men struck a projecting bunton and, tilting, hurled the men to the bottom of the shaft. This was a timber lined-shaft, but it seems to the writer that the danger is even greater in the case illustrated in Fig. 3. Here there is a temptation to load, at the bottom, material longer than the cage platform, as the shaft apparently allows plenty of room for it. Such material may have ample clearance all the way up the shaft until it suddenly strikes the remaining portion with disastrous results.

In conclusion, if Mr. Donaldson's valuable paper should have the cost comparison revised as indicated, the result will be more favorable to the excellent rectangular design shown.

When considerations other than cost are given due weight, it is believed that the rectangular design will be found the one to adopt in many cases.

MECHANICAL COAL SAMPLER

*Written for Mines and Minerals, by C. E. Scott**

The coal-sampling machines in use at the Pratt Street power plant of the United Railways & Electric Co., Baltimore, Md., have been in continuous operation for more than a year, and have given results which have been satisfactory to both the railway company and the company furnishing the coal.

Description of Apparatus Used at Plant of United Railways and Electric Co., Baltimore

The sampling machine proper, shown in elevation, Fig. 1 and in plan Fig. 2, is almost identical with the one in use at the plant of the Interborough Rapid Transit Co., New York City, described in September issue. Instead of being automatic it is operated by the weighman, who releases the coal in the sampler by pulling a rope.

The coal passes from the sampler through a pipe to a crusher, fitted with plates for pulverizing the coal, and from here drops into the quartering box which consists of series of seven riffle samplers Fig. 3; the final sample dropping into a can which may be unscrewed and sent to the laboratory.

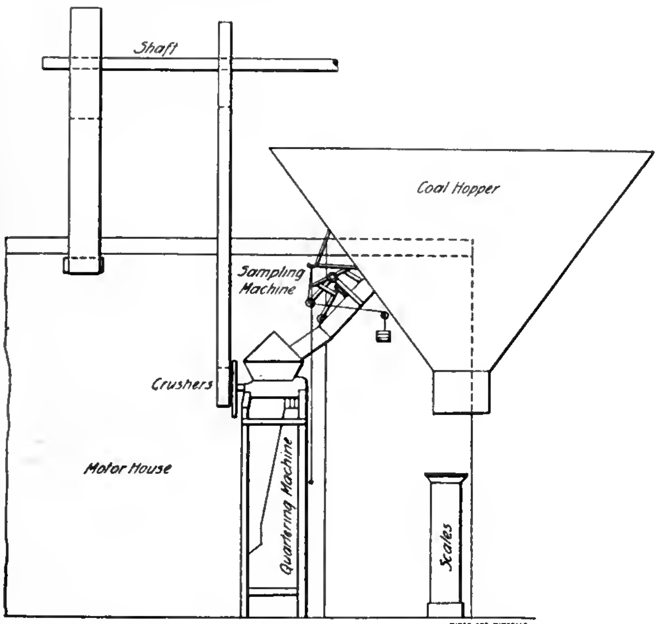

Fig. 1. Elevation of Mechanical Coal Sampler

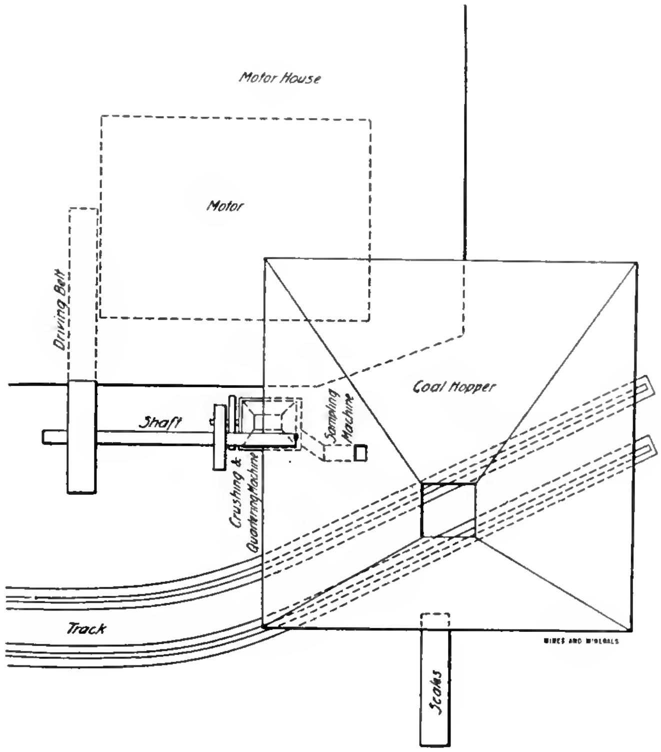

Fig. 2. Plan of Coal Sampler

Dust-tight galvanized-iron connections are made from the bottom of the sampler to the hopper of the crusher, and from the crusher to the quartering machine. A receptacle with a sliding door is also built below the quartering machine to catch the discard. The sample is not exposed to the atmosphere after it passes into the machine and loss of moisture in this direction is thus reduced to a minimum.

The quantity of coal taken for a sample depends upon the number of times the rope operating the machine is pulled, the size of the gross sample desired may be regulated to suit the demands.

At the United Railways plant the gross sample is approximately $\frac{1}{1000}$ of the total weight of the coal sampled. For example, from a barge containing 200 tons, the total weight of sample taken is 400 pounds. This sample after passing through the apparatus weighs from 3.1 to 3.2 pounds, and consists of coal which will pass a number 10-mesh seive.

*Chief of Testing Department, Consolidated Coal Co.

The uniformity of the samples taken with the machines, both as to total weight of sample and sizes of coal which compose the samples, is shown in Tables 1 and 2. From these it may be seen that the machine-taken sample shows almost constant percentage weights of each different size on successive tests,

Table 1. Machine Samples

Test	A	B	C	D	E
Number cars dumped	47	30	69	30	30
Weight of sample, pounds	253.30	151.30	350.00	150.90	173.20
Weight of sample per car dumped, pounds	5.01	5.04	5.07	5.03	5.77

Size of Coal Before Going Through Crusher

	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Over 1 inch	33.7	37.0	36.5	34.7	41.8
1 inch to ½ inch	23.9	24.6	24.9	23.4	22.4
½ inch to ¼ inch	16.0	15.5	15.9	14.2	15.4
Under ¼ inch	26.4	22.9	22.7	27.7	20.4
	100.0	100.0	100.0	100.0	100.0

while the samples taken with a shovel, show no uniformity in either total weight or percentage of sizes.

The uniformity with which the quartering machine does its work is shown in Table 3. These figures are the results attained on one sample of coal which went through the quarterer 10 times. The operation was repeated with other samples.

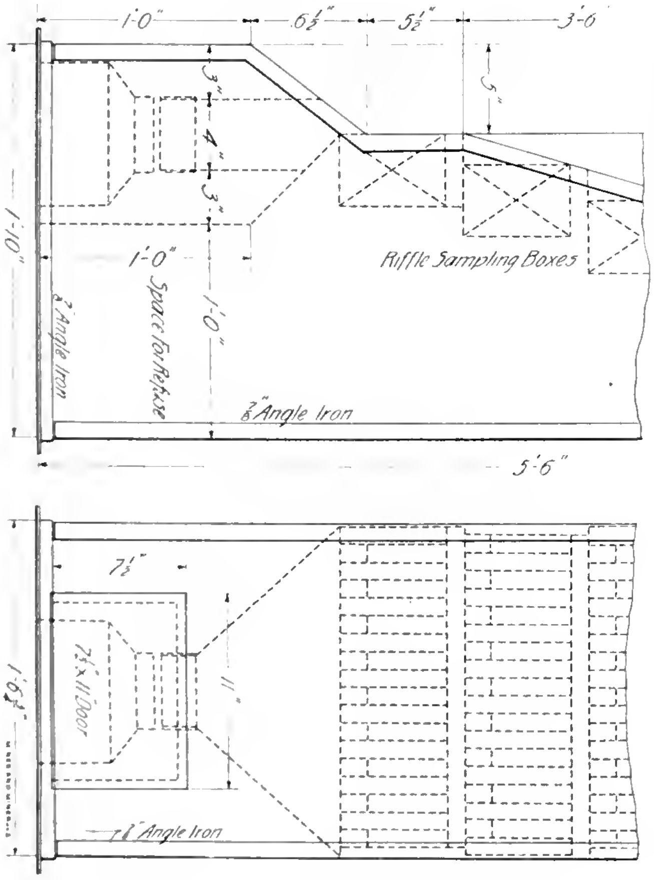

Fig. 3. Plan and Elevation of Riffle Samplers

The ratio of the weights of the samples to the weights of the original quantity of coal is almost constant, as shown in Table 3.

While it is true that the size of the gross sample depends upon the man who loads the tram cars and weighs the coal, the process is mechanical, and there is nothing to cause a variation in the quality of the sample. The machines are efficient and accurate and at their worst are better than the method of hand sampling, which has produced results so radical as to cause endless discussion between the consumer's chemist and the coal company.

Table 2. Shovel Samples

Test	A	B	C	D	E
Number cars dumped	47	30	69	30	30
Weight of sample, pounds	183.30	91.30	258.20	80.40	82.70
Weight of sample per car dumped, pounds	3.90	3.05	3.74	2.68	2.76

Size of Coal Before Going Through the Crusher

	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Over 1 inch	38.7	21.9	42.4	38.2	35.3
1 inch to ½ inch	18.6	16.9	17.9	18.6	20.2
½ inch to ¼ inch	14.0	18.0	13.4	14.1	15.1
Under ¼ inch	28.7	43.2	26.3	29.1	29.4
	100.0	100.0	100.0	100.0	100.0

Table 3. North Tower

Weight of Coal Ounces	Parts	Weight of Sample Obtained Ounces	Theoretical Weight of Sample Ounces
1,763	1 in 125	14.0	13.8
1,712	1 in 126	13.5	13.4
1,672	1 in 126	13.0	13.1
1,656	1 in 127	13.0	12.9
1,624	1 in 126	13.0	12.7
1,592	1 in 123	13.0	12.4
1,584	1 in 126	12.5	12.4
1,568	1 in 124	12.5	12.3
1,528	1 in 127	12.0	11.9
1,508	1 in 125	12.0	11.8
South Tower			
1,851	1 in 126	14.5	14.5
1,814	1 in 125	14.5	14.2
1,786	1 in 127	14.0	13.9
1,779	1 in 127	14.0	13.9
1,763	1 in 130	13.3	13.8
1,742	1 in 134	13.0	13.6
1,723	1 in 128	13.5	13.5
1,702	1 in 131	13.0	13.3
1,636	1 in 124	13.5	13.2
1,670	1 in 133	12.5	13.0

One month's record of analyses totaled and then averaged gave the following percentages: Moisture, 1.26; volatile material, 18.96; fixed carbon, 72.33; ash, 7.37; sulphur, .85. The uniformity of the results is indicated by the ash, which varied from 6.28 low to 7.97 high, and averaged 7.37 during the 31 days.

NEW WESTERN PACIFIC RAILROAD

The Denver & Rio Grande Railroad has issued a new coast to coast map, which should be in every mining engineer's office, East and West. It is descriptive of the new Western Pacific Railway, an extension from Salt Lake City to San Francisco, a line 921 miles long that has been in course of construction since 1905, and was opened for passenger traffic August 22, 1910. For 80 per cent. of its entire length the heaviest grade is $\frac{4}{10}$ of 1 per cent., about 20 feet to the mile, while the maximum grade is 1 per cent. The maximum curve is 10 degrees, and few curves exceed 6 degrees. The new line crosses the Sierras at an elevation of 5,712 feet, which is 2,535 feet lower than the Sierra crossing of any other railroad. No snow sheds are needed on this account.

There are 40 steel bridges on the line, aggregating in length 9,261 feet. There are 43 tunnels, with a total length of 45,494 feet. On the western slope of the Sierras, in order to maintain a light and uniform grade, the line rising 41 feet, loops itself within 1 mile, which forms one of the wonderful engineering features of the new road.

MINING, PREPARING, AND COKING COAL

Written for Mines and Minerals, by E. B. W.

A Description of the Methods Used and the Plant at Marting, W. Va.

The origin of coal has been traced from peat bogs to graphite and natural coke, in fact, carbon the chief constituent of coal has always been derived from organic matter. In San Domingo there is a bed of dun-colored material which is about as heavy as punk and has no resemblance to coal, yet on being ignited with a match burns and gives off the same odor as black cannel coal. This has a conchoidal fracture and might be termed white cannel coal. In the Richmond, Virginia, coal basin natural coke is found, and in Rhode Island, anthracite resembling graphite is obtained, all of which goes to show that in different places coal varying in color, texture, and chemical analysis will be found. The geology of coal is so well established that one accustomed to the rocks can determine them by casual observation from a railroad car when he is traveling through coal formations. Not all coal measures are productive, and in a new field prospecting is absolutely necessary for determining the thickness and area of a coal bed.

A chemical analysis is also a necessity in order to determine the impurities in a coal and draw conclusions on its apparent value from an economic standpoint. At one time coal was believed to exist only in that geological period which is termed the Carboniferous; later it was ascertained that excellent coal was to be found in the Cretaceous and Tertiary periods; however, no coal worth mentioning has been found below the Carboniferous formation, because prior to this time very little vegetation existed. The coal beds of the Appalachian and Blue Ridge mountains belong to the Carboniferous period, and while they are in layers, one above the other, with sandstone, slate, and fireclay intercalated, they are of different qualities. The same coal bed, even though it varies in thickness and has a great area, differs but slightly in chemical and physical qualities, so that when one versed in coal hears of a particular coal bed like Pocahontas No. 3, he understands the value of the coal whether it comes from the Elkhorn or New River districts in West Virginia. As another illustration, when one versed in coal hears of the No. 2 gas seam in West Virginia he knows its quality, whether it is mined in the Tug, the Guyandotte, or the Kanawha districts.

If the anthracite fields of Pennsylvania be neglected, most of the coal beds of the Appalachian region are almost horizontal, and in West Virginia many of them are above water level so that the coal may be mined by drifts. There are several advantages in drift mining which tend to decrease the cost of coal production, although as a rule, such mines are so far from market this advantage is overcome, and were it not for the careful preparation and excellent quality of the coals there would be little profit in mining them. Fortunately the Pocahontas No. 3 and the No. 2 gas coals are so different in quality and situation there is little competition between them, although both have strong competition from other fields. In recent years many labor-saving devices have been introduced in coal mining to decrease the cost of production and prepare coal for the market; few changes, however, have been made to improve the method of mining and reduce fixed charges. It is well known that the proper way to develop a coal property is to drive the main entries to the end boundary line and at a suitable distance, say 300 feet from this line, turn cross-entries to the side boundary lines. As the cross-entries are driven, room necks should be turned but no room mining done; after this has been accomplished a second pair of entries 300 feet from the first should be started inside the first pair, or both entries may be driven at the same time. All rooms on the first pair of entries should be started at the same time, and when they reach the boundary all room pillars should be pulled back together. If it has been customary to mine a 20-foot room and leave a 40-foot pillar in any particular field, the practice under the proposed method may be changed, say to 15-foot rooms and 15-foot pillars. In the case of the larger pillars, made necessary if they are to stand long, as almost invariably is the case where the attack is made soon after entering the mine, but one-third of the coal is won and two-thirds is left standing; therefore, in a half-mile cross-entry but 44 rooms can be opened. If coal is needed, probably not more than 10 or 12 rooms will be working on one entry at a time, because they will be attacked soon right after the entry drivers have passed them, and to increase the number of rooms another pair of entries will be started. By this means the mining becomes spread over a wide area, thereby increasing costs in several ways.

Fig. 1. Surface Plant at Marting, Fayette County, W. Va.

In the proposed case, with the smaller pillars 88 rooms can be worked at once, thus centralizing the work, and decreasing costs in every way to such an extent that the first extra outlay of capital is returned many times over. Labor, supplies, ventilation and haulage costs will be decreased; better safety to the mine insured; besides, instead of costs increasing as the mine expands, as they do on the working-in system, they will be diminishing, and better coal will be obtained by practising the retreating system. This is not a theory but a well-known fact, which has failed to be adopted in the United States because most mine operators in the past, through lack of capital, have devoted their energies to increasing their cash accounts by quick returns, and the remainder have been driving their employes to show temporary results.

If one considers the cost of narrow work and the extra expense that entails when it stands idle for years; the extra rails on the entries that are not used so long as the pillars are not

mined; the extra-room tracks that must be pulled and relaid; the loss of ties and props; the labor in fixed charges; doors, overcasts, and other arrangements for ventilation that can be discarded, it will be found that large sums of money can be saved by the retreating system of coal mining.

Fig. 2. Loading Hand Picked Splint Coal

Bituminous coal companies in Pennsylvania and West Virginia have made great strides in the last 15 years toward improvement in the preparation of coal for market. These improvements have been noted from time to time in Mines and Minerals and in this particular article the plant of Columbus Iron and Steel Co., at Marting, Fayette County, W. Va., is illustrated. Fig. 1 shows the general arrangement of the buildings, with slack bin, shop, stable and power house, in order from left to right. It also shows the trestle from the slack bin to the coke ovens and the tipple to the rear of the slack bin.

The coal mined by this company is the Olive splint and the celebrated Kanawha No. 2 gas coal, which has the following analysis at their mines: Fixed carbon, 60.15 per cent.; volatile matter, 31.90 per cent.; moisture, 1.05 per cent.; ash, 6.90 per cent.; sulphur in ash, .75 per cent.

At Marting the average thickness of the coal bed is 70 inches, the upper 20 inches of which, however, is a hard semi-smokeless splint coal. As splint coal is much harder and less frangible than the coking coal of the lower bench, it is separated in the mine as shown in Fig. 2. Splint coal has a laminated structure which prevents its breaking readily across the bedding planes. This physical condition keeps the coal from slacking during handling and is one feature that makes it a desirable domestic fuel. When splint coal is kindled, little splinters fly from it. This decripitation is due to the sudden heating which causes unequal expansion, or to the pressure of minute cavities of gas, which expand and explode. The Smithers Creek Olive splint coal is used at metallurgical plants for remelting, reheating, and annealing purposes, where long rolling-flame coals, low in sulphur, are in demand. At Marting the splint coal is prepared by carefully selecting the lumps in the mine, loading it by hand into separate cars run on wooden rails over the mass of broken coal from the lower bench, as shown in Fig. 2. When the coal reaches the tipple it is passed over shaking screens having 5-inch diameter holes.

In the preparation of the lower bench or 50 inches of No. 2 gas coal the splint coal is entirely eliminated. The No. 2 gas coal is passed over ¾-inch shaking screens previous to its going to the railroad car and is as free from slack as it is possible to make it. Usually run-of-mine contains all sizes of coal but this "¾-inch gas mine-run" receives the same careful preparation as egg and lump coal, in order that it may fully come up to the steam users' and gas makers' expectations, and always be uniform and dependable in quality. Three sizes, lump, egg, and pea coal are made at the steel tipple, shown at Fig. 3. The greater part of the slack is riddled from the coal before it reaches the weigh basket, and whatever slack is made at the shaking screens passes through them to a slack pocket in the tipple from which it is lifted by a conveyer and carried to the slack bin. Any bituminous coal heated in a retort will furnish gas, but the coal with the highest percentage of hydrocarbons will produce the most gas. The results of experiments made by the United Coke and Gas Co. on the by-products to be obtained from the leading gas coals in the United States and Canada is given in Table 1.

From the results obtained it is seen that the No. 2 gas coal of the Kanawha River district leads in the quantity of by-products, but not in coke, as might be anticipated, when coals lower in volatile hydrocarbons are compared with it. It is frequently stated that the value of a coal is indicated by the number of heat units it contains, as determined by a

Fig. 3. Tipple at Marting, W. Va.

calorimeter. While as a theoretical hypothesis this statement may approximate the truth, as a practical proposition applied to the combustion of coal beneath a boiler it is erroneous, and should be made to read, "the value of a coal as a steam fuel depends on the way it is fed to the grate and the kind of boiler it is burned under." A British thermal unit, B. T. U., is the heat required to raise 1 pound of water 1° F., and is the basis on which the heat in coal is calculated. Theoretically 1 pound of carbon should produce 14,600 British thermal units; however, since coal is not pure carbon, the heat units may be increased or decreased by the impurities in the coal. Thus the heat units per pound of combustible in No. 3 Pocahontas coal is given as 15,700; that of Thacker coal, which is somewhat higher in volatile hydrocarbons than No. 2 gas coal, is given as 15,200; while that of Olive coal is given as 14,632.

The Columbus Iron and Steel Co. have blast furnaces at Columbus, Ohio, and consume the entire product of their coke ovens, which are shown in Figs. 4 and 5. The illustrations are so good they are inserted for the benefit of those not familiar with coking operations in beehive ovens. The oven side and end walls are all that can be seen but inside these walls are hemispherical ovens built of firebrick, having a door opening through the side walls. Two ovens are built back to back making a long double row with oven doors on each side wall. The oven crowns have a charging hole in the top and all but this hole is covered with loam to prevent the heat of the oven radiating and to make it possible for men to travel over them.

On piers built lengthwise of the ovens there is a railroad on which the larry runs. In this case the plant machinery is run by electricity and the larry shown is run by a motor, where a few years ago small steam locomotives or mules drew the larry. After the ovens are charged with slack from the larry they are leveled, the door closed with brick, and the joints in the brick through which air might pass, are luted with clay. Above the brick door there is a small space left to furnish air for the combustion of the gas which rises from the coal. In Fig. 4 will be seen half-buried barrels for the clay lute. The coal is subjected to the oven heat from 48 to 72 hours, according to the size of the slack charge and the kind of coke it is desired to make. To pull the coke from the ovens the temporary brick doors are broken down, a stream of water allowed to play on the hot coke inside the oven until it is extinguished; after which the coke-drawer uses a long-handled hoe and pulls the coke from the oven. In Fig. 5 the first door is seen bricked and luted; the next has the bricks pulled down and is ready to pull, having been watered; the next oven is being pulled; the next oven has been pulled and the coke stacked on the yard; the next oven is being watered, as is evident from the steam rising through the tunnel head on top. The man in the rear is just commencing to water his oven, as may be seen from the steam coming out of the door and the distance he stands away from the oven.

FIG. 4. COKE OVENS

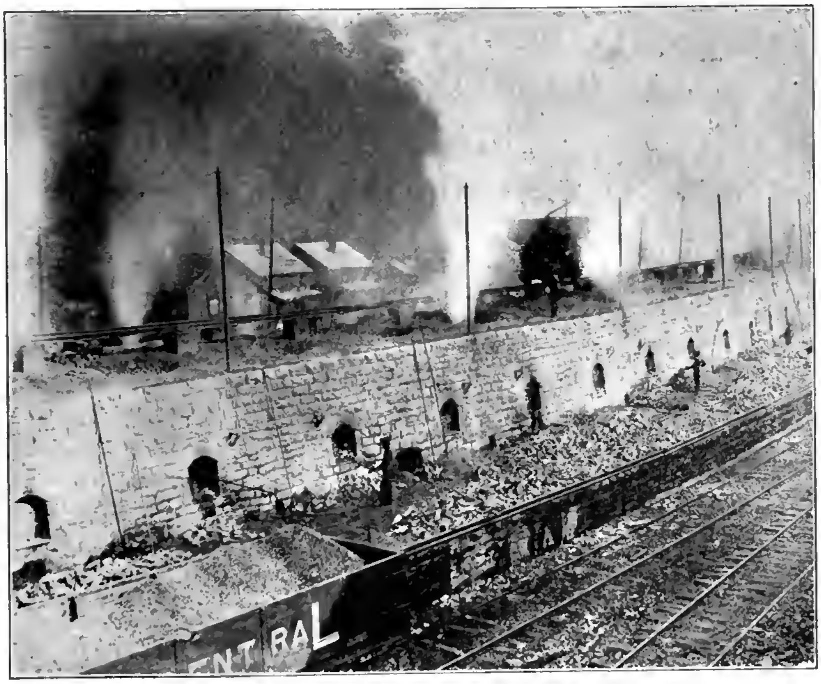

FIG. 5. COKE DRAWING

The nearer a beehive oven is made like a navel orange when bisected between its ends, the stronger and more serviceable it will be. The navel orange is not an exact sphere, nor is it flattened at the ends, yet not too oval to greatly exaggerate a hemisphere. When the crown of the hemispherical oven commences to sag it soon comes down, while a navel-orange-shaped oven will sag slightly and still behave. Ovens constructed on the later design remained unfired for 10 years, which is surely an endurance test, and since firing they have been running 5 years.

In Fig. 6 is shown the interior of the company's power house, in which electric power is generated to light the town and works, haul cars and larries, run the machinery at the tipple, etc. In 1908 the Columbus Iron and Steel Company produced 81,837 tons of coal, made 24,150 tons of coke and shipped 45,105 tons of coal. In 1909 the same company

produced 129,048 tons of coal, made 34,868 tons of coke and shipped 71,851 tons of coal. This large increase is due to the natural growth and development of a good coal property.

Table 1. Products from Gas Coals

Coal	Coke Per Cent.	Tar Per Cent.	Amm. Sul.	Total Cubic Feet Gas Per Ton Coal
Kanawha	73.60	6.40	1.010	10,289
Pittsburg	68.25	4.38	.903	8,884
Eastern Pennsylvania	78.00	2.00	.800	8,400
Virginia	66.01	4.70	1.070	10,090
Youghiogheny	75.60	4.99	1.000	9,000
Fairmont	72.58	5.22	1.270	10,200
Cape Breton	72.83	4.99	1.270	9,000

The writer is indebted to Mr. Fenton, of the Columbus Iron and Steel Co. for the use of the illustrations which enter into this article.

Fig 6. Interior of Power House

CARBIC CAKES

The "Carbic" cakes for acetylene lighting of all kinds are made of a mixture of granulated calcium carbide, sulphur, and sugar, compressed into cylindrical cakes in a powerful press. As a result of this treatment the fragments of carbide are surrounded with a protective covering which renders them proof to a large extent against atmospheric moisture, decomposition taking place only when they come in contact with moisture in the form of liquid. In this way the handling of the material is simplified and waste diminished. Further, these cakes present certain advantages in use. With carbide in the ordinary form there is apt to be a rapid evolution of gas as soon as it and the water are brought together in the generator, and in consequence the pressure may be unduly high. With the cakes, however, since the surface reached by the water consists only in part of carbide, the gas is produced more gradually and the pressure is more equable. The other ingredients in the cakes also cause the lime, which is formed by the reaction, to fall away freely from the cake to the bottom of the generating vessel, whence it can be easily washed out. In the generators designed for use with the cakes the latter are suspended in a cage and the water is forced up to them by the pressure of the gas itself, so that the generation is automatically adjusted according to the consumption. The acetylene, after it is formed, is first washed by passage through water and then chemically purified. In consequence of this purification and of the regularity of the pressure, it burns with a clear white flame, free from "haze," and does not give rise to carbonization and choking of the burners. For motor cars a device may be fitted by which the jets can be electrically lighted from the magneto.—*London Times.*

ELECTRIC MOTORS FOR ROPE HAULAGE

*Written for Mines and Minerals, by H. W. Reybold**

So much interest has been shown in the article on "Electric Rope Haulage" which appeared in the July issue, and so many requests have been received for detailed information that it has been considered worth while to give a more complete description of the steel frame hoists used, these, of course, being the most important machinery used in the work. In the article mentioned, the system of electric rope haulage in use at the Midway Mine of the Chicosa Fuel Co., Huerfano County, Colo., is very clearly described. The installation consists of single-drum electric hoists on cross-entries, and double-drum electric-driven tail-rope engines, or hoists, on levels. Each hoist handles easily one pair of cross-entries or about 48 rooms, while the tail-rope engines care for all the cars coming from 2 pairs of cross-entries or about 96 rooms working 192 men. The hoists set out the empty cars and pick up the loaded cars at the room mouths. One engineer, 1 rope driver, and 1 hoist can move as much coal as 8 or 10 drivers and mules, without the risk of killing both mules and drivers.

The hoists, as shown, are built with the entire frame of standard steel shapes. The advantages of the steel construction are readily seen, the frame can be built stiffer and more rigid, with about one-third less weight than equivalent cast-iron frame (a 30-horsepower hoist with cast iron-frame weighs 5,900 pounds while the same size with steel frame will weigh only 4,150 pounds); the frame is literally unbreakable; the hoist can be knocked down and rebuilt in a short time with little expense—a decided advantage for mountain transportation where the machine must be taken underground.

The base of the machine consists of four **Z** bars bolted together forming hollow girders with projecting bottom flanges on each side which bear on the foundation. The holes for the foundation bolts are drilled in these flanges.

The bearings for the drum are carried on two standard I beams, Fig. 1, which are in turn bolted to the four **Z** bars in the base. The motor, Fig. 3, is bolted to two small **Z** bars, which are also bolted to the base. These latter can be bolted at any desired point on the base to accommodate any style of motor that could possibly be used on the hoists. This construction lends additional stiffness to the frame, and is superior to the separate motor pad. In cases where it is advisable to place the motor either in front or in the rear of the drum, this construction is easily modified, without sacrificing any features of the standard design.

The hoists have a new patented band brake, the construction being such that the band bears on about 87 per cent. of the band ring. The power is applied from the hand lever to the brake by means of a simple, but powerful system of multi-

* Engineer for Hendrie & Bolthoff.

plying leverage, all the members of which are steel forgings. The band is supported by a bolt and spring, leaving the drum free from any drag when hoisting. The band is lined with Gandy belting which is fully as durable as wood blocks and can be renewed by any one in 30 minutes. The brake ring, or surface, on which the brake band bears is of large diameter and ample width, insuring plenty of wearing surface and reducing the liability of heating. The brake is on the opposite end of the hoist from the clutch, and the latter cannot possibly be affected in any way by the heat from the brake

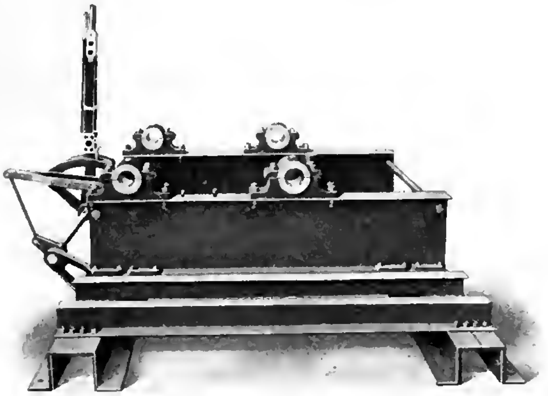

Fig. 1. Base and Drum Bearings

The clutch used on the hoists is an improvement on the well-known Lane clutch. The power is applied radially to cranks on the two halves of the clutch at the same time, releasing or tightening the band as desired. The clutch band bears directly on a flange on the drum itself, transmitting the power from the motor directly to the main gear and through the rim of the gear to the drum. The clutch is powerful and easy to adjust and maintain.

All the gears are extra heavy and milled from the solid metal. The Chicosa Fuel Co. now has at its various mines five of these hoists with single drum, and three with double drum as shown in Fig. 3.

The power used, as stated in the article in the July issue, is three-phase, 440 volt, and is supplied by two 125-kilowatt generators driven by 16″ × 16″ self-oiling engines.

NATURAL GAS AND PETROLEUM IN ALABAMA

For more than a year the existence of natural gas in considerable quantities has been known, in a small area 3 miles east of Fayette, Ala. This region was recently visited by David T. Day, of the United States Geological Survey, who reports that four successful wells have been drilled, showing gas with a closed pressure estimated at 600 pounds per square inch, and nine additional wells are in process of drilling.

The gas is found at a depth of 1,400 feet in a close-grained sandstone, estimated by the Providence Oil and Gas Co. to be 50 feet thick. Small quantities of crude petroleum similar to that usually found in the Appalachian region were encountered at various depths above the gas. The strata pierced in the drilling consist of alternating layers of shale, sandstone, and tight sticky clay, under ideal conditions for the accumulation of gas and oil.

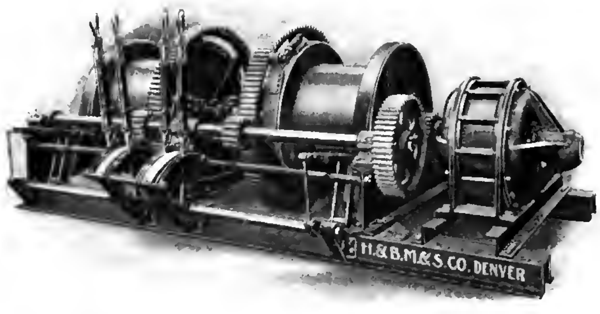

Fig. 3. Double Drum Hoist

It is estimated that five million cubic feet of gas per day can be furnished from the four wells now completed. The gas is pure and is free from sulphur.

It is difficult to determine the extent of the field on account of the overlying cap of Tuscaloosa drift by which the oil-bearing formations are concealed.

The conditions for successful gas wells are ideal in the immediate neighborhood of the present wells but it is impossible to determine how far these conditions may extend without interruption by faults or other disturbance of the necessary impervious cover. The thickness of the gas-bearing stratum and the pressure developed indicate a satisfactory yield of gas as compared with other known gas fields. The amount of development work thus far done is not sufficient to show whether a supply adequate to the needs of Birmingham for domestic and manufacturing purposes can be obtained. This will be determined, however, by the completion of the wells now drilling. Mr. Day urges the importance of detailed geologic mapping of Fayette County by the Alabama Geological Survey.

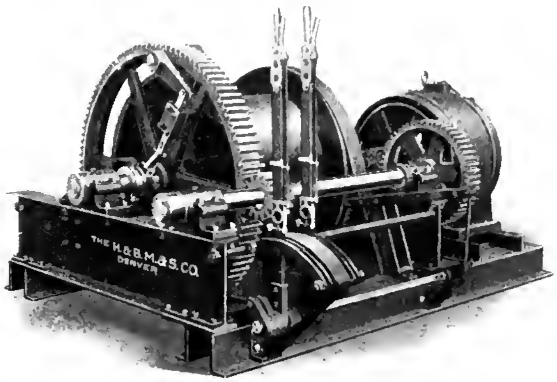

Fig. 2. Single Drum Hoist

POSSIBLE EFFECT OF THE PANAMA CANAL ON ALASKAN COAL BUSINESS

The completion of the Panama Canal may enable eastern operators to deliver high-grade coals on the Pacific coast at prices about the same as those that can be offered by operators in Alaska. Other competing fields will be those of Vancouver Island and New South Wales.

The present markets for Alaska coal may be grouped under three heads—the local market, without competition, about 120,000 tons a year; a market competitive, yet favorable, about 350,000 tons; and a competitive market, about 1,000,000 tons. These rough estimates indicate that Alaska coal of the better grade could perhaps find a market to the extent of 1,000,000 tons a year.

It is impossible to forecast how rapidly the market for Alaska coal may expand, for its expansion depends on the rate and amount of industrial advancement made along the Pacific seaboard. That the demand for high-grade steaming and coking coal will increase rapidly there can be no doubt, but that Alaska fuel will be a strong competitor with some of the imported coals and also with the eastern coals after the completion of the Panama Canal seems equally certain.

THE COEFFICIENT OF FRICTION

*By William Clifford, M. E.**

In a recent issue of Mines and Minerals one of the correspondents endeavored to show that the total pressure required to pass a predetermined volume of air through a coal mine could be obtained by measuring the rubbing surfaces and using Atkinson's formula and a certain German coefficient.

Difficulty of Calculating the Necessary Pressure by Estimating the Rubbing Surface

If it is claimed (which is not stated) that the projection of a mine, in case of a new one, should be taken, I would like to see the mine that is worked to its original projection.

A good many years ago Mr. Austin King, Sr., endeavored to test the practical value of Atkinson's coefficient by measuring roads. To this end Mr. King selected a fairly new colliery with straight roads and good roof, and made his experiments when all was still, and I understand he obtained a gauge as high as a house for the same volume of air the mine actually passed with under 3 inches water gauge. This was about the time when in Pennsylvania mine inspectors and mine foremen began to be subjected periodically to that form of mental calisthenics called examinations.

The application of formula and coefficients to a whole mine is of no value in guiding us to the obtaining of the amount of

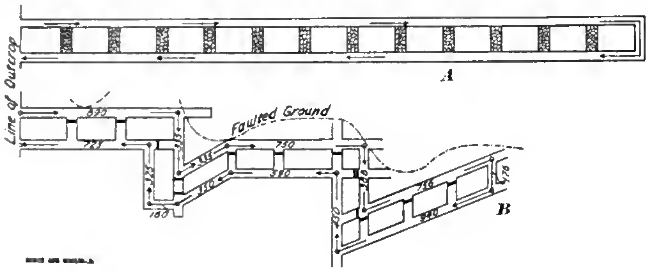

Fig. 1

pressure or motive column we must use; and if we inquire into the laws governing the friction of air in mines, as now laid down by authorities, and first put before the mining world in a concise form by the late John Job Atkinson, in a paper read before the Manchester Geological Society, nearly 50 years ago, it will be found that it was in this paper that Mr. Atkinson gave to the world his famous equation:

$$p = \frac{k\,s\,v^2}{a}$$

In this paper (which is published in small book form) we shall find, that at the very outset it reads:

"Numerous experiments have been made to find out the laws that govern the friction of air and gases, both in pipes having a uniform section, and to a less extent in the irregular airways of mines. By these experiments the following laws have been found to hold good in practice:

1. "The pressure required to overcome friction of air increases and decreases in exactly the same proportion that the area or extent of rubbing surface exposed to the air increases or diminishes." (I would add that this is true only so long as the rubbing surfaces and the initial direction of the air are parallel.)

2. "That the pressure varies inversely as the sectional area of the airway.

3. "That the pressure required to overcome friction in the same airway varies in the same proportion as the square of the velocity increases or diminishes." (I would add the same qualifying condition as in the case of Law No. 1.)

That Mr. Atkinson had in his mind individual, straight airways of uniform section, and not a district or whole mine, embracing hauling roads, turnouts, room necks, and roads, and the return airways, is plain from the way he states his examples.

For instance, in the very first one he says: "In an airway 10 feet square—100 feet area, and 25,000 feet or nearly 5 miles long," etc.

I think it is proper here to say that nothing is more unfair to the memory of so bright a man as the author of the little book "Gases Met With in Coal Mines," who sacrificed his material interests during his lifetime to the elucidation of problems affecting the safety of coal mines, and in the spreading of knowledge to that end, than to father upon him the crudities of misrepresentors of his theories. I must leave to my readers the decision of whether or not it is possible that a writer, whose lucidity of thought and expression has captivated the mining students in all countries into whose language the little manual we have referred to has been translated, would fall into the error of misapplying the rules specifically governing the flow of air in straight roads of even section, to the mixed conditions and irregular areas and surfaces of a whole mine.

Mr. Atkinson's knowledge and views were not merely academic, but were the outcome of many years of daily practice as chief manager of mines of the highest standing, and as a government inspector in the county of advanced mining, Durham, England, at a time when inspection of mines in Great Britain was very much of a parental character, and the men selected for the duty were usually eminently qualified for the role of authoritative advisers.

I have drawn two plans showing two different forms of exploitation, in order to make plain my contention that every colliery that is developed has its own particular coefficient, distinctly different from every other, and that it is safer to take the estimate of an experienced mining engineer than to rely on figures obtained by straining authorities and stating as facts things which are strictly speculations. After inspection of the two plans, the decision as to whether or not my first contention is correct, the reader can judge.

In the two mines, shown in Fig. 1, marked *A* and *B*, the roadways in each case aggregate 7,149 feet in length, and are assumed to have equally smooth walls and to be of identical cross-section throughout their length, say 60 square feet. It is desired to circulate 6,000 cubic feet of air per minute through each mine, and applying the method of whole-mine coefficient, the pressure required to put this 6,000 feet through mine *A* must equal that required to put it through mine *B*.

In mine *A*, stoppings are built at both ends of the breakthroughs, nearly flush with the face of the respective entries, for the reason that in case of an explosion the expanded gases caught in the cul-de-sac of an open-ended breakthrough, aided by the ignition of the local deposit of dust usually present, will invariably blow out the stopping at the closed end. The small openings left at the top of each pair of stoppings are 9 square inches area, which is enough to keep the spaces in the stowing clear, except in a few highly gaseous mines. The openings may ordinarily be closed after 2 or 3 years.

The mine *B* supposes a less fortunate location than *A*, and is feeling its way along the edges of an imaginary fault, and though driven on paper with the object of being irregular, it is less so than many coal mines, but it sufficiently answers the purpose of showing the futility of endeavoring to compute the total resistance of a mine by measuring the roads and applying Atkinson's formula with any of the modified coefficients.

We will now trace the air-current round these two mines, beginning with *A*. Entering at the upper road or intake, the air sweeps along in a straight line. The frictional resistance being that normally due to the velocity with which it rubs against the sides, roof, and floor, varied by striking against vertical and horizontal timbers, and perhaps under cribbing supporting high falls, or projections due to slabbing of the sides; these latter two forms of resistance afford compensations in the shape of locally increased areas.

* Jeannette, Pennsylvania. Paper presented before the Coal Mining Institute of America.

It may also be added that the workmanship of the collier enters into the attainment of results; smooth cutting and freedom from offsets, large or small, have a good deal to do with capacity of a road to pass wind. Our current in mine *A* reaches the far end of the intake, around two right-angle turns into the return; from this point to the surface it encounters substantially the same resistance that it did coming along the parallel intake road.

We will now follow the course of ventilation round mine *B*. For about 950 feet from the surface, the road is straight, following the direction of the general projection of the mine. At this point in the entry, a fault, which had shown itself on one side at 400 feet, stretches across the entry. Coming back to 890 feet a road is turned away from the fault at right angles.

(It may be here observed that none of the authorities on coefficients have given one for a right-angled turn. Daniel Murgue gives one about one-third greater for a "slightly sinuous" road than for a straight one.)

The road turned off at 890 feet continues straight to a blind end beyond the back heading; but at 335 feet a road is turned off toward the fault, which it touches at 335 feet more. Here a deflection is made to a line of direction approximately that of the base line of the mines alignment, and along the road so deflected the fault is struck again at 775 feet, and the driving continued 50 feet into the faulted ground. Back at 770 feet a right-angled heading is turned away for 368 feet, and an acute-angled road is turned off and continued for 850 feet, in the hope of getting round the end of the fault, but it is reached. At 758 feet, a cut through to the back entry is driven 175 feet. The length of the intake up to this point, plus the cross-cut 175 feet, together with the measurements along the return or back entry to surface, make 7,149 feet, the length of mine *A*.

In mine *A* are two right-angled turns. In mine *B* are five right-angled turns, four acute-angled turns, and four oblique- or obtuse-angled turns. Now if "slight sinuosity" adds 33 per cent. to the resistance of a road (Daniel Murgue's coefficient), what must a turn of 90 degrees add, and what more must a turn of about 115 degrees add, and four oblique-angled turns, which cannot be called "only slightly sinuous?"

Now, if slight sinuosity adds 33 per cent. to the resistance encountered by air, in *B* mine we have five right-angled turns, against two in *A*; four acute angles against none in *A*; four oblique angles against none in *A*; therefore, the resistance to the passage of 6,000 cubic feet of air in *B* is enormously greater than it is in *A*; whereas, by the methods of figuring adopted in the paper mentioned, the rubbing surfaces and the areas being equal, the resistance should also be equal in each mine for same velocity.

The form of *B* is not much exaggerated for the purposes of argument; in fact, falls short in its crookedness, of many mines I have known.

The block coal of Mahoning and Trumbull counties, Ohio, afforded little scope for skill in laying out a mine; its main roads must per force follow the swamps. No such excuse, however, could be made for the tortuous character of many mines in Western Pennsylvania 35 years ago.

Recently I have come across some notes by a clever recent writer which, in the main, support the position I have taken. One paragraph reads as follows:

"The hydraulic engineer can hit on one or two values of *k* that practically suffice for general use; but it is the miner who finds *k* a different value in every part of the mine. Not only the amount, but the nature of friction, varies continually. At one part it is sliding friction, at another concussional. Sometimes dry and sometimes wet friction; sometimes the friction is against trams and trains traveling in the same direction as the current. Sometimes against trains moving the opposite way. Such medley of resistances does not lend itself readily to practical, much less accurate, measurement."

The following table shows the values of the coefficient of friction, represented by the letter *k*, being the height in feet of air column of the same density as the flowing air, required to overcome the frictional resistance encountered by 1,000 cubic feet of air per minute in passing through a passage having 1 foot of sectional area, and presenting 1 square foot of rubbing surface to the air in motion.

Atkinson's Table

Nature of Material Composing the Pipe or Airway	State of the Internal or Rubbing Surface Exposed to the Wind	Observers' Names	General Temperature of the Air or Gas	Head of Column of the Same Density as the Moving Air or Gas Required to Overcome the Friction Being the Coefficient of Friction, *k*
Burnt earth	Clean	Peclet	Hot	.26881
Galleries of a coal mine.....	Ordinary state	C. C. Greenwell	Cool	.25436
Sheet iron..	New and clean	Peclet	Hot	from .10583 to .06773
Cast iron...	Ordinary	Mons. Rudler	Hot	.08466
Cast iron...	Sooty	Peclet	Hot	.05292
Cast iron...	Old, tarred	Girard	Cool	.04844
Gas in pipes, cast iron..	Ordinary	Mr. Hawkesley	Cool	.03014
Water in pipes, cast iron	Ordinary	Eytelwein	Cool	.03028
Sheet iron..	Old and rusty	Girard	Cool	.02752
Tinned iron		D'Auhuisson	Cool	.02540

Remarks.—In applying these values of *k* to the formulas since they are calculated for velocities of which the unit is 1,000 feet per minute, the real velocities in feet per minute must be divided by 1,000, to give the value of *v* in the formulas; and *v* in the formulas must be multiplied by 1,000 to give the velocity in feet per minute.

The United States Geological Survey has recently made an examination of the Dan River district, in Stokes and Rockingham counties, North Carolina, to determine whether or not it contains any important coal beds. All the known prospect pits were examined and a number of them reopened.

The coal-bearing rocks consist of a narrow belt of black slaty shale which extends from a point just north of the Virginia line southwestward through Leaksville, Madison, and Walnut Cove to Germanton, N. C. Some people in the district believe that these black shales, which they regard as a "sign of coal," are thicker where they lie under cover and that if they are followed far enough down they will be found to be coal. This idea has no foundation in fact but has been the incentive to much useless labor and unwarrantable expense. At a few places on Dan River in the black shale belt thin beds of a hard semi-anthracite have been found. This coal disintegrates very slowly and consequently should be as thick at the surface as it is underground. It varies in thickness, however, from place to place and is as likely to be thinner at considerable depth as it is to be thicker. Scarcely more than a foot of good coal has been found in any one bed in the district of 30 miles along the outcrop, a fact which further diminishes the probability of finding thicker beds below the surface.

PRACTICAL FUEL VALUES

*By W. P. Young**

Qualities that Add to or Subtract From the Value of Coal for Special Uses

Every one connected with a coal company is familiar with the fact that we receive complaints from the consumer. Generally speaking, are these complaints justifiable? Is the producer altogether at fault? How many troubles arise through selecting the wrong coals, or handling them wrongly when received?

As a sidelight on these and similar questions, it may be of interest to consider some of the effects accompanying relatively small and seemingly unimportant differences and changes in physical, mechanical, and chemical properties of various fuels, with reference to their practical fuel value, more especially in metallurgical operations.

For many years there has been a persistent belief that coal should be very lumpy in order to be good. There are some grounds for this belief, but the better effects found with lumpy coals are nearly always due to furnace conditions and not to the fuel. The modern idea of selecting a fuel suited to local conditions is gaining ground and it should be observed that this does not always mean the selection of a fuel highest in heat units, as coals of lower theoretical value may give better results.

In a recent engine test on one of the Eastern roads, a fuel running under 13,000 British thermal units replaced one of over 14,000, it being found necessary to use 25 per cent. more of the latter to make the same engine mileage. This was due to the lighter gravity and finer condition of the higher valued coal, a considerable quantity of which was lost by reason of the powerful draft.

In one of the large steel plants certain furnaces were heated by coal, the bed of fuel being about 2 feet in depth. It was found to be more economical to use a coal running 5 per cent. higher in ash than another, on account of the clinkering of the latter and consequent loss in the frequent cleaning of fires.

If the coal used be of a coking nature, the presence of fine coal does not usually cause any diminution of available fuel value.

When the blast-furnace man demands a coke that is solid and in comparatively large pieces, he is not actuated by any whim, but really needs such a fuel. To him the principal use of coke is to reduce iron from its ores, but as a matter of fact, the actual quantity so used is small compared with that used in heating the slags resulting from the earthy matter of the ores, limestone, and coke ashes, together with the losses of fuel in burning to carbon dioxide in the upper zone of the furnace, without doing practical work. By far the larger amount of ores now in use are very fine and if the coke be in large pieces, it tends to prevent the packing together of the ores and the obstruction of the blast.

Large coke presents much less surface per ton, to the action of the blast, than does that in small pieces, with a corresponding minimum loss, by burning to carbon dioxide, before doing reducing work. The film of graphite, found on some well-burned and well-drawn cokes, prevents the penetration of the blast and thus saves fuel. On the other hand, if the coke be spongy, the loss from the above cause will be high, if indeed a good deal of fuel is not crushed by the weight of the stock and blown through the gas passages.

In the carriage and storage of soft coals, the presence or absence of slack is an important factor. When moderately lumpy coals are handled roughly, as in dumping cars by turning them over, a small percentage of slack mixed through the lump, prevents breakage to a degree that is surprising, though if the coal is to be stored, for any length of time later, this good effect may be more than offset by the increased liability to spontaneous combustion, by reason of the slack preventing the access of air to the interior of the pile, as well as the fact that the slack gives up its hydrocarbons more readily and in greater volume at ordinary temperatures than does the lumpier coal. In fact it would appear that there is a decided tendency in some slack coals, for the hydrocarbons to assume the gaseous form whenever the coal is finely enough divided.

This seems to be more particularly the case with those coals whose breakage produces a very fine greasy kind of slack, from which water runs without leaving a trail of wet coal. This greasy nature is probably due to both chemical and physical conditions and is a deciding factor in spontaneous combustion on storing. Slack of this nature results from the breakage of a coal that is tough rather than hard, the harder coals usually breaking down into a coarser slack and one having more definite cleavage planes.

It would appear that the composition of the coals, in the seam is gradually changing, this change being more marked where the coals are exposed in the outcrop, or penetrated by streams of water. The hydrocarbons composing the volatile matter seem to undergo more or less decomposition with resultant changes on the rest of the coal and the production of various gases, which are either occluded, or mechanically held in the crevices of the seam. While the real nature of the volatile matter, as it exists in the solid coal, is not well understood, if indeed at all, yet it is known that various compounds were formed according to the heat and pressure, when the coals came to their present condition and generally the volatile matters of superimposed seams are similar in total percentage and character if the seams have the same physical properties; for instance, the same hardness, cleavage, and appearance of slack.

There is a relationship between the physical properties of the coal and the state of combination of its volatile contents and may I suggest that possibly the very high explosive power of some coal dusts may be due to their being loosely held together in some higher organic compounds.

The coking process depends more on the nature of the volatile matter than upon its quantity, provided there be enough present to keep the ovens in condition to fire the succeeding charge of coal.

When the charge in the beehive oven catches fire quickly, the coke will be solid in structure, while if the coal remains in the oven for an hour or more after the charge is leveled before catching up, and if it then comes to a semiplastic state slowly, the coke will be spongy and carry more of the sulphur from the coal.

A simple wetting of the slack before charging, will materially reduce the sulphur contents of the coke.

Coke men are apt to consider complaints of slightly higher sulphur and phosphorus as being whims, claiming that the furnace man uses ores running many times as high in both these elements without much trouble, but the cases are entirely different, as the sulphur and phosphorus in ores, mill cinder, etc., are liberated from them before they pass below the tuyeres of the furnace and consequently have a chance to get away, either in the gaseous state, or in the form of slags combined with lime, while the same elements in the coke pass with a certain amount of the solid coke down into the crucible of the furnace and are there greedily absorbed by the iron and it is then too late to remove them by means of lime.

The clinkering of coals in furnaces is a source of great loss in efficiency. Clinkering is caused by the presence of iron, or lime in the ash, or by the melting of the coal before combustion.

The results of clinkering are direct losses of solid fuel dragged out in cleaning fires and the heating to the melting points of slag of various compositions, requiring the use of fuel otherwise doing efficient work. Red coal, which commonly carries a notable percentage of iron oxides, combined with water, is an illustration of these sources of loss. The iron oxide is

* Read before the West Virginia Coal Mining Institute, Huntington, W. Va., December 7, 1909

reduced to metallic iron, with attendant formation of silicate of iron, and forms a particularly mean clinker with its attendant losses of heat and solid fuel. As most of the red coal is also soft and will melt under heat without complete combustion, we have a combination causing much complaint. It is surprising, however, to note the relatively great loss of heat in a coal that is so slightly different from the original solid, black fuel, as to be almost unnoticeable. This loss of heat is more frequently found where boilers are being overloaded and as a rule the consumer has no real idea of his trouble, simply complaining that the coal "wont make steam" or that it has no "life." Red coal, however, has one good point, in that it usually carries very little sulphur, and consequently can be used where an excess of this element is prohibited.

On account of the fact that the red coal has undergone changes in its volatile contents, it does not make good coke in the beehive oven.

The amount of foreign matter, as slate, bone, and sulphur streaks is usually overestimated, the total percentage in any half decently prepared coal being very small. It is rarely that total visible foreign matter in soft coals reaches two-tenths of 1 per cent. of the whole, yet one-half of this amount will bring forth strenuous complaint and the assertion that the coal "was half bone and slate."

If the foreign matter is a light bone, it will do no harm in ordinary practice and will not reduce the available heat units at all.

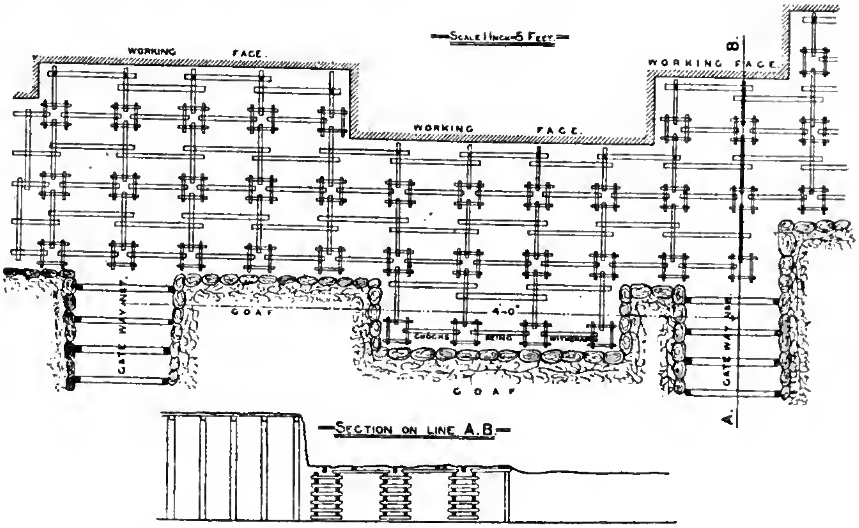
Slate is inert and only causes real losses by interfering with the draft when lying on the grates. The total quantity is too small to materially lower the available heat units.

While slates and sulphurs should be removed in all cases, it is doubtful if we should yield altogether to the whims of the consumer in the matter of the removal of the lighter bone coals, as they have a definite fuel value and should therefore be used.

Some day those following us will reproach us for the wanton waste of many thousands of tons of good fuel in days gone by in order to satisfy the unreasoning demands of consumers.

TIMBERING IN INDIAN COAL MINES

In the coal mines of England and of the continent where a treacherous roof is the rule, systematic timbering has been strongly advocated to reduce the death rate from falls of roof and sides, and in this country special rules regarding systematic setting of timber in all coal mines came into force recently. Several systems have been advanced as models, and Mr. W. H. Pickering, the Chief Inspector of Mines in India, reports that in the Punjab collieries where the conditions are somewhat similar to those of England, a system of timbering which will compare favorably with any in the world has been adopted. We reproduce a plan showing the timbering of an actual working place in Dandot coal mine. At this mine the timber is set and drawn entirely by Indians, and the system is so well carried out that during an inspection (extending over several days) no fault could be found with it. The seam is from 2 feet to 3 feet thick, and is worked by longwall method. Wooden "chocks," 2 feet square, are built at a distance of 4 feet 6 inches apart, measuring from center to center. Props are set in advance the same distances apart, and these form centers for the chocks as the work progresses. Planks $1\frac{1}{2}$ inch thick and 6 inches wide are set above the chocks and props and kept close to the face. Thus the miners are always protected by timber when working. The timber is set by specially appointed men.—*Iron and Coal Trades Review.*



PICTOU COAL FIELD LORE

C. Ochiltree MacDonald in his book "The Coal and Iron Industries of Nova Scotia," says:

"It has been suggested that the name 'Pictou' originated from the combustion of coal discovered under 4 feet of burnt clay and ashes on the East River. The Indians had a traditionary account of a fire at that point; and as 'Bucto' signifies fire in the Micmac tongue it has been conjectured that 'Pictou' is a corruption of that word, in that connection. An authority on the Micmac language has further stated that 'Pict' means an explosion of gas; and he suggests that the name 'Pictou' was given to this important district owing to the escape of natural gas from the coal underlying the East River—a phenomenon noticed and utilized by the mining classes as late as 1827. Patterson, in his history of Pictou has, however, pointed out that the phenomena of the charred coal and gas appeared only at the East River, whereas it seems certain that the name 'Pictou' was specially applied to the north side of the harbor on which no such phenomena existed. It is probable that the district has derived its name from 'Bucto,' a word applied by the Indians to a portion of the West River where one of their large encampments was burned during their absence on a cruise down the harbor. It is interesting to note that these theories derive the name of this coal field from fire; and the application of such a name to a district which has been the scene of the worst colliery disasters in Nova Scotia may be regarded as a curious coincidence.

"The productive measures of the Pictou coal field, an almost continuous section of which is exposed on McLellan's Brook, are affected by faults. The known worked seams are gaseous, and some of the coal has discharged more explosive gas than any other Nova Scotia mines. From the freshly cut coal of a Pictou colliery ventilated by 10,000 cubic feet of air a minute, gas has issued pure enough to extinguish the flame of a safety lamp held in it; and a pair of levels in solid coal has yielded sufficient gas to foul a current of 19,000 cubic feet of air per minute. Workings of the old collieries have been found infested with black damp; cars, harness, canvas cloth, tools, and even hay, lost for 20 years, have been recovered from the Deep Seam winnings well preserved by this noxious element, and when the 'Burnt Mines' were reentered in 1849 the explorers waded through black damp, with inflammable gas overhead."

POWER PRODUCTION AT COLLIERIES

*By Howard N. Eavenson**

If the mine owner or superintendent finds conditions favorable to natural drainage he is to be congratulated, and if he makes conditions favorable under adverse circumstances and without excessive cost he is to be complimented. Under other conditions pumping must be resorted to and the problem in some mines is serious enough to demand a careful investigation as to the most economical equipment. If highly corrosive water in large or small quantities is to be handled, it does not pay to install ordinary cast-iron pumps. In the larger sizes, cast-iron, wood-lined reciprocating pumps having acid-resisting metal or wood plungers have given general satisfaction and, as a rule, the inside-packed or piston pumps are not to be recommended. If the mine has air power only, the pumping is usually done by standard steam pumps, air driven, and as these pumps do not utilize the expansive force of the air when working under full load we must expect very low economy from this combination. Where electric power is available the motor-driven, single-acting triplex, or double-acting outside-packed pumps are generally selected, with geared connections to the motor, Fig. 1.

Choosing the Most Economical of Different Kind of Machines Consuming Power

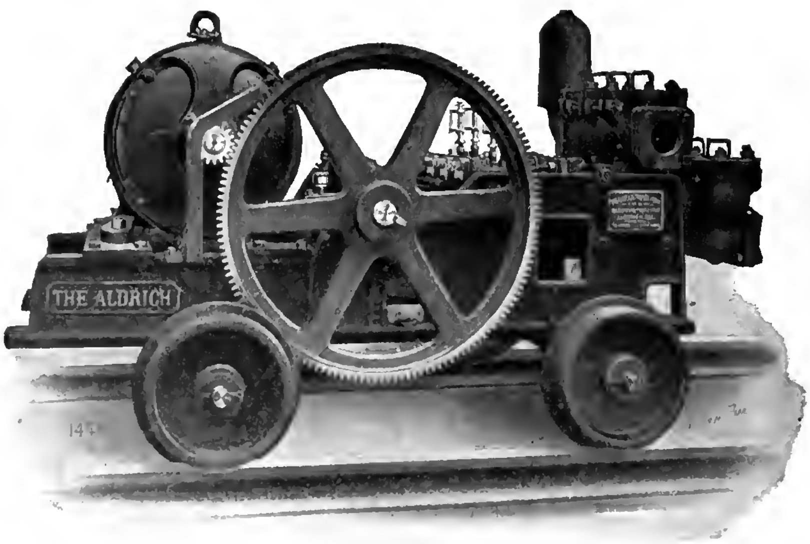


Fig. 1. Motor-Driven, Single-Acting Triplex Pump

During the last 5 or 6 years the development of the centrifugal and turbine pumps, Fig. 2, has made remarkable strides and it is now possible to get pumps of this type at from one-half to one-fourth the cost of reciprocating pumps of the same capacity and of equal efficiency and reliability. In the matter of durability the reciprocating pumps have the advantage, but considering first cost, including installation and maintenance charges, the advantages are in most cases in favor of the centrifugal pump. A case may be cited where a triplex, electric, wood-lined pump, having a normal capacity of 1,000 gallons per minute against 120-foot head, occupying a space of 1,000 cubic feet and weighing 90,000 pounds, was replaced by an acid-resisting bronze centrifugal pump, having a capacity of 1,200 gallons per minute against the same head, and requiring about the same space as an ordinary sewing machine The cost of the triplex pump was about three and one-half times that of the centrifugal, and the installation costs were in the ratio of 1 to 10 in favor of the latter. The depreciation rate and maintenance costs are considerably in favor of the reciprocating type of pump, but not by any means in the ratio of 3½ to 1.

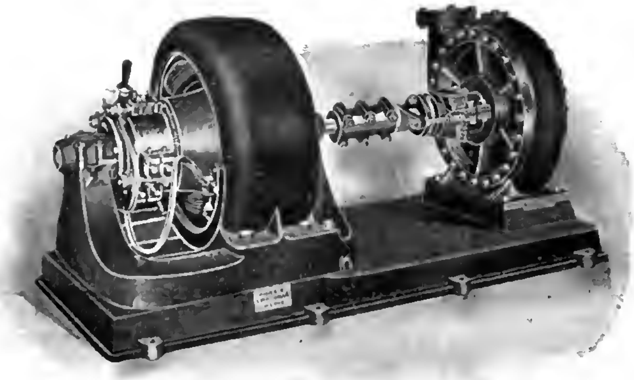

Fig. 2. Motor-Driven, High-Lift Pump for 100 Feet Elevation

*Abstract from paper read at the June meeting, West Virginia Coal Mining Institute.

It is commonly supposed that centrifugal pumps designed for a certain head and capacity will not operate satisfactorily under any other conditions. This supposition is a little at fault under the light of recent developments, as it has been found possible to so design these pumps that they will deliver under other heads than that of their normal rating, at reduced efficiencies and smaller power requirements. A case was recently observed where such a pump designed for 117 feet head and 1,200 gallons per minute was successfully used in a temporary service where there was but 19 feet head, delivering upwards of 2,000 gallons per minute with about 70 per cent. of the power demanded under normal conditions.

In ordering centrifugal pumps it is well to specify that the cases shall be split horizontally in order that the rotating parts may be inspected or removed without disturbing the pipe connections and that detachable wearing rings shall be fitted to both the pump case and the impeller.

In the matter of efficiencies, there is, on the general average, probably not a great deal of difference between the two types, the friction in the gearing and plungers, and the slippage on the part of the reciprocating pump approximately balancing the losses in the case and impeller of the direct-connected, single-stage, centrifugal pump. A common impression is that with heads of 150 feet and over, requiring two or more stages, the centrifugal pump is not adapted to mine work. This may be true under some conditions, but there are instances where these pumps are in every-day use in mines working successfully against heads approximating 1,000 feet.

Under the head of equipment for mine ventilation our interest lies chiefly in the consideration of the various types of fans; and we will all perhaps agree that there is no class of machinery used in and around mines, the development of which is in such a chaotic condition as that of the up-to-date mine fan. We find at some mines the huge, slow moving, costly, and reliable 30-foot wheels, Fig. 3, and at others the tiny, many bladed, high-speed Sirocco type, Fig. 4, having alleged double-hurricane velocities of 2 miles and more per minute through their narrow throats, and in still other cases the whirligig impeller type, Fig. 5, usually installed because it is cheap and handy.

A fan is a comparatively simple contrivance and it is not easy to understand why it has required 50 years to evolute from a Guibal to the Sirocco. In our search for light upon the subject we do not get much assistance from the fan builders as a class, for theirs seems to be an art with-

out recognized standards, though dependent upon some simple laws that have always existed.

Large fans are almost always driven by direct-connected steam engines. As a rule these engines are single expansion, with variable hand-adjusted cut-off and gravity oiling systems. As they are often run 24 hours each day under constant load, there would seem to be an excellent opportunity to cut down the fuel consumption 50 per cent. by installing compound condensing engines. In some locations this would not be feasible, on account of the lack of a sufficient quantity of water for condensing, but in other locations near small streams cooling ponds could be resorted to. Economical engines are about as reliable and durable as those of the simple type and it is reasonable to maintain that the money saved in fuel at the fan house is just as good as that saved by the high-class machinery in the power house.

Fans requiring a maximum horsepower output of 150 and under, when located within reach of a central power system and at some distance from a boiler house, are best driven by alternating-current motors, preferably of the three-phase induction type, the connections being direct in the case of high-speed fans and with belts or high-speed chains for lower speeds.

In regard to tipple equipment not much can be considered in detail in this paper as each tipple usually presents a distinct engineering problem in itself, depending upon location and method of handling and preparing the coal.

The prevailing styles in mine cars are so varied and opinion regarding their construction so divided that any attempt to pass upon their respective merits and faults would produce mostly dissenting opinions.

Taking up again mine equipment in general, there is one point in particular which should be given full consideration, that of standardization in a single mine or in a group of mines from which requisitions are sent to the same supply house.

Referring to requisitions, many of you have noted the slipshod manner in which they are often prepared, and some of us have had experience in trying to determine from them what is wanted, the good guessers generally getting there first. If there was summed up the time unnecessarily lost on account of requisitions of this class, including that of the purchasing agent, engineers, and clerks, together with the delays due to correspondence with the manufacturers on account of insufficient data, the amount in dollars and cents would be astonishing. Cases are numerous where a high-priced man from the central office is required to make trips requiring half a day or more in order to get a few measurements of the most simple nature. There should be at least one man at each mine who has had sufficient instruction to enable him to prepare legible rough sketches of parts of machines for which new parts are wanted, and it is of course essential that such sketches should be complete and the dimensions marked thereon as accurate as it is possible to make them. In ordering new parts for machines there should in all cases be obtained the name of the maker, the shop number, if any, and the pattern number if the part wanted is a casting.

Where a number of mines are operated under one management it is essential to have at the central office a mechanical department in which there are men who have had special training and considerable experience in mechanical and electrical engineering in their application to coal-mining machinery. In the files of this department there should, among other things, be kept individual records of each machine, either in the card index or loose-leaf form, so that records of new machines or transfers of old ones may be easily inserted at their proper places. It is an excellent plan to attach a brass plate to each machine upon which there has been stamped with steel dies the company's serial number and the date of purchase, these data being recorded upon the corresponding sheet or card in the machinery record.

In making up an inventory of mine equipment, the itemized present value of the different machines is often fixed by taking the cost price and deducting therefrom a sum figured from the number of years which it has been in use at an arbitrary annual rate of depreciation. This plan leads us into very serious errors, even when there are different rates of depreciation fixed for different classes of equipment, for the value of any piece of equipment depends largely upon the care which it has received, the kind of service to which it has been subjected, and the state of repair in which it has been kept. For example, a mining machine depreciates in value very rapidly during the first 2 or 3 years of its life, after which it remains in about the same average condition due to the repairs made to the various parts in order to keep it in service. The best method of determining present values consists in an appraisement made at some fixed date in each year by some qualified person, a method involving considerable work, but justified by results.

In many instances where there are groups of mines under a common management, systems of cost statements in the form of daily and monthly reports have been devised and successfully carried out, these statements showing, in connection with each machine, the nature and cost of repair parts, the amount and cost of repair labor, the amount of oil and waste used, the approximate number of days idle during the month and other information from which the manager can get a fairly correct idea as to the individual and comparative costs of maintenance and condition of each piece of equipment.

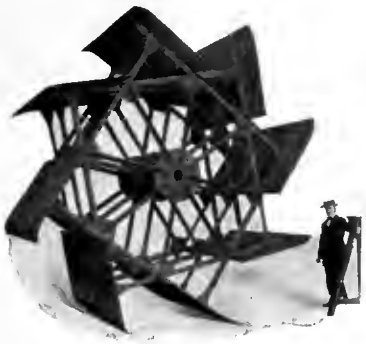

Fig. 3. Modified Guibal-Type Fan Wheel

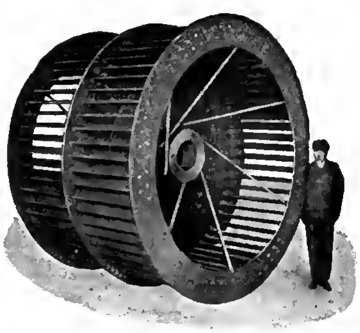

Fig. 4. Sirocco Fan

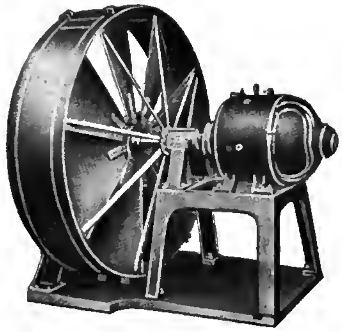

Fig. 5. Stine Disk Fan

The capacity of a revolving screen will depend very largely upon how the ore breaks. Ores which break cubical, or nearly so, in shape, go through a screen very fast, but ores which break in specules or needle-shaped particles do not screen nearly as fast as cubical breaking ore. The following average may meet the requirements of the engineer: Screen making 20 revolutions per minute, 30-mesh screen, capacity 1,000 pounds per 24 hours per square foot of screen surface; 20-mesh, capacity 1,250 pounds per square foot; 16-mesh, 1,700 pounds; 12-mesh, 2,200 pounds; 8-mesh, 3,000 pounds.

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

Note.—The following questions, selected from different examinations, are here numbered consecutively. The examination from which the question is taken and the number of the question are found at the end of each.

Selected Questions of the Illinois Examinations for 1909, Held at Springfield

Ques. 1.—What load will break a a white-oak timber 10 inches (wide) by 12 inches (deep) and 12 feet long, if the load is equally distributed along the length of the beam?—Mine Manager's Examination, Q. 3; 4-12-'09.

Ans.—The moment of inertia (I) for a rectangular beam; breadth, $b = 10$ inches; depth, $d = 12$ inches, is

$$I = \frac{b\,d^3}{12} = \frac{10 \times 12^3}{12} = 1,440$$

Assuming this beam is simply supported (not fixed) at each end, and taking the breaking fiber stress of white oak as $f = 10,000$ pounds, the load that will break the beam, in this case, is

$$L = \frac{4}{3}\left(\frac{f}{b\,d}\right) I = \frac{4}{3}\left(\frac{10,000}{12 \times 12}\right) 1,440 = 133,333 \text{ lb., or } 66\tfrac{2}{3} \text{ tons}$$

Ques. 2.—If a cross-bar 12 inches in diameter and 8 feet between notches carries a certain load, what should be the diameter of a cross-bar 14 feet between notches to bear the same load (with the same degree of safety)?—Mine Manager's Examination, Q. 4; 4-12-'09.

Ans.—For the same total load supported, the diameter of the cross-bar varies as the cube root of the length of clear span; or, the diameter ratio of two cross-bars is equal to the cube root of the length ratio. Calling the required diameter of the 14-foot bar x

$$\frac{x}{12} = \sqrt[3]{\frac{14}{8}}; \text{ and } x = 12\sqrt[3]{1.75} = 14.46 \text{ in.}$$

Ques. 3.—What power will be required to hoist an output of 800 tons of coal (per day) on an incline $\frac{5}{8}$ of a mile long and rising 2 inches to the yard, extending from the inside parting to the shaft bottom, and return the empty cars, which weigh one-half as much as the load they carry; assuming the resistance of the cars to be $\frac{1}{60}$, and the power required to move the rope equal to that required to move the cars. The speed of the rope is 3 miles per hour, and a working day 8 hours; the cars are moving $\frac{4}{5}$ of the time.—Mine Manager's Examination, Q. 5; 4-12-'09.

Ans.—This will be assumed a double-track passage in which the weight of the descending empties partly balances that of the ascending loaded cars and rope. In this case, the load on the engine consists of the gravity pull of the unbalanced load (coal and rope) when loaded trip is at the bottom of incline, plus the friction pull of the loaded and empty cars and the rope. The length of the incline is $\frac{5}{8}(5,280) = 3,300$ feet; the speed of winding is $3 \times 5,280 \div 60 = 264$ feet per minute. The time of hoisting one trip is then $3,300 \div 264 = 12.5$ minutes, which is $\frac{4}{5}$ of the total time per trip, including changing trips and delays; full time per trip is $12.5 \div \frac{4}{5} = 15.625$ minutes. The output is 800 tons in 8 hours, or 100 tons in 60 minutes, or $1\frac{2}{3}$ tons each minute. This makes the weight of coal to be hoisted each trip $1\frac{2}{3} \times 15.625 \times 2,000 = 52,083$, say 52,000 pounds, or 26 tons. Since the cars weigh one-half as much as the coal carried, the total moving load, including the empty trip, is $26 \times 2 = 52$ tons, not counting the rope, for which allowance is to be made later. The total car resistance, including both trips, is therefore $\frac{1}{60}(52 \times 2,000) = 1,733+$ pounds. The inclination of the plane being 2 inches per yard (1 in 18), the gravity pull on the rope due to the coal hoisted per trip is $\frac{1}{18}(26 \times 2,000) = 2,889$ pounds. This makes the total load on the engine, exclusive of the rope, $1,733 + 2,889 = 4,622$ pounds. At a speed of 264 feet per minute, the exerted pull would be $\frac{4,622 \times 264}{33,000} = 36.976$, say 37 horsepower. Since the question states that as much power is required to move the rope as to move the cars, this power should be doubled, giving $2 \times 37 = 74$ net horsepower. Assuming this engine to have an efficiency of say 80 per cent., the indicated horsepower of the engine should be $74 \div .80 = 92.5$ horsepower.

Ques. 4.—Give the pressure per square inch at the bottom of a column pipe 452 feet long; the pipe is pitching 42 degrees, and is full of water.—Mine Manager's Examination, Q. 6; 4-12-'09.

Ans.—The vertical rise of this pipe is $452 \times \sin 42° = 452 \times .66913 = 302.44+$ feet. The static pressure due to this head of water, or the pressure at the bottom of the pipe when the same is standing full of water, is $302.44 \times .434 = 131.25+$ lb. per square inch.

Ques. 5.—A sump in a mine is 62 feet long, 8 feet wide, and 9 feet deep, and full of water. How long will it take a 5-inch pump to empty this sump, at a velocity of 100 feet per minute, if the leakage of the valves and resistance of the pump cause a loss of 20 per cent.? There are five 2-inch pipes running full and discharging water into the sump at a common velocity of 100 feet per minute.—Mine Manager's Examination, Q. 7; 4-12-'09.

Ans.—The cubical capacity of the sump is $62 \times 8 \times 9 = 4,464$ cubic feet. The 20-per-cent. loss evidently refers to the leakage of valves and "slip" of water past the piston, or leakage of plunger packing, and relates wholly to the water end of the pump; although the mention of the "resistance" of the pump would seem to indicate that the 20-per-cent. loss was a loss in power and as such related both to the water and the steam end of the pump. But, in that case, the question would be incapable of answer because what is required is to ascertain the actual discharge of water without reference to the power necessary to operate the pump. Therefore, the mention of *resistance* should have been omitted in the question.

The piston displacement of a 5-inch pump at a speed of 100 feet per minute is $12 \times 100\,(.7854 \times 5^2) = 23,562$ cubic inches per minute, which makes the discharge, assuming a loss of 20 per cent. in the water end, $(1 - .20)23,562 =$ say, 18,850 cubic inches of water each minute. The inflow into the sump from five 2-inch pipes flowing full, at a velocity of 100 feet per minute, is $12 \times 100 \times 5(.7854 \times 2^2) =$ say 18,850 cubic inches of water each minute. Since this inflow is exactly equal to the discharge of the pump under the assumed conditions, the latter could only handle the inflow from the five pipes, and the sump would remain full of water till other means were adopted.

Ques. 6.—Give the size of pipe required to transmit 800 cubic feet of (free) air per minute a distance of 2,500 feet, the initial pressure being 100 pounds per square inch, and the plant being located 4,000 feet above sea level where the reading of the barometer is, say 26 inches under normal conditions. —Mine Manager's Examination, Q. 8; 4-12-'09.

Ans.—The question should state the loss of pressure allowed in the transmission, or the terminal pressure required, as it is possible to use any reasonable diameter of pipe, depending on the pressure required to be delivered. For example, assuming a pressure of 90 pounds is required to be delivered at the end of the pipe, makes the allowable drop of pressure in transmission $100 - 90 = 10$ pounds. The weight of 1 cubic foot of dry air at a barometric pressure of 26 inches (temperature, say 60° F.) is

$$w = \frac{1.3273 \times 26}{460 + 60} = .06636 \text{ lb.}$$

The atmospheric pressure corresponding to the given barometer is $26 \times .4911 =$ say 12.75 pounds per square inch. To produce a gauge pressure of 100 pounds at the given elevation would require $(100 + 12.75) \div 12.75 = 8.84$ compressions of the free air. Using a constant for a comparatively small pipe, say $c = 50$, and

substituting the given values, the required diameter of the pipe, for this transmission, is

$$d=\sqrt[5]{\frac{.06636\times 2{,}500\times 800^2}{8.84\times 50^2\times 10}}=3.43,\text{ say }3\tfrac{1}{2}\text{ in.}$$

QUES. 7.—(*a*) What is a safe voltage to use in a mine for electric haulage? (*b*) If the generators are producing a 500-volt current what is necessary to be done to retain the same power but reduce the voltage to 250 volts?—Mine Manager's Examination, Q. 9; 4-12-'09.

ANS.—(*a*) A current of 250 volts is generally considered safer for mine work than one of higher voltage. (*b*) In order to reduce the voltage of an electric current while maintaining the power constant, it is necessary to use a transformer to step-down the current to the desired voltage. In doing this the amperage or strength of the current is increased in the same ratio in which the voltage is decreased, and the power remains constant.

QUES. 8.—If one ventilating fan is producing a current of 25,000 cubic feet of air per minute, in a mine, what total quantity of air can be produced by the addition of another fan of the same dimensions and operated with equal power.—Mine Manager's Examination, Q. 11; 4-12-'09.

ANS.—If one fan is exhausting and the other blowing, the quantity of air will not be increased. It is impossible to run two ventilating fans tandem, since one or the other will do the work and the other will simply churn the air with no practical effect. If, however, the two fans are arranged both blowing or both exhausting, they will do equal work. In this case, the power on the air is doubled and, for the same conditions in the mine the quantity of air circulated will be increased in the ratio of $\sqrt[3]{2}=1.26$; or, the increase will be 26 per cent. of the current that one of these fans will circulate when working alone.

QUES. 9.—What horsepower will be required to deliver 1,350 gallons of water per minute against a pressure of 80 pounds per square inch, the suction lift being 20 feet, and allowing 20 per cent. for friction?—Mine Manager's Examination, Q. 14; 4-12-'09.

ANS.—A pressure of 80 pounds per square inch is equivalent to $80\div.434=184+$ feet delivery head to which must be added the suction (20 feet), making the total head against which the pump must operate $184+20=204$ feet. Allowing 20 per cent. for friction, the horsepower required for this work would be

$$H=\left(\frac{1{,}350\times 231}{1{,}728}\right)\frac{62.5\times 204}{.80\times 33{,}000}=87+\text{ H. P.}$$

QUES. 10.—Give the breaking strain of a $\frac{11}{16}$-inch, cast-steel, wire rope, of seven strands and 19 wires to the strand; also, the safe working load.—Mine Manager's Examination, Q. 15; 4-12-'09.

ANS.—American wire-rope manufacturers use five, six, and eight strands in ropes; we know of no American wire ropes of seven strands. This is probably an oversight in writing the question, or a typographical error. The breaking strain of a six-strand, 19-wire, ordinary cast-steel rope, 1 inch in diameter is 34 tons; and the breaking strain of a similar rope $\frac{11}{16}$ inch in diameter is $34(\frac{11}{16})^2=16.07$, say 16 tons. It is common mining practice, except in deep shafts, to use a factor of safety of 5, which makes the safe working load for this rope $16\div 5=3.2$ tons.

QUES. 11.—The total quantity of air passing over a certain mine furnace is 200,000 cubic feet per minute, when the furnace is burning 5 tons of coal in 12 hours; what increase of air will be gotten by doubling the coal consumption, or burning 5 tons more of coal each 12 hours?—Mine Manager's Examination, Q. 16; 4-12-'09.

ANS.—The power developed by the furnace is proportional (approximately) to the weight of coal burned in a given time; and, for the same conditions in the mine the quantity of air in circulation varies as the cube root of the power or the cube root of the weight of coal burned per hour. In this case, the ratio of coal consumption (tons per hour burned) is 2, and the power ratio is also 2, which makes the quantity (air) ratio $\sqrt[3]{2}=1.26$. The increase in circulation due to burning double the weight of coal per hour is then $200{,}000\times .26=52{,}000$ cubic feet of air per minute, making the total circulation 252,000 cubic feet per minute.

This can be shown in another way, as follows: For the same shaft conditions, the height of motive column or unit of ventilating pressure (p) varies as the temperature rise. But the temperature rise in a furnace shaft varies clearly as the coal (C) burned per hour, and inversely as the quantity (Q) of air passing per minute, or as the expression $\frac{C}{Q}$. Therefore, the pressure varies as this expression; or since for the same conditions in the mine p varies as Q^2, we have

$$Q^2 \text{ varies as } \frac{C}{Q}$$

or

$$Q^3 \text{ varies as } C$$

and

$$Q \text{ varies as } \sqrt[3]{C}$$

QUES. 12.—(*a*) How much greater resistance will a current velocity of 600 feet per minute develop than one of 500 feet per minute, in the same airway? (*b*) If the former gives a water gauge of .76 inch, what water gauge will the latter produce?—Mine Manager's Examination, Q. 18; 4-12-'09.

ANS.—(*a*) The resistance of an airway or mine is always proportional to the square of the velocity of the air-current; or, more simply, the resistance ratio is equal to the square of the velocity ratio, in the same airway or mine. Hence in this

$$\frac{R_2}{R_1}=\left(\frac{V_2}{V_1}\right)^2=\left(\frac{500}{600}\right)^2=\left(\frac{5}{6}\right)^2=\frac{25}{36}=.694+,\text{ say }.7,$$

or $R_2=.7\,R_1$; that is to say the resistance due to the 500-foot velocity is .7 of that due to the 600-foot velocity. (*b*) For the same airway, the pressure and the water gauge, like the resistance, vary as the square of the velocity of the current; or the pressure or water-gauge ratio is equal to the square of the velocity ratio; and, here also, w. g.$_2$ = .7 w. g.$_1$ $=.7\times.76=.532$ inch, which is the water gauge corresponding to the 500-foot velocity.

QUES. 13.—A compound, triple-expansion, three-cylinder engine takes steam from boilers at 192 pounds absolute pressure, and exhausts at 3 pounds absolute; what is the total number of expansions in the steam, and what number of expansions take place in each cylinder? Give also the cut-off and the relative area necessary in order to equalize the work of each cylinder.—Mine Manager's Examination, Q. 19; 4-12-'09.

ANS.—The total number of expansions in the steam is found by dividing the initial absolute pressure by the terminal absolute pressure; since the volume varies inversely as the pressure during expansion, and the volume ratio is therefore equal to inverse absolute-pressure ratio. The total expansion in this case is $\frac{192}{3}=64$ expansions. The number of expansions that take place in each of the three cylinders when the work is equally distributed is $\sqrt[3]{64}=4$ expansions. To produce this result each cylinder should cut-off at $\frac{1}{4}$ stroke. Since all the pistons have the same length of stroke, in order to equalize the work in the several cylinders, the areas of the pistons from the high-pressure to the low-pressure cylinder should bear the relation indicated by the numbers 1, 4, 16; or the diameters of these cylinders should be to each other as the square roots of these numbers, or 1, 2, 4. For example, if first or high-pressure cylinder is 6 inches in diameter, the second or intermediate cylinder would be 12 inches, and the third or low-pressure cylinder 24 inches in diameter.

QUES. 14.—The winding drum of a hoisting engine is 4.5 feet in diameter; the shaft is 300 feet deep, or 330 feet from top landing to the shaft bottom where coal is caged. (*a*) How many revolutions will this drum make in hoisting a load of men from bottom to top? (*b*) How many feet per second may the cage make in compliance with the mining laws of Illinois?

(*c*) Give the total time of making one hoist in this shaft. —Hoisting Engineer's Examination, Q. 6; 4-12-'09.

Ans.—(*a*) The circumference of this drum is $3.1416 \times 4.5 = 14.137$; but allowing for the diameter (say 1 inch) of the rope when coiled on the drum, what is called the working diameter is $4.5 + .08 = 4.58$ feet and the working circumference is then $3.1416 \times 4.58 =$ say 14.39 feet. Ignoring any stretch in the rope, the number of revolutions of the drum required to hoist 330 feet is $330 \div 14.39 =$ say 23 revolutions. (*b*) Section 28 *c* of the Illinois mining law limits the speed of hoisting or lowering men to a rate of 600 feet per minute, or 10 feet per second, except with the written consent of the inspector. (*c*) At the speed mentioned above, the time required to hoist 330 feet would be $330 \div 10 = 33$ seconds; but to this must be added a sufficient time to allow for starting and stopping the cage, and for loading and unloading between each hoist, say 27 seconds, which would make the total time 1 minute per hoist.

Ques. 15.—Taking the weight of water as 62.5 pounds per cubic foot, and assuming steam at the atmospheric pressure has 1,640 times the volume of an equal weight of water, calculate (approximately) the weight of steam that would be used per hour by a pair of engines, the cylinders being 30 inches in diameter and the stroke 5 feet, the engine making 30 revolutions per minute and discharging steam at atmospheric pressure.—Hoisting Engineer's Examination, Q. 9; 4-12-'09.

Ans.—The piston speed of this engine is $2 \times 5 \times 30 = 300$ feet per minute. The piston displacement for the two cylinders, at this speed is $2 \times 300(.7854 \times 30^2) \div 144 = 294.25$ cubic feet per minute. Assuming there is no compression, but the exhaust ports remain open to the end of the stroke, and ignoring the back pressure due to the slight resistance of the exhaust ports and valves, the piston displacement, as calculated above, may be taken as the volume of steam exhausted per minute, measured at atmospheric pressure. This steam, according to the question, is assumed to weigh 62.5 pounds for each 1,640 cubic feet. The weight of steam used per hour is therefore

$$\frac{60 \times 2{,}945.25 \times 62.5}{1{,}640} = 6{,}734.6, \text{ say } 6{,}735 \text{ lb. per hr.}$$

Ques. 16.—How would you determine the proportionate areas of the cylinders and the proper point of cut-off in each, in a compound engine of two cylinders, the initial pressure being 65 pounds above the atmosphere, and the final (terminal) pressure 10 pounds below the atmosphere?—Hoisting Engineer's Examination, Q. 10; 4-12-'09.

Ans.—Divide the absolute initial pressure by the absolute terminal pressure to find the total number of expansions in the steam. The square root of the total number of expansions, in two-cylinder compounds, gives the expansions in each of the two cylinders, which is also the ratio of the area of the low-pressure cylinder to that of the high-pressure cylinder, or the *cylinder ratio* as it is called. The square root of the cylinder ratio is the diameter ratio. The reciprocal of the cylinder ratio is the fraction that indicates the point of cut-off in the cylinder. For example, in the case stated in the question, assuming sea-level atmospheric pressure (15 pounds per square inch). The cylinder ratio, or the ratio of the areas of the low- and high-pressure cylinders is $\sqrt{\frac{15+65}{15-10}} = \sqrt{\frac{80}{5}} = \sqrt{16} = 4$. The diameter ratio of these two cylinders is $\sqrt{4} = 2$. That is to say the area of the low-pressure cylinder is four times, and the diameter twice, the same respective factors in the high-pressure cylinder. The point of cut-off in each cylinder is the reciprocal of the expansions in each; or, in this case, ¼.

Ques. 17.—There is required 12,000 pounds of coal every 8 hours to do the hoisting and pumping and to run the fans, at a certain mine when the temperature of the feedwater is 40° F. What weight of coal will be necessary to perform the same work if the feedwater is heated to 95° F.?—Hoisting Engineer's Examination, Q. 13; 4-12-'09.

Ans.—A common rule among stationary engineers is as follows: The saving of fuel by heating the feedwater amounts to practically 1 per cent. of the fuel for each 11° F. the temperature of the feedwater is raised; or in this case, the saving of fuel is $(95 - 40) \div 11 = 5$ per cent., or $(12{,}000 \times .05) \div 8 = 75$ pounds each hour.

Ques. 18.—If a certain boiler is allowed a pressure of 150 pounds per square inch, the thickness of the steel being .045 inch and its tensile strength 60,000 pounds per square inch, what should be the thickness of a 22-inch pipe of the same material to withstand the same pressure.—Hoisting Engineer's Examination, Q. 14; 4-12-'09.

Ans.—It is necessary to first calculate the diameter of the boiler from the data given; thus,

$$d = \frac{2\,S\,t}{p} = \frac{2 \times 60{,}000 \times .045}{150} = 36 \text{ in.}$$

For the same material and the same pressure per square inch; the thickness of the shell of a boiler or pipe is proportional to its diameter; or these ratios are equal; thus, calling the required thickness of the pipe x,

$$\frac{x}{.045} = \frac{22}{36}; \text{ or } x = \frac{11}{18}(.045) = .0275 \text{ in.}$$

(*To be concluded in November*)

MINE RESCUE WORK

The Department of the Interior of the United States Geological Survey, Technologic Branch, has established a mine-rescue training station at Seattle. Many of the coal-mine operators throughout the western country are taking advantage of this by sending to the station one or more men from each mining camp to be educated and trained in the art of rescue work in case of mine accidents. Certificates of competency are issued to those showing the proper proficiency.

There are a number of different kinds of rescue apparatus in use in Europe and America and it has become practically a matter of necessity, and legislation will undoubtedly soon make it a matter of compulsion, for every person or corporation engaged in operating coal mines to provide one or more suits of some approved style of rescue apparatus, the number depending upon the number of employes engaged in the mine and the extent of the operation, and to see that some of its employes are made familiar with the use of the apparatus, so that in case of accident, there may be no delay in the work of rescue.

The Northwestern Improvement Co., the largest operator and producer of coal in the state of Washington, has recently sent several of its employes to take the work at the training station at Seattle, and has also recently secured a number of suits of rescue apparatus, consisting of helmets, oxygen tanks, and all the accompanying paraphernalia, and has organized a rescue corps from among its employes, one corps for each mine. These men meet at stated intervals for practice with the apparatus so as to become familiar with it until they become proficient in putting them on quickly and understand the manner of wearing and working in the suits. This company also has plans made and is preparing for the erection of a small building, especially devoted to storing and preserving the suits. This building will contain a "smoke room" into which the employes who are members of the rescue corps will have to go, after putting on the suits, and they will there be taught how to put up a temporary stopping or perform other emergency work, while wearing the suits. The room will be tight, and filled with burning sulphur or other gas fumes in the meantime, so that a practical test can be made of the reliability of the suits. The attendance of the members of the corps at these practice meetings is made compulsory, however, a small compensation is paid for each attendance. The men are taking a good interest in the work. The apparatus is under the control of one man, who also acts as instructor in explaining its use.

KOPPERS BY-PRODUCT COKE OVENS

*Written for Mines and Minerals, by W. E. Hartman**

The Koppers by-product coke oven was invented by Henrich Koppers, of Essen, Germany. By-product coke ovens were introduced in this country some years ago and the Otto-Hoffman and the Semet-Solvay are fairly well known. In both of these types of ovens it is difficult to distribute the heat uniformly the entire length of the oven. To economize in fuel Messrs. Otto and Hilgenstock devised a method of underfiring by admitting several jets of gas to a combustion chamber from which the flame passed up the flues and out through an escape in the central part of the oven. This somewhat improved heat distribution in the Otto-Hilgenstock ovens induced Doctor Schniewind to combine the underfiring system with the regenerative system.

A Process By Which Ammonium Sulphate Is Made Directly From the Gas

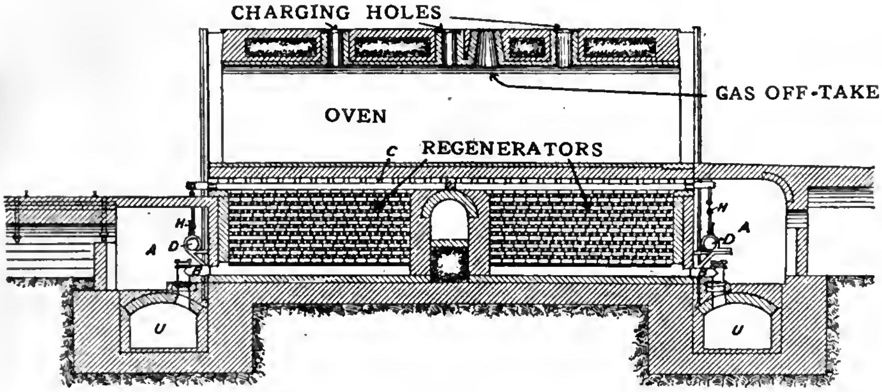

Fig. 1

The original retort ovens were non-by-product and were introduced to accelerate the coking process and increase the quantity of coke from a given quantity of coal. In the beehive oven the gas evolved from the coal unites with air admitted above the charge and by burning heats the oven, and so makes coke. At the same time, however, there is a considerable loss of fixed carbon or coke through combustion. This is avoided in the retort oven. For example, from 100 pounds of coal the beehive oven produces 66 pounds of coke, while the Koppers retort oven furnishes over 80 pounds of coke. In addition to this the comparative daily output from each style of oven is in the proportion of 2 to 1 in favor of the retort. The next step in the improvement of retort ovens was to introduce the Seimens regenerators to preheat the air for combustion of the gas. It can be readily understood that if air is heated before coming in contact with the gas for combustion it adds its own heat to that of the flame. The higher the temperature to which the gas is raised, the less gas will be required to heat the ovens. By using the regenerators, only from 40 to 50 per cent. of the gas derived from the coal is needed to keep up sufficient heat to drive off the volatile matter from the coal. It is possible by the use of Koppers improved cross-regenerators to raise the temperature of the air to 2,000° F. The regenerators are constructed of a series of bricks built up with air spaces between the brick, as shown in Fig. 1, and so, resembling a checker board, it is called "checker work." After the gases of combustion have traveled in a given direction a certain time the air entering the regenerator cools the checker work on one side, while that checker work through which the hot gases pass to the escape flue is heated. After a certain time, usually 30 minutes, the air-current is reversed and the hot checker work receives the cool air and the cooled checker work is reheated.

The Koppers oven is arranged with vertical flues *F*, Fig. 2, and is a development of the Otto-Hoffman oven. The main feature in which the Koppers oven differs from the Otto-Hoffman, is in the distribution of air and gas, which causes combustion to take place in each separate flue along the whole length of the oven. This improvement compels the hot gases to pass up each flue, instead of making their way from a combustion chamber up any flue according to the line of least resistance. The result of this perfect distribution in the Koppers oven is the production of coke uniform in quality throughout the length of the charge.

That the iron and coke industry appreciates the merits of the Koppers ovens is evident from the fact that in 7 years over 5,900 of these ovens have been constructed, and in 3 years 1,376 ovens have been contracted for on this side of the Atlantic. In analyzing the causes of its popularity it will be found to be attributed to the high quality of the coke produced; its economy in the use of gas for heating the ovens; the individual type of regenerator; its simplified construction; and the increased saving in all by-products.

By-product ovens are constructed the same as retort ovens, but have arrangements for saving the tar, oil, and ammonium, which is distilled from the coal. The dimensions of the retorts in the different types of ovens vary from 16 to 20 inches in width; from 26 to 32 feet in length, and from 5.5 to 7 feet in height. In Fig. 1 the space marked "Oven" is the retort. On each side of the retort or coking chamber, and separated from it by firebrick walls, the combustion flues *F*, shown in Fig. 2, are constructed. The flue chambers being between two ovens, heat one side of each oven. To make a good homogeneous coke, an oven must be uniformly heated, and this the Koppers oven accomplishes through the combustion of gas in separate flues. There being 30 flues on each side of this oven, each supplied with a gas nozzle, there is a combustion of gas at 60 different points, which subjects the coal charge to the same intensity of heat at all points and the desired uniformity in the quality of the coke is accomplished.

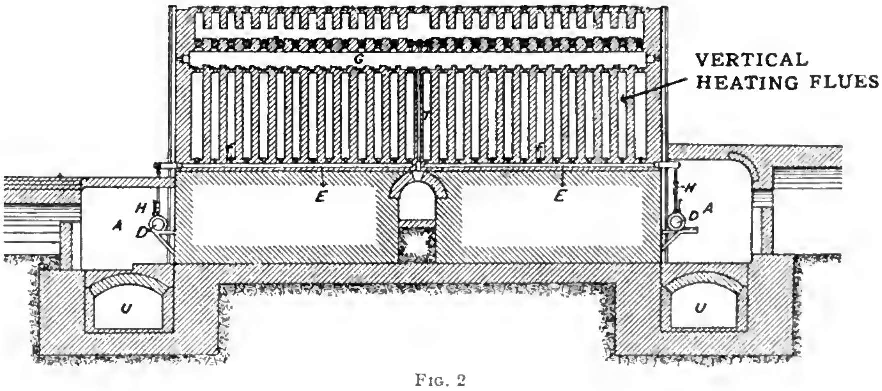

Fig. 2

The Koppers oven is exceedingly simple in design and the combustion of gas in the heating flues is easily regulated as the burners are all accessible for inspection, or adjustment, by means of openings into the vertical heating flues, on top of the ovens. An additional advantage gained by this uniform dis-

*Gas engineer for Koppers, Contractor for By-product Coke Ovens, Joliet, Ill.

tribution of heat, is the shortening of the coking time, thus increasing the efficiency of the ovens.

In the by-product regeneration coke oven, the gases evolved from the coal are conducted to the condenser and saturator house, where the tar and ammonia are recovered. Some of the cleaned gas is then returned to heat the ovens, while the surplus gas is available for power purposes or for distribution to domestic consumers. It is in the percentage of surplus gas that the different types of ovens essentially differ from each other. The Koppers oven, because of its improved system of heating flues and its efficient regenerator chambers, is remarkably low in its fuel consumption, and the yield of surplus gas is 50 to 60 per cent. of the total quantity evolved from the coal. Usually the regenerators of by-product ovens consist of two long chambers running the length of the battery and in case repairs to the regenerators are required this arrangement necessitates the whole block of ovens being shut down. To obviate this disadvantage and to enable the hot air to be more satisfactorily distributed to the heating flues, the Koppers system of regenerators was introduced. In this system there is a separate pair of regenerators, as shown in Fig. 1, for each oven in the battery. During a period of 30 minutes air is admitted into the regenerator at one end of the oven, and after being heated by contact with the hot checker brick in one-half of the regenerator, it enters the vertical heating flues where it unites in combustion with the gas entering the flues throughout one-half of the oven length. The products of combustion pass up these heating flues and down the vertical flues throughout the other half of the oven length, then through the other half of the regenerator, finally through flue *B* to the stack flue *U*. In their passage through the regenerator the waste gases heat the checker brick, and after 30 minutes, the gas valves and air dampers are automatically reversed. During the next 30-minute interval, cold air and gas enter at the opposite end of the ovens; the air is preheated by the previously-heated checker brick in that half of the regenerator, and combustion takes place in the vertical flues, which during the previous period served for the passage of the waste gases to the regenerator. The principal advantages of the Koppers cross-regenerator over the long regenerator type is that it permits of a better regulation of the air supply for each oven, and this air is heated to a higher temperature, thus promoting fuel economy.

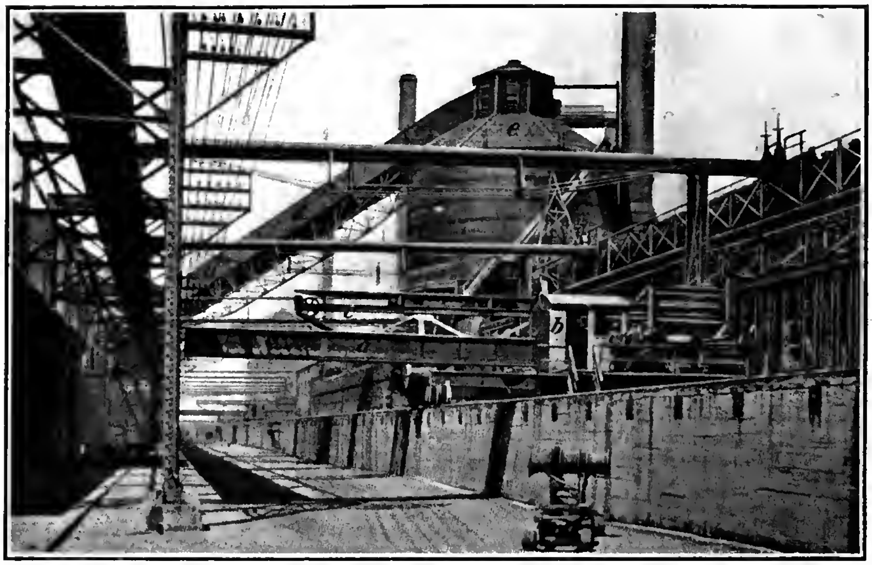

Fig. 3. Pusher Side of Koppers Coke Ovens at Joliet, Ill.

The working of the Koppers oven is exceedingly simple, and its construction is such that it is stronger than any other type of retort oven. The oven walls consist of a series of hollow columns reaching from the bottom to the top of the structure. Added to this, the uniformity and regularity of heating is conducive to a long life and a low repair account. Fig. 3 shows the pusher side of the ovens at Joliet plant of the United States Steel Co. The ram *a* projects from the lower rear of the pusher house *b* while the leveling machine *c* is above the ram and slightly to the rear of the pusher house. There is a belt conveyer housed in *d* that raises the coal to the top of the coal storage bin *e*.

Koppers patented direct process for the treatment of the gas and the recovery of ammonia has been installed in 28 plants, including 2,693 Koppers by-product coke ovens. In the old system of treatment, the gas was first cooled in condensers to remove the tar and was then washed with water in a series of

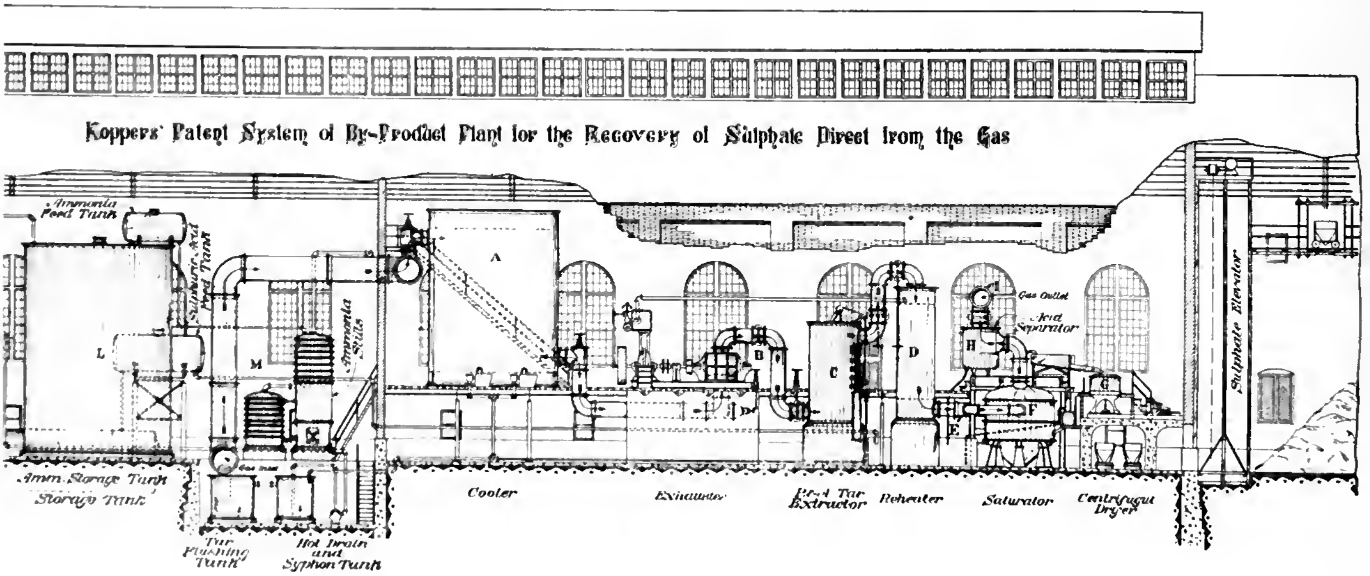

Fig. 4

scrubbers to remove the ammonia. The ammonia was collected as a solution of weak liquor which was then concentrated by treatment with steam in ammonia stills. The product from the stills was either in the form of concentrated liquor, containing 15 to 20 per cent. of NH_3 ammonia, or the hot concentrator vapors were passed into sulphuric acid saturators to form ammonium sulphate salt.

In the Koppers direct process, the former complicated process is much simplified, a larger yield of ammonia is recovered from the gas, and a superior quality of ammonium sulphate is produced.

In the Koppers direct process, the tar is removed by condensation in a tubular condenser *A*, Fig. 4, and by mechanical friction in a P. & A. tar extractor *C*. The gas, free from tar and at a temperature of 90° to 100° F., is then reheated by passing through a reheater *D*, the heat being supplied by the exhaust steam from the exhauster *B*, which apparatus pumps the gas with a constant vacuum from the ovens and forces it through the by-product apparatus. In the reheater, the temperature is raised from 155° to 165° F., at which temperature the gas passes directly into the sulphuric acid saturator *F*. Here all of the ammonia in the gas unites with the sulphuric acid in the bath and is recovered directly as ammonium sulphate. The gas, free from tar and ammonia, next passes through *I* into the balancing holder, not shown, which forces some of it back to the oven burners to heat the ovens. The balance of the gas, amounting to from 50 to 60 per cent. of the total, is available for gas engine fuel or other purposes. If it is desired to market this surplus gas, it is necessary to pass it first through iron oxide purifiers to remove the sulphur existing as hydrogen sulphide, and then into a storage holder supplying the distribution system.

Koppers direct process has many advantages over the old system of gas treatment. Besides being a much simpler process, it is decidedly more economical in operation. In this process, the only ammonia liquor to be handled is that which condenses out of the gas in the foul gas main, coolers and tar extractors; while in the old system, the gas is scrubbed with water to dissolve out the ammonia, thus producing large volumes of ammonia liquor to be stored and concentrated, before the ammonia can be absorbed in the saturator. All this handling of ammonia liquor results in more or less loss of ammonia, and is the reason why the direct process gives a much higher yield of ammonia per ton of coal. Also, the expense of recovering ammonia is less by the direct process, owing to the large amount of ammonia liquor to be pumped and concentrated in the old system.

A NEW TILE-LAYING MACHINE

Written for Mines and Minerals, by Bert Lloyd.

The accompanying illustrations are self-explanatory of a device that has recently made its appearance in Southern Colorado, which bids fair to reduce the cost of coke-oven maintenance, at the same time increase the production of a battery of beehive ovens.

Fig. 1. Tile-Laying Machine

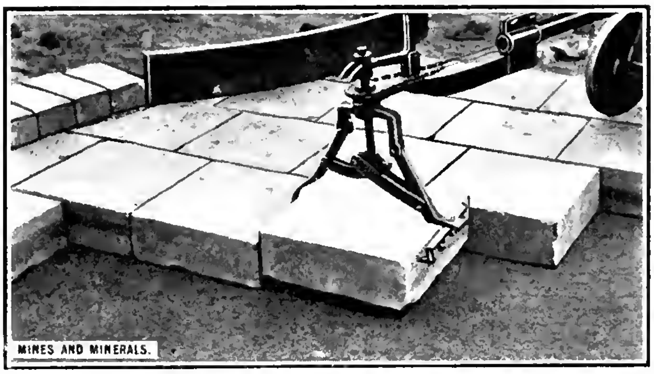

Fig. 2. Laying the Tile

By its use, a mason with a helper can relay the bottom of a 13-foot beehive oven with 12″×12″×4″ floor tile within 4 hours after the oven has been regularly drawn. This time includes the removal of the old tile, sanding the oven floor, and laying the new tile, then if the oven charge is slightly reduced the oven may be drawn in its regular order, and it will produce as high a grade of coke as though the bottom had not been disturbed.

The oven, therefore, loses absolutely no time in its operation; a very important item in cases where every oven is needed to produce coke; also the expense of reheating the oven with wood and small charges of coal is entirely eliminated.

The tile-laying machine as shown consists of a pair of tongs attached to a pipe bar by a clamp. Wires pass through the pipe bar and can be manipulated by the operator by means of levers so as to open and close the tongs as shown in Figs. 2 and 3.

The device is fully protected by patent, and now that its great value has been thoroughly demonstrated, its inventor, Mr. Michele Falcone, is negotiating for its manufacture in quantities sufficient to meet the demands that will undoubtedly be made as soon as its expense-reducing capabilities are known.

Accompanying the machine is a small adjustable metallic diagram, drawn to scale, by the use of which the tile around the edge of the floor may be scribed and cut to any exact fit before being placed. This is also an invention of Mr. Falcone, and has proven an invaluable adjunct to the main device.

Fig. 3. Machine Inserted in Oven

PROTECTIVE VALUE OF HUMIDITY

Written for Mines and Minerals, by James Ashworth, M. E.

Does Moisture Have Any Protective Value Against the Extension of Explosives?

The disaster at the Marianna Mine, in Pennsylvania, particularly directed the attention of mining men to the long and continuous debate which this subject has caused, and it is probable that when the full report of the experiments made at Altofts, in England, by a committee of the Associated Coal Owners is published, it will cause even more interest to be attached to the subject.

Before referring to the lessons taught by the Marianna explosion, the writer proposes to make a few remarks on the long papers contributed to the American Institute of Mining Engineers by Mr. Carl Scholz, and later by Mr. A. Haas. The authors of both papers appear to have based their arguments on very insufficient data. Thus, in none of the cases referred to, do the authors give the weight of water vapor per cubic foot of air, though both refer to "percentages of humidity." Now, the percentage of humidity does not offer any universal datum line from which the value of the percentages can be readily compared. Again, neither of the authors gives a statement of the condition of the outside atmosphere during, or at the time of, any of the disasters; nor do they say whether or not they occurred at times of greatest demand for fuel. Further than that, neither of them ventures an opinion as to the percentage of water saturation which is necessary to make the ventilating air-currents safe during any particular period of the year. As these details are not given, the writer will endeavor to prove that spraying and watering as practiced, and as suggested by Messrs. Scholz and Haas, cannot make a mine safe, and that it cannot control the extension of an explosion after it has once been properly initiated.

Experiments made in Great Britain on the rate of explosion in gases (Prof. H. B. Dixon) demonstrated, and the results have remained unquestioned, (1) that an explosion is impossible in an absolutely dry atmosphere; (2) that mixtures of air and explosive gases require 5 per cent. of water vapor per cubic foot to produce the most violent effects. Now 5 per cent. of water can only be present in the air in the form of steam, and therefore we drop at once into line with those people who concede that mine air ought to be artificially warmed and dampened. But a coal mine ventilated with a steamy air would certainly be a novelty, and the important subject we have to consider is not solely its problematical protective value, but also its effect on the miners' health, and on the roadways of the mine. Wet air is therefore a most serious proposition, and when studied from a really practical point of view, means that there must be present not less than 25 grains of water vapor per cubic foot; that an increased mortality from falls of roof and sides must result; and that the repair costs of every mine will be immensely increased. Supposing that these preliminary difficulties are surmounted, we have then the temperature to deal with. It has been found that 98° F. is the limit of heat in which a strong man can do any work when the air is saturated with moisture (18.7 grains per cubic foot) and therefore, we have at the outset the clearest proof that it is quite impossible to apply sufficient water in this form to restrict the flame of an explosion. From actual experience in English deep mining, it has been found that air having a temperature of 87 degrees, and carrying 13.6 grains of water vapor per cubic foot, is more oppressive to work in than air of 89½ degrees carrying 7.9 grains; and that men working in an atmosphere of 86 degrees containing 11 grains of water per cubic foot complain greatly of exhaustion. In Scotland, a temperature of 80 degrees, with 10¼ grains of water per cubic foot of air was found to be so exhausting that only certain men could work in it. The capability of a miner to work in a hot damp mine depends not only on the weight of water vapor in the air, but also on the velocity of the air, which ought not to be less than 300 feet per minute. This speed gives a sense of coolness to the skin, without being high enough to make the current dusty. Hence, it results that there are three principal factors which must be observed for the sake of the miners' health and efficiency; viz., (1) the temperature of the air-current, (2) its humidity, and (3) its speed.

The arguments of Messrs. Scholz and Haas go to prove that a certain number of grains of water are valuable in the ventilation air-current because their cooling effect disposes of a certain number of British thermal units, if the flame of an explosion comes in contact with them; but the writer considers that the practical demonstrations of the Marianna Mine explosion effectually disposes of this theory. According to the information at hand, this mine was most thoroughly and effectively watered, the intake air being dampened by the discharge into it of the whole of the exhaust steam from the pumping engines. It needs no argument to convince any person who is slightly acquainted with coal mining, that the air on entering a mine at the tunnel mouth, or the pit top, is of varying temperature, according to the period of the year; and for the same reason that its water content varies. On following this air into the mine, we find that it immediately commences to increase in temperature, and therefore its capacity to absorb water increases; but we also find that at a certain point the heat of the air reaches a normal degree all the year around. This fact is perhaps the most noticeable in a mine worked from a deep shaft, as then the normal point is found at or near the pit bottom, and in like manner if the shaft is damp, the air contains a regular charge of watery vapor. There is no doubt that dampness from sprays will cause some dust to clear out of the air more readily than if the air were quite dry; but even then it will not cause all the dust to fall; and the dust which the writer always considers the most dangerous, viz., the very dry and impalpable which is produced every moment by friction during the transit of the coal from the face to the pit bottom, still floats along in the air supported (if from a gaseous mine) in its own balloon of gas. This gas is stored in the pores of the coal, and is dissipating every moment and mixing with the air of the mine. The only place in a deep pit where water sprays can be applied with advantage, is at and about the pit bottom, where the air is cool, and where, when saturated with water, it would not contain more than, say, 4 or 5 grains of water per cubic foot of air.

Opinions differ greatly as to the quantity of coal dust it is necessary to have in the air to form an explosive mixture, and the writer is of opinion that the quantity normally found in a brisk air-current is amply sufficient for the purpose. The fine dust which has already settled on the timbering, sides, and floor, may play a part, but if it does, it is in a secondary sense, that is, after the flame has in passing distilled gases from it, and thus created that deadly atmosphere of gases of which carbon monoxide is the chief and most dreaded ingredient.

During the time the British coal-dust experiments were being made at Altofts, England, no difference in effect produced by an explosion was observed between the times when the air circulating through the testing gallery was saturated with moisture, and other occasions when the air had only 3.7 grains as a water content.

In many explosions, take for instance Udston, in Scotland, the worst coking effects were in rooms where there was standing water on the floor. At the Marianna, the places naturally wet showed evidence of as severe, or even more severe, effects from flame than the drier places. In the case of the Universal Colliery, in South Wales (very full reports of which are available) the whole of the east side districts were visited by the flame, although they were naturally wet, and the return air from the east district was practically saturated with water (nearly 8 grains per cubic foot). In this case the wetness of the strata combined with the dampness of the air did not restrain the flame.

The dampness of the air may also assist in the production of another phenomenon of colliery explosions; viz., that of percussion, and the writer is of the opinion that an excess of dampness in the ventilating current will thus assist in the extension of the area affected by an explosion. At the Universal Colliery, South Wales, this percussive effect was particularly demonstrated, and left indelible traces in the Ladysmith district, where men were struck dead in the positions and attitudes they were in at the moment of the explosion. At the Monongah explosion, Prof. H. M. Payne informs me that there were a very large number of cases where men were thus transfixed by death, with food in their hand or in their mouths, and so little disturbed that the caps were not blown off their heads. The fact of this phenomenon being present was also attested by the fact that in at least three places the indications were such that the initiatory point of the explosion might have been attributed to any of them. Without the effects of air percussion, or, as some prefer to style it, concussion, can be counteracted, the question of the safety supposed to be attained by watering is scarcely worth troubling about, and watering simply becomes a question affecting the sanitary condition of the pit. Wherever watering can be carried out without injury to the miners, health, and to the roadways of the mine, it may be applied judiciously in the main shunts or sidings, by spraying each car of coal as it passes underneath at a slow speed. This is a most effective way of minimizing dust, and a woodcut of this arrangement was, the writer believes, attached to Mr. Scholz's paper on watering.

The question of the prevention of explosions is not one of local or district importance, but is one in which the whole world is interested. It has been clearly demonstrated that the use of explosives is really the most serious danger in a dusty mine. We must therefore look for a radical cure by finding a safer mode of breaking down coal, or in the abandonment of blasting. As this cannot be always economically carried out, blasting ought to be restricted to a charge limit. In North Staffordshire, a leading engineer expressed his opinion that if the charges of high explosive were limited to 10 ounces, and reasonable care was exercised, mining would be practically safe. Then again, the question has arisen as to what constitutes a "dangerous" atmosphere. In England this has been to some extent answered by Messrs. Cadman and Whalley, in a report made to the Royal Commission on Mines, in which they suggest that 2 per cent. of gas in the return air or ventilating current should be considered dangerous. Heretofore, it has been thought impossible for any ordinary man to detect this percentage by a safety lamp flame, but now with the aid of a magnifying glass a trained man with sound eyes may see the cap of 2 per cent. of firedamp on the flame of a double-gauze bonneted Marsaut lamp, fitted with a wick .45 inch broad by .10 inch thick, when the flame is reduced down to $\frac{1}{10}$ of an inch high. It is not, however, at all likely that this percentage will be accepted by mine owners in England as "dangerous," though they might agree to 3 per cent. This is a most serious question for the owners and officials of all gaseous mines, especially where the hardness of the coal or the roof necessitates blasting, and if such drastic regulations were introduced into the collieries of the United States, the effect would doubtless be even more serious than in England, where the sale price can be more readily advanced to meet the extra cost of production. So far as blasting in the coal mines of the United States is concerned, the remedy lies mainly in the use of an increased number of shot holes, with a decreased charge (charge limit) and the usage of such high-class explosives as may be approved by the rules regulating mining in the several states. So far as watering is concerned, it was suggested by the three foreign experts who recently made an inspection of several coal mining districts at the request of the Federal Government, that the places where shots were to be fired should be well watered for 20 yards. It must, however, be remembered that, if a shot blows directly down the center of a road, this watering can only give the minimum of protection, and therefore it is practically certain that a double hurdle of wet blankets would be much more effective and less costly.

In concluding these short notes, the writer expresses his firm opinion, based on practical experience, that as demonstrated by a large number of colliery explosions, the humid state of the ventilation air-current of a mine has no retarding influence on the progress of either a coal-dust or a firedamp explosion.

TRADE NOTICES

The J. C. Stine Co., of Tyrone, Pa., is installing a 10-foot centrifugal fan, complete, with a 50-horsepower medium-speed engine at the mines of the Duncan-Spangler Coal Co., Inc., in the Clearfield, Pa., region. This fan casing is being built entirely of iron and steel, making it fireproof and practically indestructible. The fan will replace one 12 feet in diameter, and is guaranteed to circulate twice the quantity of air. The Stine fan is of the double inlet type, which has proved so satisfactory at many other mines, and we hope, when it is in smooth running order, to publish a report of tests showing its efficiency.

The J. C. Stine Co. has won an enviable reputation in all parts of the country for the successful production of coal-mining machinery, capable of effecting marked reduction in mining costs. A new bulletin just issued by the company is of interest to coal-mine managers, and will be mailed free on request.

The General Electric Co., recently shipped to the Rochester Coal and Iron Co., Punxsutawny, Pa., two switchboards, one of 18 panels for the main station and one of 14 panels for the substation. The entire switchboard equipment, including ammeters, instruments, and circuit breakers, was furnished by the General Electric Co.

The Westinghouse Electric and Mfg. Co. has recently received an order from the La Blanca and Anexas Mining Co. for 40 motors to be used in the company's mill at Pachuca, Mexico. The motors ordered range in size from 5 horsepower on the pulp thickeners, to 75 horsepower on the tube mills. The order also includes seven 250-kilowatt O. I. S. C. transformers, and one 12-panel switchboard.

Kolesch & Co., 138 Fulton Street, New York, have recently published a new and revised form of traverse sheet. The old sheets are used by surveyors, who will be interested to know that they are now in a position to procure a uniform-sized sheet for their calculations. The sheet is divided from left to right in columns headed as follows: Line; Bearing; Distance; Logs of Sines and Cosines; Addition of Logs; N; S; E; W; Coordinates; D. M. D.; N. D. A.; S. D. A.; Remarks. Size of sheet 19 in. × 15 in.

The Jeffrey Mfg. Co., of Columbus, Ohio, has changed the location of its Denver office to the rooms in the First National Bank Building. This company also maintains a corps of engineers at its branch offices in Chicago, St. Louis, Denver, Montreal, Pittsburg, Charleston, W. Va., Boston, New York, and Birmingham. There are also nearly 100 Jeffrey agencies in other cities in the United States and abroad.

SOCIETIES

The American Society of Engineering Contractors held their annual convention in St. Louis, on September 27, 28, and 29, in the Coleseum. The local committee of arrangements was E. H. Abadie, chairman; J. L. Westlake, W. C. Swartout, and L. C. F. Metzger. Papers were read by J. B. Goldsborough and Ed. Wegmann, on "Dam Construction for City Water Supplies," and by George C. Warren on "Work Preliminary to Street Paving and Road Work." A banquet was held, and several sight-seeing trips made to important engineering works in and around St. Louis.

SAMPLING COAL AND COKE*

By E. G. Bailey, M. E.†

Taking Samples from Vessel Cargoes, Mechanical Conveyers, Carts, Stock Piles, Bins, Etc.

It is useless to attempt to take a representative sample of coal from a vessel unless it is loading or discharging, for a sample taken from the hatches of a loaded vessel would probably consist of coal from only as many cars as there were hatches, while there may have been 100 to 300 cars of coal emptied into the cargo. Occasionally it is necessary to take a sample from the broken surface of a cargo that has been partially discharged, but the amount of coal accessible to the sampler is so small a proportion of the total cargo that such samples should be avoided if possible. Sometimes cargo coal is sampled as the vessel is being loaded, in which case the sample is taken from railroad cars as they are dumped on the pier, but the majority of cargo samples are taken as the vessel is discharging. The total amount of original sample to be taken should be governed by the quantity and size of impurities in the coal, rather than the amount of coal to be sampled.

The method of accumulating the sample will depend a great deal upon the local conditions. If the coal is being discharged into a hopper and thence to a mechanical conveyer, industrial railway, carts, or railroad cars, the sample can be taken from them. Taking samples from mechanical conveyers is described later under that subject. If the sample is taken from an industrial railway, a shovelful should be taken from every so many cars, the number of cars per shovelful being estimated from the capacity of the cars, the size of the cargo being sampled, and the quantity of coal desired for the sample. If the sample is taken from railroad cars, the number of shovelfuls per car should be determined in like manner, and in either case the shovel should be pushed deep into the coal in order to bring the portions of the sample from beneath the surface. The shovelfuls should be taken alternately from different parts of the surface, in order to prevent an undue proportion of coarse or fine, which may tend to be separated when dropped or run into the cars. The coal is more uniformly mixed by the time it is discharged into the cars and dumped in larger quantities, thus giving less chance for segregation of slate than when loading railroad cars at the mines, hence many precautions which are necessary to obtain a representative sample from an individual railroad car loaded at the mines may be disregarded in sampling cargo coal under similar conditions.

It is sometimes necessary to hold up the grab bucket every so many trips and take a shovelful directly from it, but this retards the discharging and causes additional labor, especially in cases where more than one tower is being used for discharging.

If it is impossible to obtain a sample by any of the foregoing methods it can be taken from various parts of the exposed surface in the vessel as the coal is discharging.

A special moisture sample should always be taken.

Some authorities claim that more than one sample should be taken and analyzed in order to determine the true quality of even 500 tons of coal, but one sample, properly taken and reduced, will represent 5,000 tons or more just as accurately as one sample will represent a 50-ton carload. The following data, taken from a 6,000-ton cargo during the entire time of discharging, bear out this contention:

Variation between results of one 2,300-pound sample and average results from twenty 135-pound samples: Ash, +.06 per cent.; sulphur, +.01 per cent.

Variation between results of one 2,300-pound sample and the average results from four 560-pound samples: Ash, −.04 per cent.; sulphur, +.02 per cent.

* See also article Coal and Coke Sampling in Mines and Minerals for September, 1910.

† Fuel Testing Co., 220 Devonshire Street, Boston, Mass.

Other similar data taken from 20 consecutive cargoes of 5,000 to 7,000 tons capacity, where three 1,000-pound samples were analyzed and compared with one 3,000-pound sample from the same coal, are given Table 1:

Table 1. Variation Between Results of One 3,000-Pound Sample and the Average Results From Three 1,000-Pound Samples

Cargo	Ash	Sulphur
1	+.03	+.06
2	+.15	+.02
3	−.03	+.01
4	+.09	+.12
5	+.22	+.01
6	−.04	−.04
7	−.02	
8	−.20	−.03
9	−.05	+.02
10	−.04	+.05
11	−.02	+.03
12	−.22	+.02
13	+.02	+.02
14	−.23	+.02
15	−.43	+.03
16	+.01	+.02
17	−.10	+.13
18	−.05	−.03
19	−.07	−.01
20	−.11	+.05

The difference between the results of one sample and the average of several is, with very few exceptions, within the limit of accuracy in making check analyses from the same pulverized laboratory sample. There is no doubt but that a 12,000-ton cargo of coal could be represented by one sample with equal accuracy, if the sample were properly taken and reduced.

Sampling From Mechanical Conveyers.—Sampling coal or coke is simplified when it can be taken from a mechanical conveyer. In many cases the coal has been crushed before it is delivered to the conveyer, so that a smaller sample need be taken than if it were accumulated from the run-of-mine or larger coal.

The two types of conveyers most generally used are the belt and bucket. When sampling from the latter, an entire bucket may be dumped at certain intervals, or a shovelful may be taken from the buckets as they pass. A 3- to 5-pound shovelful is ample if the coal has been crushed to 2-inch or smaller. The portions of a sample may be taken from a belt conveyer by shovel, providing care is used to obtain a true proportion of the coarse and fine. There is a tendency for the fine coal to settle toward the middle of the belt and the lumps to remain on the surface and roll to the outer edge, hence it is better to scrape off a complete cross-section of the strip of coal at certain intervals.

The quantity of coal to be taken for each portion of the sample should be determined from the quantity of coal to be sampled and the size and quantity of the impurities, so the required amount of gross sample will be accumulated by the time the coal to be sampled has all been handled by the conveyer. The time between taking the different increments of sample should be varied according to the rate at which the coal is passing, rather than equal periods of time. This is especially necessary when the coal is coming from a discharging vessel and is unloaded more slowly near the last when the vessel is being trimmed and cleaned up.

Mechanical Sampling.—Whenever coal is being received regularly at any one place and samples are to be taken frequently, a mechanical sampler should be installed if possible. A mechanical sampler is merely an automatic method of accumulating portions of a sample from coal as it is being handled, and is usually confined to sampling crushed or fine coal from mechanical conveyers or gravity feeds.

When coal is periodically dropped from a weighing or measuring hopper, a small opening 4 to 6 inches square can be opened every time the hopper is emptied, and the original sample accumulated in this manner. A moving bucket or spout can be arranged to periodically move across a stream of coal falling from a hopper or conveyer. A miniature bucket conveyer, with one bucket, can be arranged to travel under a stream

of coal and carry the portions of the sample to any desired place before dumping it. In the case of a bucket conveyer, one or more buckets may be arranged to dump into a chute. A scraper may be periodically lowered on to a belt conveyer, and various other devices made to suit the local conditions However, in all of them great care should be used to prevent an undue proportion of lump or fine, and also to adjust the mechanism so the required amount of sample will be taken from the desired amount of coal.

If possible, all subsequent crushing and dividing of a sample should be done mechanically. There are a few satisfactory kinds of crushers, and other cheaper ones will undoubtedly be placed on the market as the demand for them increases. A series of riffle samplers, as shown in Fig. 1, or a modification of it, is undoubtedly the best method of dividing a sample.

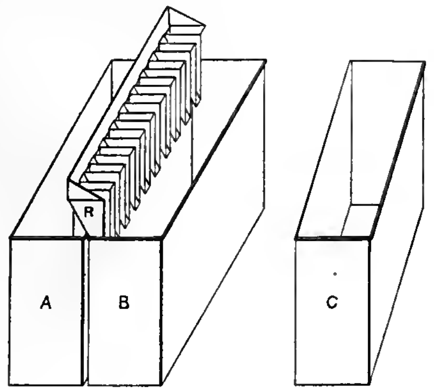

Fig. 1. Riffle Sampler

Sampling From Carts and Wagons.—Coal delivered by wagon is frequently purchased on the analysis basis and samples are usually taken as the coal is delivered. Shovelfuls should be taken throughout the entire quantity as it is being dumped or shoveled out, in about the same manner as in the case of a railroad car. As a rule, the sample is accumulated from several wagon loads, and may represent one day's delivery, or else may be taken throughout a period of one week. In any case, the entire sample should be kept in a hermetically sealed can until it is all accumulated, or else a special moisture sample should be taken. The fact that only a few tons are delivered during the time covered by a sample does not obviate the necessity of taking a sufficiently large sample that it will be truly representative, for no sample at all is better than inaccurate or nonrepresentative figures.

Sampling in Boiler Plants, Gas Houses, Etc.—Samples of coal are frequently taken in boiler plants to represent the coal being burned on a test, in which case the sample should represent the coal as weighed to the boilers. If the coal comes from overhead hoppers, a shovelful should be taken from the spout or hopper at regular intervals. If the coal is brought in by wheelbarrow, industrial railway car, or wagon, the shovelfuls may be taken from the coal as loaded, after it is dumped on to the floor, or from the wheelbarrow or cart itself. The shovel should always be pushed deep into the coal and filled from coal below the surface. It must be remembered that the quantity of coal sampled does not govern the size of sample to be taken, for the sample taken from 5 tons used on a boiler test should be just as large as a sample taken from a 50-ton railroad car. A very common error in sampling coal as weighed in boiler or other plants is due to escape of moisture from the sample. A loss of 2 per cent. moisture will cause an equivalent error in the calculated boiler efficiency. Failure to take special moisture samples has been the cause of many erratic and erroneous results from boiler tests. The loss of moisture from coal between the time it is discharged from vessel or car until it is weighed to the boilers, especially where it is stored in overhead bins, accounts for many apparent discrepancies in weights if the moisture is properly determined at the two places.

Sampling From Stock Piles and Bins.—There are few places where it is more difficult to obtain a truly representative sample of coal or coke than from a large stock pile or bin. There is so small a proportion of the total quantity available near the surface that at best a sample can only approximately represent the total pile. Where coal is dropped from one overhead position, and the coal forms a conical pile, that on the surface can represent only the last of the coal dumped. A pile of this shape containing 1,000 tons has about 25 per cent. of the total quantity within 1 foot of the surface, and larger piles have a still smaller percentage of the coal available. If the coal has been dropped from an overhead track or trolley and has formed a long pile of triangular cross-section and 25 or 30 feet high, there is less than 10 per cent. of the coal within 1 foot of the surface. But such a pile usually has the advantage of representing on its surface some of the coal from practically all parts of the cargo or cars discharged. However, in either case there is the additional difficulty of obtaining a true proportion of lumps and fine coal. When coal is dropped on to a pile, the larger lumps and heavier pieces of impurities roll to the bottom and the finer coal remains in the center of the pile and on the top.

If a conical pile is divided into four parts by passing lines about it equally spaced between the bottom and top, the relative volume and surface between them is as follows:

	Percentage of Total	
	Volume	Surface
First, or top part	1.6	6.3
Second part	10.9	18.7
Third part	29.8	31.2
Fourth, or bottom part	57.7	43.8
Total	100.0	100.00

From this it would appear that 57.7 per cent. of the sample should be accumulated from the bottom part of the pile, because that is the percentage of coal contained in this part of the pile. But it contains some fine coal in the center and only the coarser coal on the surface, so it would not be right to take 57.7 per cent. of the sample from the large lumps alone. It has been found by actual experiment that the true proportion of lumps and fine can only be obtained by taking equal increments of sample from equal areas of the exposed surface, even though they do not represent equal volumes or quantities, but at best it must be remembered that only the coal near the surface is available when the sample is taken by shovel.

From the total approximate area of the surface of a pile and the quantity of sample to be taken, one can estimate the area from which a shovelful should be taken. For instance, if a 1,500-pound sample is to be taken from a conical pile containing 1,000 tons, there will be about 11,000 square feet of surface exposed, and 100 15-pound shovelfuls should be taken, or one shovelful to every 110 square feet, or from points about 10 feet apart.

The best method of taking the sample is to begin 3 or 4 feet from the bottom and take shovelfuls at the predetermined distance apart or along the pile on the same level. Then start a certain distance up the pile and circle it again, and so on, keeping the distance between points of taking shovelfuls as nearly equal as possible. One shovelful should be taken from near the surface, the next one deeper, the next still deeper, the next from the surface, and so on, in order that the sample will be taken from different strata. The depth to which one may dig depends a great deal upon how wet the coal is and how easily is slides By beginning at the bottom of the pile and working around and up, the coal which slides down does not interfere

with that part of the pile not already sampled, as would be the case if the work were started at the top.

Sampling from a bin is even more difficult and unsatisfactory than sampling from a pile, owing to the restricted surface exposed.

Sampling by Pipe.—The difficulty of digging deeply enough into a car, pile, or bin with a shovel when sampling coal has led many people to suggest the driving of pipes or tubes and withdrawing them full of coal. Some advocates of this method claim satisfactory results from it, but a great deal of practical experimenting with pipes 3 or 4 inches in diameter has proven it to be unsatisfactory, especially for coal containing lumps. If the coal packs, it quickly plugs the end of the pipe and very little coal is obtained from any considerable distance below the surface. If there are lumps as well as fine coal, there is great difficulty in obtaining a representative proportion of the lumps, as they tend to split open and permit the pipe to pass between the parts rather than filling with a core out of the lump. As a rule, that coal which is already in the pipe is jarred out when it strikes a lump. A coal-mining auger encased in a pipe or tube has given little better results, for with this arrangement it is possible to fill the pipe with coal, providing the spaces between the flat sides of the auger and pipe are large enough for the largest pieces of coal to pass freely. In coarser coal, the auger tends to push the lumps to one side or glance past them, but if one is hit fairly it may be drilled through; however, most of the fine coal made from drilling the hole drops out as soon as the auger cuts through to the bottom side of the lump. It is practically impossible to drill through a lump of slate or hard bone when lying in a pile of coal, hence the sample taken by pipe or encased auger would tend to be better than is the actual coal. The accumulation of a sample by pipe is much slower than by shovel and it does not obviate the necessity of taking a large sample. In short, the small-pipe method of sampling coal is not practical nor accurate, regardless of how nice it looks theoretically, but the use of larger pipes of 10 or 12 inches in diameter may be possible under certain conditions.

A variety of methods have been used to crush coal in the laboratory from 4 mesh or larger to 8 or 10 mesh. Jaw crushers and other types of machines have been used, but a bone mill has proven to be the best all-around machine for this purpose.

The division of a sample in the laboratory after it has been crushed may be done by thoroughly mixing it on a table or cloth and dividing it into four parts by means of a spatula. Special quartering machines may be obtained on the market but a riffle sampler has proven to be the most satisfactory method of dividing samples, and it has considerable advantage both as to speed and accuracy. A sketch of this sampler is shown in Fig. 1. Its operation is as follows: A sample which has already been crushed and is ready for further division is placed in can *C*. The riffle sampler *R* is placed astride the adjacent sides of cans *A* and *B* and the sample in can *C* is poured on to the top of the riffle *R*. This riffle consists of 20 spouts or troughs ½ inch wide, the adjacent ones pointing into opposite cans, and the stream of coal passing out of can *C* is divided into 20 parts. Half of the sample will then be collected in each of the cans *A* and *B*. Can *B* is then replaced by can *C* and the part of the sample in *B* is poured on to the riffle and can *C* will then contain one-fourth of the original. The operation can be repeated until it is reduced to the quantity which it is desired to pulverize. The riffle sampler shown in Fig. 1 is simpler than those usually described as it does not have any frame nor legs but merely rests on the adjacent edges of the two cans. This form of riffle is more accessible and easier to clean than are some of the other patterns.

It is so often desirable to have a considerable quantity of sample on file that several hundred grams should be pulverized and retained. The final sample should be pulverized to at least 60 mesh, while 80 mesh is preferable, but anything finer than this is both unnecessary and undesirable. The final pulverizing should be done in a ball mill.

There are nearly always some particles of bone, or other hard material, in the sample which are not readily pulverized; however, it is necessary that everything should go through a 60- or 80-mesh sieve, hence the entire sample, after it is thought to be pulverized to this degree of fineness, should be tested by putting all that is fine enough through a 60- or 80-mesh sieve. The remaining quantity, if a large percentage, should be returned to the ball mill, but if only a few grams, it can be reduced in a hand mortar. It is absolutely necessary that all the sample go through the sieve and it should then be thoroughly mixed. Instances have been frequently encountered where a sampler merely dipped out a quantity of coal from that which was crushed or partly pulverized and sifted enough of it through the 60-mesh sieve until the desired quantity of sample was obtained, and all of the coarser material was discarded. In many laboratories there seems to be a prevailing tendency for the sampler to discard the small quantity of material which is not readily pulverized. As errors arising from this cause often exceed 5 per cent. in ash and 1 per cent. in sulphur, it is certainly not asking too much of the chief chemist or man responsible for the work of the laboratory to occasionally follow samples through the complete operation and investigate every detail in order that errors may be eliminated.

Sixteen-ounce cream jars with straight sides and screw tops are preferable to bottles for keeping laboratory samples.

Mines and Minerals

Vol. XXXI—No. 4. SCRANTON, PA.—NOVEMBER, 1910—DENVER, COLO. Price, 25 Cents

COAL MINING IN OKLAHOMA

*Written for Mines and Minerals, by Willis P. Thomas**

The coal measures of Oklahoma are embraced in an area of approximately 20,000 square miles, of this 1,000 square miles is estimated as workable coal. The production at the present time comes chiefly from LeFlore, Haskell, Latimer, Pittsburg, Atoka, Carter, and Coal counties, all of which are in the coal belt, shown in Fig. 4. Coalgate is in Coal County.

Extent of Development. Quality of the Coal. Methods of Preparing, Mining and Hauling

Geographically the beds are a part of what is known as the Western Interior Coal Fields, the coal-bearing rocks belonging to the Pennsylvania series of the Carboniferous. The different beds, of which there are 12 or more, vary from a nearly semi-anthracite to a low-grade bituminous. The most persistent and valuable beds are the Upper and Lower Hartshorne and the Lower McAlester. There are four others which are of less importance, but commercially valuable; namely, the Upper McAlester, the two Witteville beds, and the Cavanal. The quality of the last four being inferior to that of the first three beds, they have not been developed to any great extent. The Lower Hartshorne bed lies on what is known as the Hartshorne sandstone, and where this sandstone reaches the surface it has been badly broken, due to folding, and besides has weathered until a distinct ridge has been formed, by means of which the Lower Hartshorne is easily traced from near Fort Smith, Ark., across the state line to Lehigh, Okla., a distance of over 100 miles. The upper Hartshorne is separated from the lower Hartshorne by about 50 feet of shale. Where worked the lower bed has an average thickness of 4½ feet, the upper bed about 4 feet. From 1,000 to 1,200 feet above the Upper Hartshorne is found the Lower McAlester bed, which excels in quality all other coal beds in this vicinity. It varies in thickness from 2½ to 4½ feet.

Fig. 1. Rock Island Coal Mining Co., Shaft No. 6

The development and mining have been done principally along the Rock Island; Missouri, Kansas & Texas; St. Louis & San Francisco; and Fort Smith & Western railroads. These roads have opened up quite a field and have made a wide outlet for the coal produced. However, oil and gas for fuel purposes and the competition of adjoining non-union fields have greatly retarded development and production the last few years. The coal mined at the present time is excellent steam fuel, very hard and capable of standing long transportation. The combustible volatile matter runs high, making the coal available for gas purposes. The following table shows that the Lower Hartshorne compares very favorably in quality with the Pittsburg seam of Pennsylvania, which is one of the best gas and coking coals in the country.

	Lower Hartshorne		Pittsburg Seam	
Moisture	1.46	1.30	1.22	1.28
Volatile matter	39.04	38.90	34.30	38.10
Fixed carbon	53.10	52.15	56.95	54.38
Ash	6.40	7.65	6.41	5.44
Sulphur	1.33	1.58	1.07	.79

The miners are paid for their coal on the mine-run basis, with the result that the quantity of slack produced has become a question of great importance. In order to make the slack more valuable, Mr. Carl Scholz, President Rock Island Coal Co., has recently erected a briquetting plant at Hartshorne, Okla. This plant has been running for some time successfully, making about 100 tons of briquets a day.†

This branch of the coal industry has not proved a solution of the slack problem in Oklahoma, as the market for this material is limited. Several of the larger companies are equipped with coke ovens, but these are operated only intermittently. Table 1 gives a comparison of the Hartshorne and Alderson (McAlester bed) coal and coke with that from the Connellsville region.

Throughout the field, wooden tipples, such as are shown in Figs. 1 and 5, are the rule, although the newer tipples will probably be of steel, as the Rock Island Coal Co. has recently had one constructed.

Self-dumping cages of different styles and hoisted in balance are used almost entirely at the shaft mines. The boiler plants are all equipped with horizontal return-tubular boilers, which are hand fired.

To prepare the coal for market, double balanced shaking screens are used, although several operators are equipped with slack storage bins where pea and slack are separated with rotary screens.

Usually four grades of coal are produced termed lump, egg, nut, and slack. In Fig. 1 the lump coal is loaded into box cars; the slack goes to the bin at the left, and from this bin is fed to the boilers or shipped. The waste rock is hoisted up the incline

* Wilburton, Okla.

†See Mines and Minerals, Vol. 30, page 581

to the left of the tipple in a car; the trestle, which rests on the rock pile, is extended from time to time as demanded.

The coal formations in this field have been faulted and folded, making the coal difficult to mine in comparison with most other fields. The mines are opened by slopes or shafts, sometimes by a combination of the two; of necessity the mines are slope mines whether opened by slope or shaft.

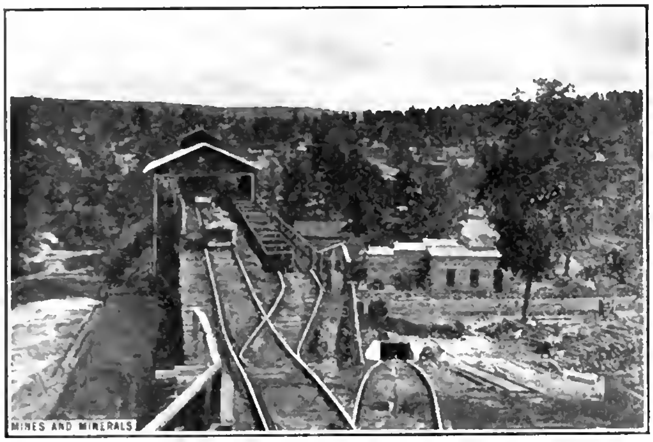

Fig. 2. Tipple Approach, Great Western Coal & Coke Co. No. 3 Slope

Fig. 3. Fan House and Tipple, Slope No. 3, Great Western Coal & Coke Co.

Fig. 2 shows the Great Western Coal and Coke Co.'s No. 3 slope, at McAlester, Okla.; also the approach to the tipple. The brick fan house is shown to the right above the slope mouth. The fan house and tipple is shown in Fig. 5.

Where a shaft is used, a main-haulage road is driven each way from the shaft parallel to the outcrop. From these main entries, cross-entries are driven to the rise and dip, off of which are turned the working entries. These entries are from 150 to 300 feet apart, depending on local conditions. Rope hoists, sometimes underground, sometimes on the surface, handle the cars in trains on the slopes.

Longwall advancing has been tried but never carried on successfully. The method commonly used, and the system now required by the new state mining law, is the double-entry room-and-pillar system. The top entry, being dry, is generally used as the haulageway, the water draining to the lower entry. Rooms are turned off the upper entry, directly up the pitch or at some angle to it; as a rule, rooms are from 200 to 275 feet deep, 20 to 25 feet wide, with room necks 8 to 10 feet in width. Four different methods are in use to place cars at the working face of rooms. (1) Up to 10 degrees the mules pull directly up the pitch. (2) At one mine double rooms are used, 40 feet wide. A track is carried up each side of the room and the rock gobbed in the center to throw the air to the face. At the end of each track near the face a post is placed which carries a sheave through which passes a $\frac{3}{8}$-inch wire cable. When a car is loaded on one track the cable is fastened to the loaded car, the other end of the cable goes around the sheaves and is attached to an empty car at the mouth of the room on the opposite track. The loaded car is then let down, which at the same time places an empty at the face on the other track. (3) At some mines, where the pitch is steep, a sheave is fastened to a post near the face of the room, a cable is then fastened to the car and the mule goes up and pulls down the room. This method gives the mule the advantage of the downhill pull. (4) At Coalgate, Okla., several mines are equipped with electric locomotives, which are provided with a drum and cable; this cable is taken up the room around a sheave and attached to a car. By this means empties are hoisted up and loads let down from the rooms.

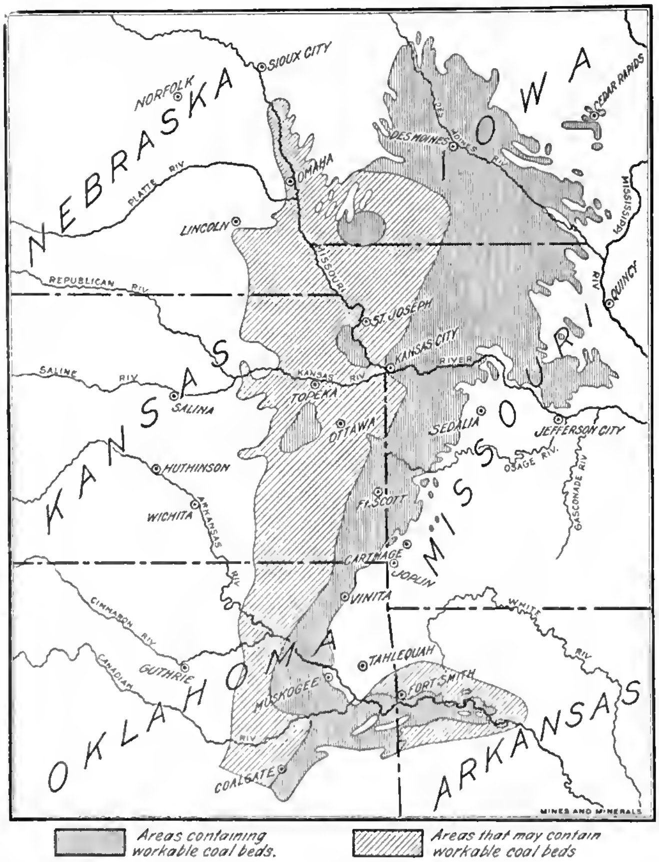

Fig. 4. Map Showing Location of Oklahoma Coal Fields

Where the pitch of the coal exceeds 20 degrees the coal is brought to the entries in chutes.

Pick mining is the rule throughout the state; vertical cuts being preferred to undercutting, the coal being shot from the solid. The steep pitch, the lack of competent runners, and the general antagonistic position of the miners, has worked against the adoption of machines. However, the Sullivan Machinery Co. have apparently solved the chain-machine problem for this field in their low-vein machine, for at Coalgate No. 5 shaft, Coalgate, Okla., they are working successfully up a 13-degree pitch, and cutting across the vein on a 25-degree pitch. Paying the miners on the mine-run basis as at present, will soon force the operators to the more general adoption of machines in order to increase the percentage of lump coal. Machines would also be of great benefit to the mines by reducing the heavy shooting which now takes place, and which proves to be disastrous to the roof at times.

TABLE 1. ANALYSES OF COALS USED IN TEST AT CHOCTAW COKE WORKS, ALDERSON, OKLAHOMA

Locality	Moisture	Volatile Matter	Fixed Carbon	Ash	Sulphur	Phosphorus	Remarks
Alderson lump.....	1.48	35.81	56.71	6.00	1.050	.020	McAlester seam
Alderson slack.....	1.71	34.16	55.69	9.24	1.020	.018	McAlester, washed
Alderson slack.....	1.61	29.50	53.77	15.12	1.100	.018	McAlester, unwashed

2 parts Alderson, 1 part Hartshorne.	.46	1.77	83.33	14.44	1.770	.026	Slack, washed

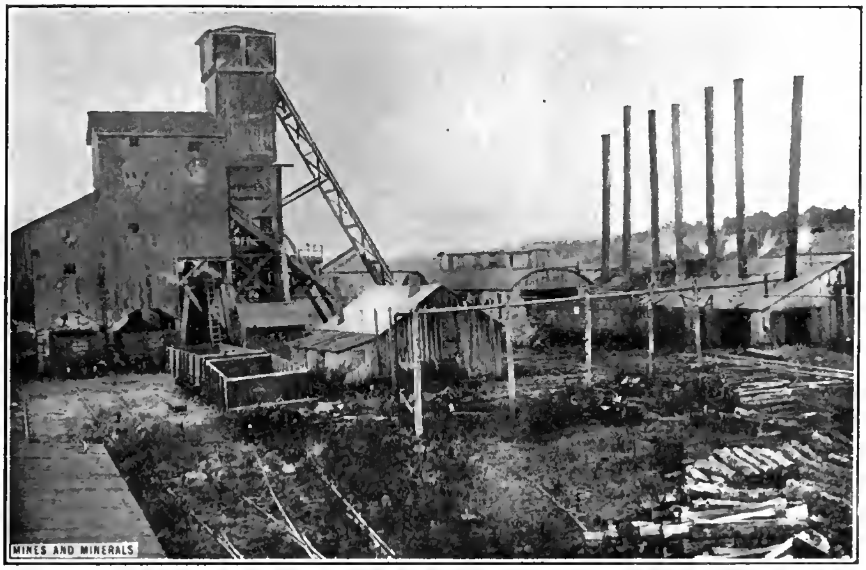

FIG. 5. OSAGE COAL AND MINING CO., SHAFT NO. 5

The amount of coal recovered by present operations will run from 50 to 70 per cent. This is as much as can be obtained under the present methods, drawing pillars is rarely practiced, the mines not being developed with this end in view.

The state mining law requires that all dry mines be sprinkled and kept in a damp condition. This was done by most of the larger companies before the law was passed. The method commonly used was to provide each entry with a sprinkling line of 1½- to 2-inch pipe to which hose connections could be made at regular intervals. These lines also served as a means of fighting fires which are frequent in certain parts of the field.

When the supervision of the mines passed from federal to state control the amount of air required for each man and mule was greatly increased. This increase made necessary the installation of many new fans at mines in different places. The tendency at present is to install fans of small diameter and high speed.

Owing to the many unfavorable conditions under which the mines of this state have to work, the cost of operation is high. The quality of the coal is such, however, that the mines are able to compete with the other operations in the Western Interior coal fields which are able to produce coal at a lower cost per ton.

The large increase in the production of oil and gas has been a serious blow to the coal-producing states of the Southwest, and Oklahoma has probably suffered the most, as the increase has been greater within the boundaries of this state than any other. However, the coal field will prove to be one of its greatest assets, and be one of the prime factors in the building of a great, new state.

AMERICAN *vs.* EUROPEAN COAL MINES

*Written for Mines and Minerals, by Henry M. Payne**

A Discussion of Foreign Mining Methods and Conditions. Points of Difference from American

During the past 3 years a number of the officials of the largest coal-mining operations in the United States have visited the mining districts of Europe, and a diversity of opinions and a multiplicity of suggested reforms have been the result.

The writer spent the summer of 1909 in the principal mining districts of England, Wales, Belgium, Germany, and France, devoting his time to the study of the coal-mining industry in these countries, and its aspect, not only from the standpoint of economic, labor, and general industrial, conditions, but also with regard to cost data, power equipment, methods of prospecting and development, systems of mining instruction in the universities, technical and mining schools, the Government Testing Stations and coal mines regulations, and a careful compilation of such facts as would make possible a valid comparison, as indicated in the title of this discussion.

One important condition to be clearly understood, is the short haul everywhere in Europe. For instance, from Yorkshire or Shropshire in the North of England, or from the famous Rhonddha and Taff valleys, in Wales, is less than 200 miles from London, while much of the product of these fields goes to Liverpool and Cardiff for sea trade, a distance of less than 50 miles. In Belgium, scarcely any of the coal travels 50 miles from the mines. In Germany the greater part is coked at the plant, and in France the entire output is consumed within 200 miles of its origin. On this account, small cars, a plentiful car supply, and limited freight rates (in Belgium and Germany over government-controlled railroads), all render simple, our American problem of the expeditious disposition of the product.

Another matter which attracts the attention of the American abroad, is the character of the labor. There, mining is a trade, almost a profession, and descends from father to son. The mining schools in many sections are supported by a pro rata tax on the output, by the coal companies direct, and the sons of their employes are entitled to free tuition. Returning after this course, the son becomes his father's helper, and eventually his successor. It was stated on more than one occasion that the *good* miners are so well paid and so satisfied that they stay at home, and that with very few exceptions the foreign labor which comes to the United States is in no sense comparable to the real miner in his home country.

Again, the coal, both in its nature and geological formation, is in many cases so different from ours, as to render a comparison of methods or conditions, impossible or unjust. In Belgium and Northern France especially, seams of coal less than 2 feet in thickness, are mined at great depths, with dips exceeding 60 degrees, and large quantities of gas to contend with.

* Mining Engineer, Morgantown, W. Va.

It is true, that because of the superior personnel of the miners abroad, living conditions among them are materially superior to American mining towns. The miner's houses, notably at Broadsworth, England; Gelsenkirchen, Germany; Bois du Luc, à Trivieres, Belgium; and Lens, France, are neat, clean, comfortable brick and stone houses. There are thrifty gardens, casinos, public playgrounds, schools, churches, and hospitals, for the use of the miners and their families.

To sum up general impressions, England and Wales stand preeminent for underground detail and perfection of construction; Belgium for its hospital and rescue equipment, and the things which tend toward the preservation and comfort of human life; Germany for its magnificently equipped mining plants and power houses, and its wholesale attempts to keep down ankylostomiasis by elaborate baths for the miners emerging from the pit; and France for its *finesse* in laboratory research, chemical and electrical experiments. It should not be inferred from this that any of these countries are lacking in other material matters, for in Germany, at the Shamrock mines, in Herne, is one of the most complete rescue stations in the world, and the mines at Gelsenkirchen have been described for their elaborate equipment; but these conclusions are merely indicative of national type.

Belgium, as a country, occupies a unique position. For its size it is the most densely populated country in Europe (being double that of England), and in no other country in the world is the national wealth so evenly and widely distributed. There are neither millionaires nor paupers in Belgium, living is extremely cheap, and wages higher than anywhere else in Europe.

A movement now very general in France is the mutual aid society, by which schools are conducted, the sick are nursed, land and houses purchased and built by the miner. These societies are on the order of American building and loan associations.

In Germany the miner contributes a small amount per week from his wages, toward a general fund, from which, in case of accident, sickness, or death, he draws benefits augmented by duplicate payments by the company itself.

The English "model village" of Broadsworth, located about 6 miles from Doncaster, is extremely interesting. Here there is the cooperative store, the model tenements, the public lyceum, the athletic field, churches, schools, a hospital, and a fine, manly, intelligent and thrifty lot of miners, interested in self-betterment by means of lecture courses and night schools.

Without fear of contradiction, it may be said that Americans do not know what a dusty mine is, until they have visited the deep, thin-seam mines in Belgium, and Pas-de-Calais district in France. Here the coal is such that the air is continually filled with the dust, and may be likened to a whirling blizzard in which coal dust takes the place of snow, and in which the temperature varies from 85° F. to 113° F. The visitor is invariably supplied with a skin-tight skull cap which fits on under the leather mine hat, to keep the dust out of the hair, and this dust decomposes so rapidly that the clothing worn in the mine must be washed at frequent intervals on account of the fearful odor.

Under these conditions, with thin coal, and the dip so steep that room-and-pillar work or longwall are impossible; where ascensional ventilation from level to level, through long and tortuous workings is necessary, and where the amount of gas exceeds that found in any of our American mines, it is obvious that comparisons are useless.

On the other hand, in some parts of Germany, the mines are developed so nearly like those in America, that only the vast amount of timbering, or the amplified systems of rope or gasoline haulage, excite our interest.

In some parts of England and Wales, the coal is very friable, and in non-coking districts the slack is waste, so that the long-wall system is extensively followed, in order that the roof pressure may be utilized. The miner lays the lumps of coal by hand into his "curling box," a sort of sheet-iron scoop, with side handles, and then carefully empties this into the car, to avoid breakage. The purpose of the scoop-shape is to enable him to use it for throwing the slack back into the gob pile. In such mines as these, the percentage of waste exceeds that in this country.

In the matter of haulage and loading the output, there is no doubt that American mines take the lead, but for the amount of coal which they put out, and with the facilities for handling it, women and girls doing much of the tipple work on the continent, the European equipment is ample.

The average miner is considered to have done well if he sends out 1 ton a day, or about one-third the American average.

By-product coke ovens are practically the only ovens in use. Many plants operate a brick-yard in connection with the mining and by-product industries.

The matter of organization in the executive department abroad is excellent, because the miners have lived all their lives in that one district, speak the same dialect, and have grown up under the system.

Summed up, it would appear that in Europe, the matter of timbering is carried almost to an extreme, while the ventilation and roadways are poor, resulting in reduced output and increased cost of operation. The social conditions are uniformly excellent, and the installation of a mining plant is a matter of permanent investment, to be handed down to posterity. Great attention is paid to the gas, dust, safety lamp, and explosives proposition, and the drilling of corps of men for work with rescue apparatus and in fighting mine fires.

But in America, there are, speaking as a whole, larger mines, enormously increased output, longer haul, both in the mines and to the market; a very complex labor problem, involving wages, languages, social conditions and the general question of efficiency; competition to be met in the selling of the product; industrial conditions to be complied with in its preparation; and greatest of all, a series of new conditions constantly arising, and presenting hitherto unsolved problems, involving the production of a maximum output at a minimum outlay, coupled with the preservation of human life, and the conservation of mineral resources.

It may perhaps have been true, a few years past, that in unwonted development, thirst for mineral commercial supremacy, and lack of research along these lines, the American mines were for a time not so completely safeguarded against loss of life as European, nor was such prevention wholly possible until a sufficient period had elapsed in mining development, to learn the individual equation controlling mines and differentiating them from the older collieries of Europe (and even in the past, while the death rate per thousand men employed, has been high, the rate per ton of coal mined has compared favorably with the world. And it should be borne in mind that there have been *recent* disasters abroad, of considerable magnitude).

With the Testing Station at Pittsburg; with the rescue stations already in existence and those soon to be established; with the individual research now being carried on by large coal companies and mining schools; and with the earnest desire of the American coal operators and the American people to safeguard human life, it may safely be said that American mines compare favorably with any other coal mines in the world.

More than 300,000 families in the United States are today living in homes of their own on lands made productive through irrigation. The 13,000,000 acres under water are yielding up annually harvests valued at more than $250,000,000. The 40,000,000 acres of irrigable land for which there is water available will, when reclaimed, provide homes for 1,000,000 families or 5,000,000 men, women, and children, and, together with the towns and cities developed in connection with their settlement, will support a population of 10,000,000 people.

FIRST-AID CONTESTS

Written for Mines and Minerals

Annual Contests by Teams of the Different Collieries of the Pennsylvania Anthracite Region

Pennsylvania-Hillside Contest.—Probably not since Dr. M. J. Shields, the pioneer, organized the first first-aid mine corps in America, at Jermyn, Pa., in 1899, has such a methodical exhibition of preliminary relief work been given as that seen at Valley View Park, Inkerman, Pa., on September 17.

The Pennsylvania-Hillside contests for the cup donated by W. A. May, General Manager of the Pennsylvania Coal Co. and the Hillside Coal and Iron Co., held in the forenoon were preliminary to the annual National Red Cross contests in the afternoon.

Three interesting events formed the program, and apparently there is as much rivalry among the various colliery teams of this company as between the teams of different coal companies. Seven teams competed in the three events for the May cup, and spice was added to the exhibition because the four best teams in this contest were to represent their company in the afternoon contest of the Red Cross Society. The rules governing this contest were as follows:

First-Aid Men Going to Dinner, Philadelphia and Reading First-Aid Field Day

There will be no time limit allowance for any event, but the team finishing a problem will stand erect in the rear of the subject and the captain will announce "Time"—indicating that the problem is completed. The whole seven teams will perform in each event simultaneously.

The marking of this contest shall be as follows: Each team, operator, and operators shall start in each event with a credit of 100 per cent. and shall be marked with the following discounts for each mistake:

For loose or "Granny" knot	5
For loose bandage	5
For loose splint	5
For wrong artificial respiration	5
For not stopping bleeding	10
For not treating shock	10
For not doing the most important thing first	5
For slowness in work	5
For awkward handling of either patient or stretcher	5
For failure to be antiseptic	5
For captain's lack of command	5

In these events certificates were given to the teams ranking second and third, while the winner captured the cup. The first event was the dressing of a fractured jaw and a bleeding arterial ear wound by one man. William Davis, No. 5 colliery, first added 85 points to his team score in this event. The second event allowed three men to operate on a subject who was supposed to have been injured by a premature blast, with the result that flying coal had fractured his nose and caused profuse hemorrhage. There were also cuts on the head, while the upper right arm and the lower left forearm had simple fractures.

This called for the critical work and the expert bandaging in which George Rickert, William Gilmartin, Ralph Frater, of the Barnum colliery team, excelled, and which added 90 points to their colliery score. Chief interest centered in the third and final event as full teams were involved, the cup was to be won, and winning teams entered in the afternoon Red Cross contest.

The Forest City Hillside team won this event and added 95 points to the colliery total. The teams were made up of the following men:

Avoca, Pennsylvania—Ludwig Weichel, captain; Wm. Creeden, Ed. Warren, Chas. Warren, John McDermott; subject, Wm. Semmens.

No. 14, Pennsylvania—Arthur Brown, captain; John Dick, Thomas Yates, Arthur Wilson, David Jones; subject, Arthur Ramage.

No. 5, Pennsylvania—Peter Hoolihan, captain; Theo. Holland, John Holland, William Davis, Bernard Corcoran; subject, George Hindmarch.

Forest City, Hillside—Thomas C. Harvey, captain; Maurice Johns, Jas. Chidinski, George Parry, Edward Walsh; subject, Alex. Jones.

Dunmore, Pennsylvania—Edwin Shopland, captain; William Miller, William Pratt, William Hill, Patrick Haggerty; subject, William Watson.

Mayfield, Hillside—Bloss Leitinger, captain; James Hanophy, Harry Williams, Joseph Kerins, Vincent O'Neill; subject, Edward Powell.

Barnum, Pennsylvania—R. Eugene Smith, captain; George Rickert, William Gilmartin, Ralph Frater, Joseph Jackson; subject, John Lumley.

The order in which the teams finished and their score was: No. 5 Colliery, 250; Avoca, 240; Forest City and Barnum, 225; Dunmore and Mayfield, 205; No. 14 Pennsylvania, 195. No. 5, Avoca, Forest City, Barnum, and Dunmore, entered in the afternoon events.

The full summary showing the points gained in each event and the final score follows:

	1	2	3	Total
Avoca	75	85	80	240
No. 14	70	60	65	195
Forest City	60	70	95	225
No. 5 Colliery	85	75	95	250
Dunmore	65	65	75	205
Mayfield	55	80	70	205
Barnum	50	90	85	225

Dr. J. B. Mahon, of Pittston, who supervised the morning contests, is in charge of the first-aid work of the Hillside Coal and Iron Co. and Pennsylvania Coal Co. collieries. The judges of the morning's work were Drs. C. H. Lake, of Kingston; J. W. Geist, of Wilkes-Barre; and Thomas Monie, of Archbald. Lunch was served on the ground at noon, during which event acquaintances were renewed.

At the close of the exercises H. M. Wilson, of the Federal Bureau of Mines, lectured on rescue apparatus, after which a practical demonstration was given in an improvised mine.

The register of first-aid corps of the company shows that there are 76 corps distributed at the different operations.

The corps from each district competed together and the grounds were arranged so that as many as 10 teams could compete at the same time.

In the district contests, different problems were allotted as follows:

1. Compound fracture of skull and jaw.
2. Compound fracture of thigh. Laceration of hip. Dress with spica.

Ambulance, Philadelphia and Reading Company. Will Carry Four Patients

PHILADELPHIA & READING COAL AND IRON CO.

The sixth annual competitive drill of the First-Aid Corps of the Philadelphia & Reading Coal and Iron Co. was held on September 17, 1910, at Lakeside Park, East Mahanoy Junction, Pa. The importance of this work in the estimation of both the management and the employes is shown by the attendance and the interest shown. About 1,600 officers and employes of the company and invited guests were present. General Manager W. J. Richards was in charge and the contest was directed by Dr. G. H. Halberstadt, who is instructor of the corps. The judge of the contests was Dr. J. B. Rogers.

George F. Baer, President of the Philadelphia & Reading Coal and Iron Co., and the Philadelphia & Reading Railway, was present, having, as he said, canceled other engagements to permit his attendance. Other prominent officials and guests were as follows:

Vice-President Theodore Voorhis; General Manager A. T. Dice; Division Superintendents Turk and Keffer; Frank Smink, President of the Reading Iron Co.; Doctor McKee, surgeon for Lehigh and Wilkes-Barre Coal Co.; William Curran, of the Lehigh and Wilkes-Barre Coal Co.; Dr. Joseph A. Holmes, Director of the Bureau of Mines of the United States Government; Robert A. Quinn, General Manager of the Susquehanna Coal Co.; W. A. Phipps, General Manager of the Ashland Coal and Coke Co., of West Virginia; Baird Snyder, Jr., General Manager of the Lehigh Coal and Navigation Co.; T. M. Righter, coal operator, Mount Carmel; Judge O. P. Bechtel, Judge A. L. Shay, Judge C. N. Brumm, Judge MacHenry Wilhelm, County Commissioners Gardner, Crone, and Boyle, and several clergymen, school superintendents, and doctors.

Shamokin District Corps, Subjects Bandaged Ready for Inspection. Philadelphia and Reading Contest

3. Fracture of arm. Laceration of shoulder. Dress shoulder with spica.
4. Fracture of collar bone.
5. Laceration of foot and leg. Dress with spiral reverse.
6. Laceration of left ear with injury to right eye.
7. Rescue from electrical current, and dress the burns of back and shoulder.
8. Crush of pelvis. Laceration of hip. Dress with spica.
9. Handling by one, two, three, and four. Crossing obstruction and artificial respiration.
10. Dislocated hip.

The following teams were winners and entitled to enter in the final competition: Tunnel Ridge, Bear Ridge, Brookside, Knickerbocker (inside), Sterling, Bast (outside), Potts (first lift), Kohinoor (inside), West Shenandoah (outside), Reliance (outside), Wadesville, Eagle Hill, John Veith, and Glendower.

After the completion of the district contests those present, accompanied by three brass bands, marched to a nearby grove where all were guests of the Philadelphia & Reading Co. at a banquet. The large number, over 1,400, were seated without confusion at tables spread with white linen and glittering silver. The menu was as follows: Clam chowder, chicken croquettes, fillet beef, potatoes, peas, cold slaw, potato salad, corned beef, sliced ham, sliced tongue, rasped rolls, chow chow, gherkins, crackers, cheese, ice cream and ices, fancy cakes, coffee, cigars.

In the afternoon the final competitions took place. The problems were as follows:

1. Compound fracture of forearm with laceration of hand and fingers. Dress hand and fingers with spica bandage.

2. Patient caught by belt in engine house. Laceration of head, arm, and leg. Check hemorrhage on the spot and carry patient to hospital, complete dressings prepared to take ambulance.

The winners and the percentages attained were as follows: Wadesville, 100; Glendower, 98; Reliance, 95; Tunnel Ridge, 95; Bast (outside), 94; Bear Ridge, 90; Brookside, 90; Kohinoor (inside), 85; Knickerbocker (inside), 85; Sterling, 85.

After the completion of the final contest the members of all the corps formed in a hollow square and President Baer in a short speech presented the blue pennant and blue badges to the Wadesville team who were the winners.

Dr. J. A. Holmes, Director of the Bureau of Mines, presented a red pennant and badges to the Glendower corps who had the second highest rating, and who were the winners last year. Red pennants and badges were also presented to the other teams mentioned above. After the awarding of the prizes there was an exhibition of the use of Draeger rescue apparatus.

Special trains carried the men to their homes, starting at about 5 P. M.

FIRST-AID CONTEST OF PENNSYLVANIA RAILROAD COLLIERIES

Five hundred members of the First Aid to the Injured Corps of the Susquehanna, Summit branch, Lytle and Mineral coal companies, controlled by Pennsylvania Railroad Co., embracing 13 collieries, employing 20,000 men and boys in the Schuylkill, Shamokin, Lykens, and Luzerne districts, from Nanticoke to Pottsville, participated in the first annual aid to injured contests at Edgewood Park, Shamokin, Pa., September 3, a special train over the Pennsylvania Railroad conveying one-half of the corps from the Nanticoke region. The contests were to have been held in the open field, but rain shifted the exercises to a dance pavilion. Surgeons in charge were Drs. F. L. McKee, Wilkes-Barre; G. M. Stites, Williamstown; J. M. Maurer, Shamokin; J. B. Rodgers, Pottsville. The events were as follows:

Fracture of the lower jaw and a penetrating wound of the right eye

DR. M. J. SHIELDS, ORIGINATOR OF FIRST-AID INSTRUCTION IN COAL MINES OF THE UNITED STATES

Burns of the face and neck.

Fracture of the right collar bone and a compound fracture of the left forearm, with bleeding of bright-red blood in spurts.

An explosion; rescue and carry to dressing room with coat and pole stretcher; examine and find subject unconscious, with a fractured right collar bone and left thigh, also bleeding from a wound on top of the head.

Wound of the lower portion of the left thigh, severe bleeding in jets from the thigh wound; dress injuries, place subject on the hospital stretcher and into ambulance.

The winning teams were as follows:

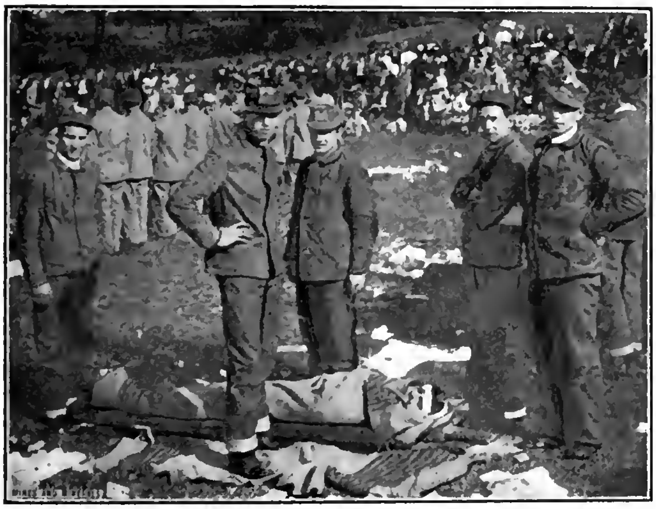
First event, Scott Shaft, Shamokin, William Horn, captain; second, Hickory Ridge, Thomas Howells, captain; third, Nanticoke, No. 7, George McGinnis, captain; fourth, Lykens, A. F. Minnich, captain.

French bronze medals were awarded to the first three, and a silver cup to the fourth. The latter will be subject to annual contest, and must be won three times, to be held permanently.

THE ANTHRACITE RED CROSS CONTEST

In the summer of 1859 M. Henri Dunant, of Switzerland, witnessed the terrible sufferings of the wounded on the battlefield of Solferino. M. Dunant described what he had seen in a pamphlet, which was generally circulated throughout Europe, and aroused such interest that in 1864 a convention of representatives from many of the civilized nations was held in Geneva. From that resulted what is known as the first "Red Cross Treaty." This treaty was subsequently revised at a convention held in Geneva in 1906, at which 43 nations were represented, and provides in time of war for the protection of hospital formations with their personnel of the army, navy, and the recognized official Red Cross societies. Out of compliment to Switzerland, the Swiss flag, with its colors reversed, was adopted to designate these hospital formations and thus the Red Cross on a white ground became the flag of humanity.

The Red Cross societies of the world have a membership of nearly 5,000,000. Japan alone, has a membership of 1,400,000,



FOREST CITY TEAM, WINNERS OF W. A. MAY CUP, PENNSYLVANIA-HILLSIDE CONTEST

WOODWARD COLLIERY TEAM, D. L. & W. WINNERS OF MUCKLE CUP, RED CROSS CONTEST

while the American Red Cross has not 20,000. Since its reorganization, in 1905, the American National Red Cross has rendered active and sympathetic aid, after such serious disasters as the Philippine typhoon, the San Francisco fire and earthquake, the Gulf storm, the Monongah mine explosion, the Mississippi cyclone, the Chelsea fire, the Georgia, South Carolina, and Texas floods, the Michigan forest fires, etc., besides sending aid to the Chinese and Russian famine sufferers, the Kingston, Valparaiso, Calabrian, and Sicilian earthquake unfortunates. It now maintains a corps of physicians who travel around the bituminous coal fields and instruct the miners in the various collieries to apply first aid to the injured. It is well known that many lives and limbs may be saved if the injured are afforded temporary relief immediately or shortly after an accident has occurred, and prior to the arrival of a surgeon. It is with this end in view that first-aid corps have been established in nearly all civilized mining communities.

The anthracite miners have been drilled in first-aid work for a number of years and anually there is a competitive contest under the auspices of the Red Cross Society, for the large silver cup, which was donated as a prize by Mrs. John S. Muckle, of Philadelphia, Pa. The contest was held this year at Valley View Park, Inkerman, Pa., on September 17. While competitive contests are incentives to excel in this special line of work, the fact remains that if any one is trained so as to render efficient aid to the injured, his merit is recognized, and on this occasion Red Cross medals and certificates were awarded to individual winners and a silver cup to the best team. This acknowledgment of proficiency is after all the chief aim, as it is highly probable the holders of the medals can accomplish the same practical results as the winners of the cup.

Whereas, in the anthracite fields, each large coal company is interested in "first-aid work" to the extent that each of the collieries has a corps of trained men it is customary to hold local contests and send the winning teams to the Red Cross contest which is not a local affair but open to all teams.

Considerable rivalry exists between the teams and each watches the moves of the others and comments on the work, down to the outfits. For instance, one team remarked that another team had steel-tipped instead of copper-tipped drills for stretcher bars. In explanation of this, the anthracite miner uses a straight drill which has a cutting edge at one end, while the other end is upset to form a tamping bar. The Pennsylvania Mine Law requires that the tamping end be copper tipped, and the team in question had brought their practice drills instead of their working drills.

The third annual contest of the National Red Cross Society was held at Valley View Park, Inkerman, Pa., on September 17. Twelve teams entered the contest, and to the layman all did equally well, but to the judges, Major Charles Lynch, Captains H. H. Baily and M. A. DeLaney, all United States Army surgeons, there was a difference.

The following teams were entered: Coxe Bros. Derringer colliery; Lackawanna, Woodward; Lehigh Valley, Seneca; Lehigh Valley, Primrose; Lehigh Valley, Wyoming Division team; Temple Iron Co., Lackawanna colliery; Temple Iron Co., Harry E.; Avoca, No. 5, Dunmore, Forest City, and Barnum, of the Erie system.

Previous to the contest, and while the teams were arranging their first-aid kits, Major Lynch handed each team captain a copy of the list of the accidents which were to be demonstrated. The captain then instructed his team mates. At a given signal 12 men were seen trying to lift 12 supposedly injured men and after doing so, carrying them to a place of safety. This is an extremely difficult undertaking, particularly if the injured man is unconscious or unable to aid his assistants, for which reason it is not probable that any one man loaded down with an oxygen helmet can perform this work.

Contest for Muckle Cup, Anthracite Red Cross Contest

Each of the teams treated their subject for the same injury at the same time, and while this kept the three judges moving from group to group, the events were conducted with precision and smoothness.

The first contest was a one-man event. The injured man was lying on an electric wire badly shocked and unconscious. He was to be removed in two minutes and an attempt made to restore him to consciousness. This event was won by the Derringer team of the Lehigh Valley Coal Co. South Pittston district of the Pennsylvania Coal Co. was second, and Seneca colliery of the Lehigh Valley Coal Co. third.

In the second event two men formed the team to treat a man burned about the face. The treatment of a burn of the first degree was applied and the man carried 20 feet to a place of safety. The Harry E. team of the Temple Iron Co. was first, Forest City team of the Hillside Co. second, and Primrose colliery of the Lehigh Valley third.

The third event required three men in the team. The subject had a crushed chest and abdomen with fracture of the lower ribs, due to a heavy weight falling on the body, and was

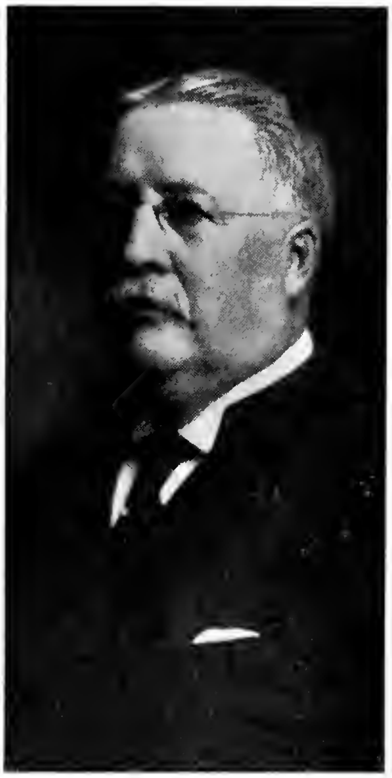
to be carried 30 feet by employing any material at hand for any kind of a stretcher. The Woodward colliery of the Lackawanna Coal Co. was first, Wyoming division of the Lehigh Valley Coal Co. second, and the Avoca team of the Pennsylvania Coal Co. third.

The fourth event called for a full team of five men and was the most interesting and spectacular event of the day. The patient was supposed to have been in an explosion where a fall of rock had followed and he had received a simple fracture of the lower jaw; a severe cut on the palm of the right hand from which blood was spurting in bright-red jets; also a simple fracture of the left thigh high up just below the body. The teams were to dress all wounds and injuries and load the patient on a stretcher. This event was won by the Woodward colliery team of the Lackawanna Coal Co., composed of John Thomas, captain; Neil McCole, John Richards, Benjamin Lewis, David Phillips, and William Martin, subject.

By winning the fourth event the Woodward colliery team of the Lackawanna Coal Co. captured the Muckle cup.

One notable feature at this contest was the large gathering of prominent mine officials, interested friends of the contestants, and people prominent in the coal fields. The audience in number exceeded that of any previous year, which goes to show that the people generally appreciate and approve of this good work.

The first-aid work is being extended to all parts of the country by the American Red Cross Association. Dr. M. J. Shields, who was the originator of the movement in America and is now of the Medical Reserve Corps of the United States Army, is visiting the different coal regions for the purpose of helping to organize the corps under local management, and operators at whose works no such corps are in existence will be afforded valuable assistance by him.



Dr. J. B. Mahon, Instructor in First Aid, Pennsylvania-Hillside Collieries

NEW OHIO MINE LAW

The following notice has been sent out by the State Mining Department of Ohio, to mine operators, miners, oil-well drillers, manufacturers of illuminating oils for use in mines, and all others interested in the operation of mines:

The new mining code passed March 23, by both Houses of the Ohio Legislature, and approved by the signature of Governor Harmon on April 11, 1910, is now in full force.

Many important changes have been made in the old law, and many new provisions, which were necessary to cover new conditions and new dangers.

The duties and obligations of owner, lessee or agent, and all employes in the mines, have been carefully and impartially considered and clearly defined.

The dangers liable to result to life and property in the operation of mines from the hitherto "wild-cat" system of drilling oil and gas wells through workable veins of coal and abandoning them without leaving any record, have been fully provided against. Any person, firm or corporation desiring to commence the drilling of an oil or gas well that will penetrate a vein of coal must first secure permission in writing from the Mining Department, and comply with all the provisions of law pertaining to that work.

The manufacture, sale and use of impure oil for illuminating purposes in the mines is prohibited, and an effective means of detecting it provided.

The sizes of miners' lamps have been regulated, and open torches as stationary lights in mines have been prohibited.

The volume of air has been increased so that better and more powerful artificial ventilation equipments will be necessary in many instances.

Penalties in all cases of violation, and a quick and ready means of prosecution, are also provided. A person cannot longer ignore or violate any provision of the mining law with impunity, and when brought before the lower court waive examination and give bond to appear before the Grand Jury of the county, taking unscrupulous and undue advantage of the interval to prevent the forthcoming of evidence against him. For the first offense his case must be put on record by trial before a Justice of the Peace, while it is new and the evidence obtainable. State and county lines are sometimes convenient landmarks to those who disregard law, and are sometimes used by criminals, as well as witnesses, to defeat the ends of justice.

The new code was the work and recommendations of a Commission composed of three operators, recommended by the operators, and three representative miners, recommended by the miners, and appointed by Governor Harris, and the writer, who was selected by the other six members and also appointed by Governor Harris as the seventh member.

We fully realize that objections may be taken to some of the provisions of the bill, but it could not be expected that an entire code of laws could be drafted covering so many new and varied conditions in mines, that would not have some defects. From time to time, necessary changes can easily be made.

In the consideration of almost every question, the cost of the production of coal, the liberties of the employes, or the increased responsibility of some person, was necessarily affected, necessitating in most instances keen argument, in which the interests of all were zealously guarded and logically protected by their respective representatives. To secure a unanimous and harmonious agreement, and insure a good code of laws, it required reasonable concessions from both sides, which was commendable to both parties, and the fact that Governor Harmon sent the recommendations of the Commission to the Senate and House of Representatives, accompanied by special message of approval, and that both Houses of the Legislature enacted them into law without a single change, or a dissenting voice or vote against them, is the highest compliment that could be paid to the Ohio mine operators and miners.

Sixty days, after the passage and approval of the bill, has been allowed to give time to prepare to meet its requirements. This provision was made so that there could be no misunderstanding on that point, and no room for any excuse of ignorance of the law. All must be prepared to meet with a reasonable compliance of the new law, or the inspectors will be compelled to seek an application of the penalties. This must not be understood to mean, however, that there will be any change of policy on part of the Department, or that the inspectors will pursue any harsh, radical, unreasonable or unfriendly course. It means that the law will be reasonably and judiciously enforced alike to all, and we trust they will have the friendly cooperation of all to that end.

Copies of the entire code can be had by writing the Secretary of State, or George Harrison, Chief Inspector of Mines, Columbus, Ohio.

EXPLOSION AT PALAU No. 2 MINE

Written for Mines and Minerals, by Special Correspondent

Extent and Cause of the Explosion. Rescue Work. Unauthorized Explosives

At about 11 o'clock, Friday night, September 30, an explosion of dust occurred at Palau Mine No. 2 of the Coahuila Coal Co., at Menor, about 20 kilometers (12½ miles) from the mining town of Las Esperanzas, in the State of Coahuila, Mexico. The press dispatches reported that from 150 to 300 men were in the mine; that all of them were killed; and that the mine was the same one in which a similar disaster occurred several months ago. The facts are that there were between 80 and 85 men in the mine at the time of the accident, and this was not the second explosion at this mine. The previous explosion was at Palau No. 3 an entirely different mine,* owned by the same company. It was supposed at first that every man in the mine was killed by the force of the explosion, or was asphyxiated by the afterdamp, but on Tuesday, October 4, four days after the explosion, a group of six Japanese miners were found alive in the sixth south entry, the entrance to which had been closed by an immense fall of rock which prevented the afterdamp from reaching and overcoming them. The latest report places the number of dead at 78. Ten miners belonging to the night shift were saved by the fact that they were in jail for gambling. Had the accident occurred in the daytime the loss of life would have been doubled or trebled.

Fig. 1. Repair Work on Slope, Palau Mine No. 2

Palau No. 2, as shown in Fig. 1, is a slope mine, the slope being driven on the coal which dips about 10 degrees toward the east from the outcrop. The slope has been driven down about 1,100 meters (3,600 feet), with entries to the north and south every 100 meters (325 feet). The side entries extend approximately half a mile to barrier pillars 40 meters (130 feet) in width, separating the workings of mine No. 2 from those of Nos. 1 and 3, to the south and north. As the mines are both gassy and dusty it has been considered advisable to keep the several workings entirely separate, so that a fire or explosion in one mine would not be communicated to the others. Mine No. 2 is the largest of the five mines owned by the Coahuila Coal Co., and is the main source of fuel supply for the National Railways of Mexico. It has a capacity of 1,000 metric tons per day (metric ton 2,204 pounds).

The force of the explosion of September 30 was terrific, blowing down all the timbers in the slope, from the eighth entry to the surface. For 200 feet or more from the mouth of the slope the surface was lifted into the air and falling back crushed the timbers and lagging and entirely closed the mine. Fig. 1 shows the repair work necessary at this slope. Although there were large accumulations of dust in the slope, which was also the intake for the air, there was no evidence of an explosion in the slope above the sixth entry. The dust was, however, forced out of the slope in a great cloud, and after reaching the outside air ignited with a burst of flame that was seen in the town of Muzquiz, 5 miles distant. The fan house was blown down, but fortunately the fan and engine were not seriously injured, and 2 hours after the accident the fan was again in operation, but although entrance was made to the mine through the second opening, about 50 feet to the south of the main entry, it was impossible to penetrate far enough into the mine to rescue the entombed miners, as the ventilating current and air stoppings had been destroyed and the air was short-circuited to the fan. General Manager Ludlow and General Superintendent Jones, summoned from Las Esperanzas by a courier, arrived at 2:30 o'clock in the morning. The first rescue party was organized within 2 hours after the explosion occurred. This party was soon overcome by afterdamp, and a second party sent to relieve the rescuers was also overcome All were brought to the surface, however, and resuscitated after a few hours. It was believed from the first that on account of the destruction of the ventilating currents there was no possibility of any of the men being recovered alive, but the rescuers worked with an earnestness bordering on frenzy to recover the bodies before decomposition should have rendered them unrecognizable. These efforts were rewarded by the rescue of the six Japanese miners 4 days after the explosion. The neighboring mines contributed to the rescue work by sending their superintendents with picked men who rendered invaluable assistance. The company maintains a supply of Draeger helmets and oxygen apparatus and a force of men trained in their use, but owing to the heavy falls and the small spaces left to crawl through, it was simply impossible for the rescue parties to avail themselves of this aid. Fig. 2 shows a rescue party composed of Japanese and Mexican miners taken just before they entered the mine.

On the evening of Sunday, October 2, the rescue parties had penetrated to the eighth lift, and nine bodies, two Mexicans and seven Japanese, which were found in the sixth north entry, were brought to the surface. All had been asphyxiated. Thirty-two more bodies were found on Monday, October 3, by which time decomposition was so far advanced that it was impossible to tell whether the deaths were due to suffocation or to the force of the explosion. At that time it was estimated that it would take at least a month to repair all of the damage to the mine, and it may be that length of time before the last body is recovered.

An instance of oriental peculiarity was evinced during the early part of the rescue work, when General Manager Ludlow, struck by the fervor with which the Japs were removing the debris from the mouth of the slope, suggested paying them by the car of dirt removed instead of by the day. They at once quit work and would not return until he promised not to pay them. They were working for the rescue of their friends or their bodies, and were incensed at having a money consideration placed upon their labor.*

The exact cause of the explosion will probably remain a matter of conjecture. As gas was present in some quantity, particularly in the lower levels, safety lamps (Wolf) were used, and it is against the rules to carry matches into or to smoke in the mines. Evidence seems to point to a windy shot as the initiating cause. All of the coal is "shot from the solid," and paid for on the mine-run basis, and while there are no labor unions, the contracting miner is able to do much as he pleases through the competition for labor in the Coahuila coal-mining district. If he is not allowed to mine his coal according to his own sweet will at one mine he will go to and be welcomed at some other, as the supply of labor is insufficient to produce coal to meet the active demand. Under such conditions it is possible that contractors may permit rules and regulations to be disregarded.

* See Mines and Minerals, Vol. 30, page 462.

* This is not alone an oriental peculiarity. Miners in this country, white or black, will do the same, in fact risk their own lives in the hope of saving their comrades, and without thought of reward.

The contract mining system in Mexico, is somewhat different from that in the United States. A contract miner in Mexico takes the contract for mining so many rooms, or even one or more entries, at so much a ton delivered at the neck of the room or at the parting. The contractor employs and pays the men who actually mine the coal. He will employ as many as 75 or 100 men. The company pays the contractor, and his employes do not appear on the rolls of the company. The company, however, employs a timekeeper who counts the men in the mine after the shift has gone to work. This official was in the Palau Mine at the time of the explosion and was killed. Drivers, car runners, door boys, and other laborers, except miners, are employed directly by the company. The division of authority and responsibility brought about by the contract system is of doubtful wisdom, and operators are as a rule opposed to it, but it is a condition forced upon them by the labor situation in the Republic of Mexico. One of the contractors lost 32 men in the explosion at Palau.

Strong probability attaches to a windy shot as the cause of the explosion by the fact that the miners are in the habit of buying cheap grades of dynamite from the small stores in the town, and smuggling this into the mines instead of buying the safety, or "permissible" explosives which are the only kind provided by the company. Almost prophetic, and to some extent exonerating the management for this explosion, is the following letter of General Manager Ludlow to the agent of the dynamite company. The Coahuila Coal Co. is controlled by the railroad, but the mines are operated under lease by the Mexican Coal and Coke Co., of which Mr. Ludlow is the General Manager. Mr. Ludlow's letter is dated September 28, only 2 days before the accident, and is as follows:

LAS ESPERANZAS, COAH., September 28, 1910

DEAR SIR:—In confirmation of our conversation, I desire to impress upon you the continued risk that we are running at our Palau mines through the use of dynamite against our instructions.

We will not sell dynamite to the miners working in mines where tests have shown that an explosion is liable to be caused by the use of dynamite that would be avoided by the use of safety powders, such as Carbonite and Grisutina.

The miners do not like Grisutina, as they claim it does not do the work, and are therefore buying dynamite outside of our property, from the merchants at the little town of Cuchilla.

These merchants are now doing a large business in this dynamite, and we feel that almost any day we may have an explosion caused by its use that will destroy a great many lives and possibly the property.

I have previously written and asked if you could not arrange with the dynamite company to prohibit the sale of dynamite to miners working in gassy mines.

We care nothing about the profit on the explosive that we sell, but we want to protect the lives of the men and avoid a serious accident.

Both in Europe and the United States, a great deal of attention has been give in the last few years to the use of proper blasting powders, and the laws in some of the states of the union hold the superintendent personally responsible for any powder, except the approved safety powders, being used in his mine.

In this country, with the powder all sold through one company, it would appear to be a matter of very easy regulation if you could impress upon them the danger to the lives and property that is caused by their selling through outside agents to our miners an explosive that is known to be unsafe, for the sale of which a company in the states would be criminally liable.

All the powder that is sold in this town of Cuchilla is sold to miners who can do all the work required of them with safety powders, and it is not necessary that any merchant there should carry any dynamite.

There is one shaft sinker working for us who should be allowed to use dynamite. If the dynamite company does not want us to sell him dynamite, we have no objections to their naming some one else to handle that particular business, but we must insist that the dynamite company assume the full responsibility for all losses of life or damage to the mines that may accrue to their continuing to thwart our endeavors to confine the use, for blasting in our dangerous mines, to the safety powders.

I would appreciate your calling the attention of the powder company to this matter and asking if something cannot be done in regard to it. Very truly yours,

(Signed) EDWIN LUDLOW, General Manager

MINING ENGINEER

The United States Civil Service Commission announces an examination on November 9, 1910, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of mining engineer in the Bureau of Mines, one of the stations of which is located at Pittsburg, Pa., at salaries ranging from $2,400 to $3,600 per annum, and in other branches of the service.

Competitors will not be assembled for any of the tests.

FIG. 2. RESCUE PARTY AT PALAU MINE

The examination will consist of the subjects mentioned below, weighted as indicated: (1) Education and technical training, including postgraduate work, 25; (2) technical and professional experience, 45; (3) publications on mining engineering or allied topics, 30. Total, 100.

It is desired to secure persons having broad training and experience in mining, ore dressing and smelting, and in the treatment and preparation of coal, ores, and other mineral substances. They should be fully qualified to undertake original investigations into the causes of waste in mining mineral products and to suggest remedies therefor.

Applicants must have reached their 21st birthday, but not their 50th birthday, on the date of the examination.

This examination is open to all citizens of the United States who comply with the requirements.

This announcement contains all information which is communicated to applicants regarding the scope of the examination, the vacancy or vacancies to be filled, and the qualifications required.

Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for Form 304 and special form. No application will be accepted unless properly executed and filed with the Commission at Washington prior to the hour of closing business on November 9, 1910. In applying for this examination the exact title as given at the head of this announcement should be used in the application.

KELLERMAN MINE, KELLERMAN, ALA.

*Written for Mines and Minerals, by Neill Hutchins**

The Kellerman Mine is owned and operated by the Central Iron and Coal Co., of New York, with general offices at Holt, Ala., at which point the company operates one modern blast furnace, a soil-pipe foundry, nodulizing plant, 164 beehive coke ovens, and 45 retort, or by-product, ovens. Holt is situated on the east bank of the Warrior River, 5 miles north of Tuscaloosa; Kellerman is 17 miles north of Holt. Both places are connected with the Mobile & Ohio Railroad, and the Alabama Great Southern Railroad, at Tuscaloosa, by the Warrior Southern Railroad, a branch line of the Mobile & Ohio Railroad, extending from Tuscaloosa to Kellerman. The Kellerman Mine is in the foot-hills east of the Warrior River, where the company has 5,000 acres of coal lands, covered with virgin timber, well drained and easy of access to the coal markets and manufacturing centers of Alabama. Five miles from the western boundary of the property is the Warrior River. This stream, as the result of extensive government improvements in the nature of magnificent locks and dams, will, in connection with the Tombigbee and Alabama rivers, soon be navigable all the year around from a point north of Kellerman to the Gulf of Mexico, at Mobile, Ala. Lock No. 16, west of Kellerman, is in course of construction, and with its completion, and that of locks numbered 17, 18, 19, and 20, the stream will be navigable up its two forks—the Sipsey and Locust —to the extensive Warrior coal basin, at a point within 12 or 15 miles of Birmingham. The Central Iron and Coal Co. is the only company that has so far sent coal into Mobile via the all-water route. This was done last year, the coal being transferred direct from river barges on to vessels in Mobile Bay. The Kellerman Mine is at the terminus of the Warrior Southern Railroad, originally constructed for the express purpose of handling the raw material and finished products of the Central Iron and Coal Co. This railroad from Tuscaloosa to Kellerman runs through virgin forest, numerous tunnels, high trestles, etc., which add to the picturesqueness of the route. The road has a 3-per-cent. down grade all the way from Kellerman to the manufacturing plants at Holt.

Location. Transportation Facilities. Method of Handling and Preparing the Coal

Fig. 1. Entrance to Kellerman Mine

The tract of 5,000 acres, in which the Kellerman Mine is as yet the only opening, contains the Milldale and Brookwood coal seams, which in this territory run together, the Milldale, or bottom, seam being 20 inches high, and the Brookwood 60 inches high. These beds of coal are above the valleys draining this region, thus making a drift mine easy of operation. Test borings have located the Pratt coal seam 600 feet below the Milldale and Brookwood beds, where it shows a thickness of 42 inches. Assuming that it will take years to exhaust the Milldale and Brookwood seams, the fact that the Pratt seam is in easy striking distance enhances the value of the property. As previously stated, the coal outcrops on the hills and ridges above the draining valleys. From the mouth of the mine, shown in Fig. 1, the coal rises gradually until the center of the field is reached. This natural condition makes the drainage of the mine a simple proposition of cutting sufficient drainage ditches to the outcrop at the different points, so that the water may flow by gravity. This method of unwatering eliminates the expense of pumping which is so often a serious factor in coal-mine operations. Only five or six small Cameron pumps are required for raising water from swamps here and there in the mine to the drainage ditches. All of the pumps are operated by compressed air supplied from the compressor plant.

Tipple, Etc.—The coal-mine tipple is situated about 600 feet from the mouth of the mine. It is a frame structure about 210 feet long, equipped with Phillips cross-over dump, Fairbanks scales, and slate-picking belt. The coal is delivered from the tipple to a $36'' \times 42''$ roll crusher operated by $11'' \times 14''$ twin engines. After leaving the crusher the coal is carried by conveyers to the washer plant, shown in Fig. 2, alongside the tipple. After going through the washer the coal is passed through a large revolving screen with $\frac{3}{4}$-inch holes. The fine coal passing through this screen goes into the washed slack coal bin; the rest of the product, being a fine nut coal, is desirable for steam purposes. By this practice about 80 per cent. of the product goes to the washed slack coal bin, and the remainder, or nut coal, goes either to the washer boilers for fuel by means of conveyer, or to nut coal bin for loading into railroad cars for the market.

Washer.—The washer is of the Stewart type with four jigs, having an average daily capacity of 1,100 tons of coal, and is operated by twin engines with $14'' \times 16''$ cylinders. The engines also operate the dry and wet coal elevators. It is proposed to add two additional jigs to the washer and thus increase the output about 500 tons. The refuse from the washer is raised by conveyers to the top of the washer building and passes off to the dump 300 feet distant through an 18-inch cast-iron split pipe, which is made in 5-foot sections and elevated on the trestle shown in Fig. 2.

A stream of water passing through this pipe keeps the refuse in motion. The coal from the washer is carried by conveyer to a 250-ton coal bin and loaded from the bin into railroad cars. All of the washed product of the Kellerman Mine is shipped to the manufacturing plants of the company at Holt.

The steam plant consists of five 80-horsepower and one 150-horsepower horizontal boilers. Nut coal is used for fuel. This has been found satisfactory and as compared with run-of-mine coal has increased the steaming efficiency of the plant. By using nut coal only four of the boilers need be operated to furnish all the steam required for the compressor plant, washer, crusher, etc.

The haulage equipment of the Kellerman Mine is considered to be among the best in the state. The main entry follows a barely perceptible ascent until the center of operations, nearly a mile distant, is reached. The main entry is partly double tracked with 40-pound rails. There are 300 two-ton mine cars, 32 inches high, 44-inch gauge, and equipped with Lobdell wheels and axles. The loaded cars are gathered from the various cross-entries by mules and delivered on the main entry to compressed-air locomotives of H. K. Porter Co. make with cylinders $9\frac{1}{2}$ in. $\times$ 14 in. Sixty mine cars are delivered to each locomotive, making a trip of 120 tons of coal which each

* Ensley, Ala.

locomotive delivers from the gathering point to the tipple. Two 15-ton compressed-air locomotives of the size mentioned are used on the main haulage, while one 10-ton air locomotive of H. K. Porter make, with 7"×14" cylinders, is used for gathering purposes at some points in the mine. The haulage equipment, as well as tracks, is an attractive feature of the mine.

The retreating method of room and pillar mining is employed. Rooms are driven 22 feet wide, and as fast as the entries are driven to the outcrop pillars are pulled. In this manner it is conservatively estimated that 90 per cent. of the developed coal is recovered. This is a feature of the mine peculiarly worthy of mention, inasmuch as very few coal mines afford opportunity for recovering this percentage of developed coal. The advanced workings are all in an area of not over 1 mile from the end of main entry inside, and on account of the natural drift of the bed, the coal after being loaded in cars is very easily gathered. All the product is pick mined. The roof is of good sound rock and accidents from rock falls are infrequent. The height of the bed makes it desirable coal to work, and labor is usually to be had in abundance. The contract system of labor is employed to a considerable extent, laborers being employed by and working for contractors.

The mine is ventilated by three air-shafts driven from the surface down to the coal. The principal intake is the main entry, although the various drainage ditches mentioned serve as intakes. The air circulates freely throughout the mine, and by means of a small furnace at each air-shaft is conveyed out of the mine. The ventilation being almost a natural proposition, the mine is remarkably free from gas. This feature has often been the subject of favorable comment by the state mine inspectors.

The average daily output of the mine is about 1,200 tons, although it has reached 1,600 tons from this one opening in one day. The large output will probably be maintained as soon as additional coal-washing facilities have been provided. The mine employs about 180 miners and 120 laborers both inside and outside of the mine.

The compressed-air plant is on the opposite side of the tipple from the washer, and a short distance from the steam plant. It is housed in a substantial brick structure 44 ft.×80 ft., with hip roof, covered with galvanized iron, and has a concrete floor, making it practically fireproof. This structure contains

Fig. 2. Steam Plant, Tipple and Washery, Kellerman Mine

three Ingersoll-Rand, high-pressure, three-stage compressors, each 18 in.×13 in.×9 in.×3¾ in.×24 in. A 4-inch double extra-heavy pipe line conveys the air from the compressor to the end of the main slope in the mine. A number of stations are provided at convenient points in the mine for charging the locomotives. An average pressure of from 800 to 900 pounds is maintained on this line. The compressor house also contains a small electric generator, which furnishes electric lights around tipple, washer, the company's office, store, and superintendent's residence.

All water necessary for washing is secured from Davis Creek, at a point two miles north of Kellerman, where the company's pumping station is located. One 80-horsepower and two 60-horsepower boilers more than supply steam for the large pump, which is an 18"×27½"×10½" compound duplex pot-

Fig. 3. Commissary, Kellerman Mine

valve type. A large special Cameron pump is also maintained at this point as a spare. The pipe line from pumping station to reservoir is 1½ miles long, and is built of 8-inch pipe. Owing to elevation of the reservoir above the pumping station, a working pressure of 300 pounds per square inch at the pumps is necessary. The pipe line, with its universal, no-lead joints, has given satisfaction on this high-working pressure. The reservoir is located on top of a hill overlooking, and about half a mile from, the washing plant. It is cement lined, with natural rock bottom, and has a capacity of 1,000,000 gallons. The elevation is sufficient for a good pressure at the washer. Two 5-inch pipe lines deliver water by gravity from the reservoir to the washer.

The company has a laboratory and a chemist, who makes frequent daily analyses of washed coal, as well as refuse, and keeps the washer foreman and superintendent fully informed as to results being obtained.

Two lines of standard fire-hose with nozzles are connected up at all times with the line from the reservoir for use in case of fire at the tipple or washer. Casks filled with water and containing fire-buckets are also conveniently located. A night watchman is employed who carries an approved watchman's clock.

All dangerous points where sprocket wheels, etc., operate about plant are protected with railings or other safety devices. The company, in keeping with other large operators in this district, is giving this matter considerable attention now.

The town is well arranged and contains 195 tenement houses, 85 of which are for white, and 110 for negro employes, all on high ground, with special view to natural drainage. The negro houses are on the hill east of the mine, and are separated from white quarters by a valley. The white houses are convenient to and just west of the mine. Most of the white tenements are attractively painted and present a good appearance. In many respects it is a model camp. The management has always been particular to have it so. Visitors frequently comment favorably on the general neat, attractive appearance of not only the camp, but the plant, roadways, and structures about the mine. Among other structures there is a stable with a stable lot for the company's 33 large mules, probably the finest mine stock in the state. Near the mine entrance is a combination roundhouse for air locomotives and blacksmith shop. The commissary, shown in Fig. 3, is attractive and well stocked with general merchandise. The local mine office is

near the store in which rooms are provided for the superintendent, resident mining engineer, timekeepers, etc. Both white and negro employes have their separate schools and churches, erected with assistance of company, on lands donated for that purpose. Eight-months public schools are maintained.

The mine was opened in April, 1901, and was named for C. R. Kellerman, the first chief engineer of the company. During the life of the mine it has had only two superintendents, Mr. C. E. Crandall, who served the company in that capacity until recently, and Mr. S. J. Routledge, the present superintendent, who comes from the Tennessee Coal, Iron and Railroad Co., after long experience in same capacity in the Pratt field. Only three different mine foremen have been employed. The present foreman, Mr. Geo. Burgess, is an ex-employe of the Tennessee Coal, Iron and Railroad Co., with years of experience in the Blue Creek fields of that company. Mr. G. H. Howell is resident engineer; Mr. C. M. Ayers, Holt, Ala., is chief engineer.

As an index to the character of the mine and its present condition the following extract is quoted from State Mine Inspector's report of July 19, 1910:

"Ventilation in good shape. Mine naturally damp in character. General conditions way above the average."

EXPLOSIVES

Investigations have stimulated the powder manufacturers to devise comparatively safe explosives and have resulted in the submission, for investigation by the government at the Pittsburg testing station, of nearly 100 different explosives, of which 45 have now passed the government tests and have been listed as "permissible."

On May 15, 1909, the Geological Survey issued Explosives Circular No. 2, giving lists of permissible explosives. On May 16, 1910, a third list was issued, including all permissible explosives tested up to that date. This list shows that 14 additional explosives have been placed in the permissible class since the issue of Circular No. 2. These are as follows:

Ætna coal powder D, Ætna Powder Co., Chicago, Ill.

Coal special No. 3-B and Coal special No. 3-C, Keystone Powder Co., Emporium, Pa.

Eureka No. 2-L. F., Tunnelite No. 6-L. F., and Tunnelite No. 8-L. F., G. R. McAbee Powder and Oil Co., Pittsburg, Pa.

Titanite No. 3 P, Waclark Titanite Explosive Co., Corry, Pa.

Trojan coal powder A Trojan Powder Co., Allentown, Pa.

Detonite special, Detonite Co., Cincinnati, Ohio.

Monobel No. 2, Monobel No. 3, Carbonite No. 4, and Hecla No. 2. E. I. du Pont de Nemours Powder Co., Wilmington, Del.

Kanite A, W. H. Blumenstein Chemical Works, Pottsville, Pa.

A COAL-LOADING MACHINE

Written for Mines and Minerals, by William Whaley

Apparatus for Use in the Mine to Load Coal into Mine Cars. Loads 1¼-Ton Car in 3 Minutes

For several years the engineering firm of Meyers & Whaley, of Knoxville, Tenn., has been engaged in the development of a shoveling machine that would load coal from the face of a room or entry, or rock from a tunnel face. The first machines built were tried at the mines of the Wind Rock Coal and Coke Co., Wind Rock, Tenn., of which Mr. C. H. Thompson is general manager.

The first machine built was a crude experimental affair, merely intended to ascertain if the peculiar motion given the scoop blade would actually shovel coal from the ground and deliver it to a conveyer. The machine was built on a wooden frame mounted on ordinary mine-car trucks. It had a rubber-belt conveyer to take the material delivered by the shovel back to the car and a motor with necessary gearing to drive the conveyer and the crank-shaft of the shoveling device. This machine loaded several cars of coal and proved by its action that the shovel principle was correct. It was then abandoned and a complete machine designed and built.

Fig. 1. Coal-Loading Machine. Shovel Moving into Coal

Fig. 2. Coal-Loading Machine Loading into Conveyer

This second machine was put to work in the Wind Rock Mine and thoroughly tested at different times extending over a period of nearly 3 years. During this time the rear conveyer was changed to suit larger cars. The machine did excellent work, loading 1¼-ton cars in about 2 to 3 minutes. However, the Wind Rock Co. was unable to keep the machine supplied with cars and the handling of a large number of cars became a serious matter. Owing to these difficulties the Wind Rock machine loaded only 60 to 70 tons per day, whereas it had the capacity and ability to load 100 to 125 tons if the car supply had been properly regulated. Owing to these circumstances the owners of the machine discontinued the experiments at Wind Rock and built another and heavier machine for a somewhat larger seam of coal. In Fig. 1 the machine is shown pushing the shovel scoop into the broken coal at the room face, and in Fig. 2 the scoop is shown subsequent to discharging its load on the traveling belt, and prior to its return to the coal pile. The experimental runs with the Wind Rock machine having furnished data for other machines it was withdrawn from active service, although it was in good condition and at present is on exhibition and running in the main building of the Appalachian Exposition, at Knoxville.

The next machine was designed and built for a 5-foot seam of coal at Middlesboro, Ky. Upon completion of the machine and before installing, it was found that the mine entries and

wires were too low to allow its passage, and as the United States Coal and Oil Co., at Holden, W. Va., had asked for this machine, it was decided to put it in their mines. This company has one of the finest plants in West Virginia and every facility and convenience for handling and caring for mechanical equipment. It also has a very fine seam of coal averaging 6½ feet and not varying more than a few inches from this at any place. The floor is exceedingly hard and smooth, the roof is perhaps the best of any seam in this country. Rooms are driven 36 feet wide and absolutely no props are used in the mines. The company uses large low cars well adapted for loading with the machine.

The coal at Holden is a peculiarly, hard, tough bituminous coal, known as No. 2 gaseous. Its coherent qualities make it somewhat difficult to shoot down and nearly as hard to shovel as large lumps of limestone. However, in spite of the physical

The territory in which the machine worked consisted of seven rooms recently turned off the airway in No. 5 mine, a sketch of which is given in Fig. 4. Much of the work was done on curves. The rooms ranged in width from 21 feet to 27 feet and all but two had two tracks. The rooms were on the butt end of the coal which greatly increased the difficulty of shooting coal down.

The company had no difficulty whatever in keeping the machine supplied with cars, which were hauled to and from the side track on the entry by a mule.

The crew of the machine consisted of four men, as follows: One machine runner, one man in front, and two men to handle cars and pick slate.

The United States Coal and Oil Co. was much pleased with the results obtained. The machine used at the Holden Mine is shown in plan and elevation in Fig. 3.

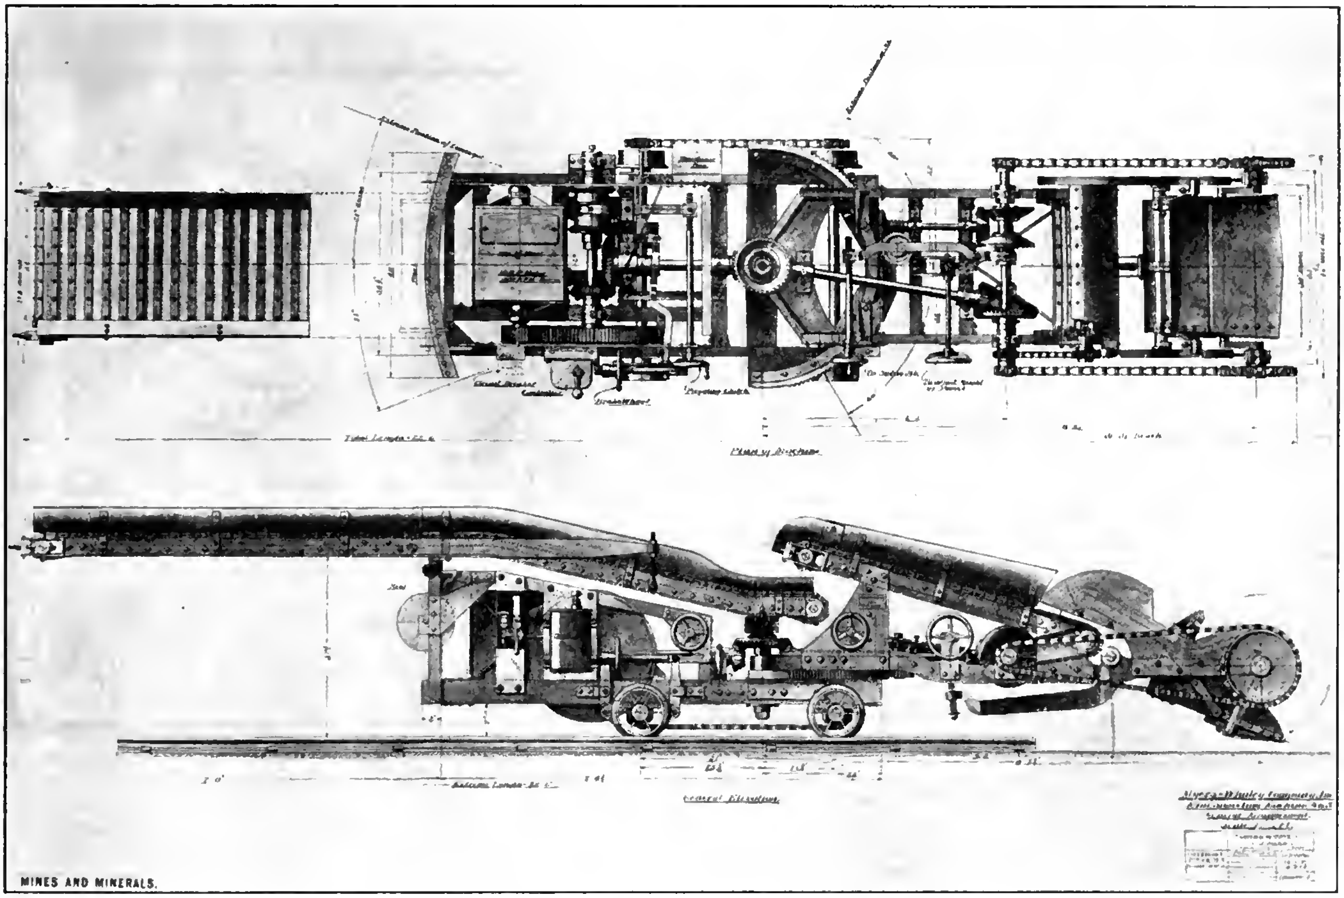


FIG. 3. PLAN AND ELEVATION OF COAL-LOADING MACHINE

condition of the coal the machine was very successful in handling it.

During six days of its operation a record was kept of all features of the run, cars loaded, time required to load and shift, time to change the machine and time lost for any cause. During the six days the machine loaded 768 tons of coal, the time of loading and shifting cars being 36 hours, 6 minutes; time changing the machine 4 hours, 21 minutes; time lost, 14 hours. 33 minutes; total time, 55 hours. The machine loaded out four rooms per day and part of the lost time was due to delay in shot firing, in waiting on smoke to clear out of the room, and other items not chargeable to the machine. A copy of daily report of the last day of this test run is given in Table 1.

In spite of the delays and lost time the machine averaged 128 tons per day. The lowest day's work (due to lack of coal) was 90 tons, and the highest 150 tons. The average time of loading and shifting a car was 8.4 minutes, or 21.3 tons per hour.

The front part or jib of the machine on which the shovel is mounted swings laterally as directed by the operator covering a space 19 feet wide. The yoke supporting the shovel is provided with a vertical adjusting device, operated by a hand wheel, to adapt the shovel to work above the track or to shovel over any irregularities in the bottom. The shovel can be raised to clear the track or lowered to shovel 8 inches below the top of the rail. As the shovel scoop is 30 inches wide it receives lumps up to this size. The rear conveyer can be adjusted vertically, and shifted laterally so that cars can be loaded on sharp curves or even on a track parallel to the loading track. This conveyer is a moving apron 24 inches wide and forms an excellent table from which to pick slate before it goes into the car. The machine is provided with propelling gear and is controlled by hand wheels located on one side and convenient to the operator.

The plan of working face in a Holden Mine room, shown in

Fig. 5, also shows the method of loading out a room from two tracks by means of the machine.

This is the first description of the machine given to the public; up to this time the machine has been carefully developed and tried out and it is no longer an experiment.

There are numerous other applications of the machine which have been considered; for example, as a traction shoveling

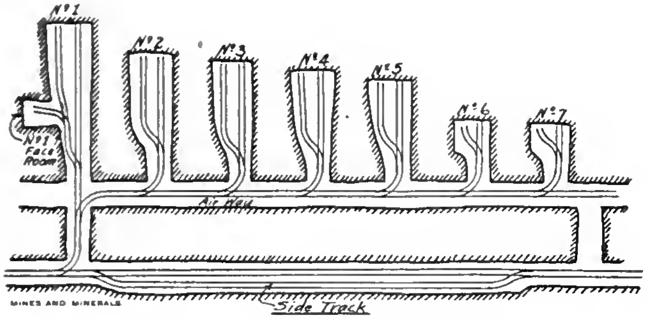

Fig. 4. Mine Plan for Machine Loader

device for stock yards and similar work, to load wagons or railroad cars. A machine has also been designed especially to work on coke-oven wharves to load coke into railroad cars. The machine is adapted to loading broken rock from tunnel faces, although such machines must be specially designed for the purpose.

Table 1. Loader's Daily Report

Holden, W. Va., August 31, 1910

Sixth day of official test run.

Time Started 7:30 A. M.	Time Started 12:33 P. M.	No. of Men Working:
Time Stopped 12:03 A. M.	Time Stopped 5:32 P. M.	A. M. 4
Total Time A. M. 4 hours 33 minutes	Total Time P. M. 4 hours 59 minutes	P. M. 4

Working Place	Time Loading and Shifting Cars	Time Changing Machine	Time Lost	Total Time Consumed	Cars Loaded
No. 6 room......	1 h.	3 m.	1 h. 1 m.	2 h. 4 m.	24 tons
No. 7 room......	2 h. 29 m.	25 m.	23 m.	3 h. 17 m.	54 tons
No. 1 face room (neck)........	1 h. 45 m.	24 m.	26 m.	2 h. 35 m.	33 tons
No. 1 room......	1 h. 25 m.	11 m.	none	1 h. 36 m.	39 tons
Totals......	6 h. 39 m.	1 h. 3 m.	1 h. 50 m.	9 h. 32 m.	150 tons

Remarks:—Time lost No. 6 room — loose setscrew on conveyer sprocket tightened between 7:30 and 8:15 = 45 minutes. Off track 7 minutes; pulling down coal 9 minutes. Total, 1 hour 1 minute.

Time lost No. 7 room—waiting on driver 1 minute; off track 5 minutes; pulling down coal, 17 minutes. Total, 23 minutes.

Time lost No. 1 face room neck—off track, 9 minutes; pulling down coal 17 minutes. Total, 26 minutes.

Time lost No. 1 room—none.

J. B. Haile, Machine Runner.

Report by W. Whaley

TRADE NOTICES

The Denver office of the Jeffrey Mfg. Co. has been removed from 1711 Tremont Place to the First National Bank Building.

The Pittsburg Testing Laboratory has moved its New York office to 50 Church Street, Hudson Terminal Building.

The Ohio Brass Co., Mansfield, Ohio, has issued a New Mine Catalog, No. 9, which is a valuable reference book for mine managers, superintendents, and mine electricians.

The Carnegie Steel Co., of Pittsburg, Pa., has issued a pamphlet on Vanadium Steel which will be found interesting and useful by all steel workers.

The Minneapolis Steel and Machinery Co., of Minneapolis, Minn., have been designing, manufacturing, and erecting mining, milling, and smelting structures for some years. Some of the buildings they have designed have been photographed and incorporated in a neat pamphlet for distribution. This company's structures are all steel.

Owing to the great increase in business in the vicinity of Atlanta, Ga., and Rochester, N. Y., the H. W. Johns-Manville Co. has recently opened a new office in each of these cities. The Atlanta office is located in the Empire Building, in charge of Mr. W. F. Johns, who has been traveling this territory for the company for a number of years, and the Rochester office is located at 725 Chamber of Commerce, in charge of Mr. H. P. Domine, formerly with the Buffalo branch of the company.

The Stromberg-Carlson Telephone Mfg. Co. has had its factory buildings at Rochester, N. Y., photographed from a height of 65 feet. This is in the form of a souvenir postal card, which shows the immense area covered, together with the system of lighting and ventilation.

On September 1, the General Chemical Company of California, succeeded to the business and connections formerly enjoyed by the Peyton Chemical Co. Unfinished transactions, as well as future business, will have the attention of the new company. All

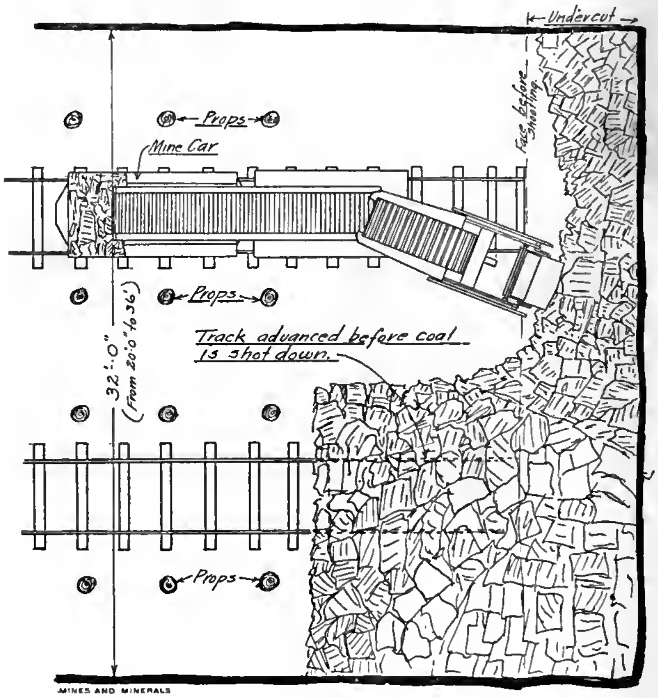

Fig. 5. Working Face in Room, Holden Mine

communications should be addressed to General Chemical Company of California, Royal Insurance Building, San Francisco.

The Ball Engine Co., of Erie, Pa., has recently installed high-class engines at plants of the following coal companies: Bailey Wood Coal Co., Wood Bay, W. Va.; Rosiclaire Lead and Fluorspar Mines, Shawneetown, Ill.; Sycamore Coal and Coke Co., Williamson, W. Va.; West Kentucky Coal Co., Wheatcroft, Ky.; Webb Coal Mfg. Co., Rayford, W. Va.; Barnes & Tucker Co., Barnesboro, Pa.; Gulf Smokeless Coal Co., Tams, W. Va.; Big Sandy Coal and Coke Co., Marytown, W. Va.; Pittsburg Coal Co., Cecil, Pa., and Burdine, Pa.; By-Products Coal Corporation, Solvay, Ill.; Pittsburg-Belmont Coal Co., Neffs, Ohio.

A feature of the Beaver die stock, in addition to not having to change dies, is the universal chuck which centers and grips all sizes of pipe by shifting a cam. It is complete within itself, no loose parts to change or get loose. Since only one set of dies is used only one set must be purchased when dull, and the usual expense from broken grip screws and lost bushings is eliminated, also the lead screw is a small separate piece for cheapness in repairing in case of wear. It is made by The Borden Co., Warren, O., whose No. 11 catalog, showing a complete line of die stocks, may be had on request.

SAMPLING COAL AND COKE*

By E. G. Bailey, M. E.†

(Continued from October)

Sampling Coke.—The same general method can be used in sampling coke, whether at beehive ovens, by-product ovens, gas plants, blast furnaces, or elsewhere. Coke is much more homogeneous than is the average coal and a much smaller original sample than would be required from coal of the same size is usually ample. As a rule, coke is made from slack or crushed coal, and the present tendency in its manufacture is to pulverize all coal or slack to half-inch or finer in order to make a more homogeneous and stronger coke. The handling and mixing of the coal in the bins, larries, and ovens also minimizes errors arising from variation in the quality of coal from different parts of the mine. At some by-product coke plants, where coal from different mines and mining regions is mixed, the uniformity of coke depends upon the thoroughness with which the coals are mixed.

Taking Samples from Vessel Cargoes, Mechanical Conveyers, Carts, Stock Piles, Bins, Etc.

No guide, corresponding to the size and quantity of impurities in coal, can be adopted in determining the size of sample of coke which should be taken to secure any desired degree of accuracy, but practice has proven a 100-pound original sample to be ample in most cases. If extremely coarse coal containing a high percentage of impurities has been used to make the coke, a larger sample should be taken. A safe guide is to take the same weight of coke for a sample as would be required to be taken from the coal of which the coke was made in order to obtain the same accuracy.

While different pieces of coke vary in their appearance, some being very bright and silvery, others dark and discolored, the physical appearance is no indication of the percentage of ash, sulphur, or phosphorus present, hence it is difficult, if not impossible, for one to select either a good or poor sample, so far as chemical analysis is concerned. It is better to select the longest and most slender pieces in taking a sample, in order that the coke from the top to bottom of the charge may be represented, and selecting the more slender pieces enables a greater number of pieces to be taken from more different parts of the ovens, or shipment, for the same total weight of sample. If the coke contains much large slate and bone, these impurities may predominate in the shorter, thicker pieces of coke, in which case the larger sample should include pieces of the various sizes and shapes. In general, samples taken from the coke yard should consist of long slender pieces, selected proportionally from the different ovens. Samples of coke from railroad cars should be taken while the car is being unloaded if possible, but the chance for error in sampling from the top of the car is much less than in sampling coal in this manner.

There is one point of particular importance which should be remembered, especially when crushing the coke by machine or pulverizing it in the laboratory—this is the abrasion of iron or other material by the coke and consequent contamination of the sample with such material. Coke is extremely hard and readily cuts iron or even hardened steel, and errors arising from this cause have been known to increase the percentage of the ash.

Sampling Ashes.—Samples of ashes and refuse from various kinds of furnaces are frequently taken for the purpose of determining the extent of loss in the form of combustible matter. It is very important that such a sample should contain a proportional part of all refuse whether taken from the pit or drawn from the grates when the fire is cleaned. Two or more shovelfuls should be taken from each wheelbarrow or car of ashes taken from the furnaces during at least one cleaning period, or the period covering the total time between fire cleanings.

If the percentage of combustible contained in the refuse alone is desired, no attention need be given to the moisture in the ashes while taking and reducing the sample, as the analysis of this material should be on the dry basis; however, if the ashes are being weighed, a special moisture sample should be taken and the weights corrected to the dry basis. When mixing and breaking samples of dry refuse to be used for the combustible determination, it is better to dampen them to prevent loss of the fine dusty ash, as well as for the convenience of the sampler.

It is often desirable to sample separately the refuse from the ash pit and that removed from the grate when cleaning fires, especially in boiler tests used for comparing the efficiency of different types of grates and stokers, or the sifting tendency of different kinds of coal. The large clinkers, which are generally present, necessitate a larger sample being taken for the sake of accuracy, for it is evident that an extra 10-pound clinker in a 100-pound sample would cause an unallowable error. The necessity for taking a large sample and the possible error may both be minimized by picking out all clinkers larger than 1 inch, and weighing them separately from the ashes, and recalculating the analysis to include this percentage of clinker as ash. The additional information gained by determining the amount of actual clinker is well worth the trouble of picking them out.

The quantity of sample taken from ashes and refuse, free from large clinkers need not exceed 200 pounds, but with large clinkers present the sample should be two or three times this size.

Shipment of Samples.—Samples sent to the laboratory should consist of 3 pounds or more of 4-mesh or finer. The most convenient container is a $500 coin sack, for all but the special moisture samples. The latter, which have been described, should be shipped in hermetically sealed tin or glass jars, preferably the ones in which they were accumulated, unless proper facilities are available to crush and mix them. If the 2 quarts or more of this special moisture sample can be rapidly crushed in a bone mill or similar equipment and returned directly to the original jar, it can then be thoroughly mixed by shaking, and a few ounces put into a small can or jar which can be hermetically sealed and placed in the coin sack with the other sample taken from the same material. If glass jars or bottles are used for this purpose, they should be enclosed in a mailing case or similar precautions taken to prevent the breakage of the bottle in shipment.

All samples should be plainly marked, giving the name or number of the sample, date, and by whom it was sent.

Reduction of Samples in the Laboratory.—No matter how much care is used in taking a representative sample and reducing it to a few pounds of 4-mesh size, it may still be made valueless through improper methods of further reducing and pulverizing it in the laboratory. It is necessary to maintain a definite relation between the size of the coal or coke and the quantity of sample to be divided whether the sample weighs 1 ton or 1 gram. The prevailing tendency in many laboratories is to reduce the sample to a smaller quantity than it should be for a given size, which may cause an error of several per cent.

The variation between the results obtained in different laboratories is more often traceable to error in reducing the samples than to any other one cause. Whenever a sample is to be divided and sent to different laboratories to check the accuracy of an analysis, it should always be pulverized to 60-mesh or finer and thoroughly mixed before dividing, in order to eliminate a chance for inaccurate reduction of the sample. As a guide in reducing a sample the following table should be used:

Size of Coal	Sample Should Not Be Divided to Less Than
4 mesh	1,100 grams
8 mesh	120 grams
10 mesh	55 grams
20 mesh	3 grams

DATA OF PETRODYNAMICS

Written for Mines and Minerals, by R. Dawson Norris Hall

The Mode of Action of Shear Showing How It Results in the Breaking of Rock Strata

Shear is the sliding of one part of a body past another part, and the strain caused by the shearing stress is resisted by the shearing strength of the body. This shearing strength is similar to friction for it acts along the breaking surface known technically, as the "surface of rupture." Friction, like shear, is a resistance to sliding, but whilst friction is the result of lack of smoothness in touching surfaces whereby they indent one another as a pinion sets its teeth into a rack, shearing strength arises from the actual sticking or cohesion of the two surfaces to one another, owing to the presence of certain cementing materials. In carboniferous measures these may be bituminous cements or the oxides, hydrates, and silicates of iron and alumina, or many other compounds. In all shearing, when pressure holds the two surfaces together, the shearing strength is augumented by the resistance the material offers to friction when the two surfaces are parted.

Clearly not all breaking is shearing. If an iron bolt is loaded with weights, as in Fig. 1, it will break at right angles to the direction of the pull of the weights. Obviously such a breaking is not a shear, for instead of the pull being along the breaking surface, it is approximately at right angles to it.

As has been said, friction best illustrates shear. Let a block A, Fig. 2, be taken resting on a level surface B. Attach a light string C to the end of the block and pass it over a pulley D. We can increase the weight E, which is hung from the string C till the block moves steadily forward.

The resistance to motion is equal to the weight E (when E is of such weight that the block does not move with increasing speed), and it acts along the touching surfaces of A and B; namely, along $a\,b$, and the force or weight E acts along the line $d\,e$ parallel to $a\,b$. Thus the line of the pull is parallel to the resisting surface (which corresponds to the breaking surface in the case of shear). It is a matter of no importance, within certain limits, where the string is attached to the block A, the pull of the weight will equal the resistance on the surface represented in the drawing by the line $a\,b$.

There may be several light strings like C attached to A; namely C_1, C_2, C_3, as in Fig. 3, passing over pulleys D_1, D_2, D_3, with weights E_1, E_2, E_2, loading their extremities. The strain on $a\,b$ will be equal to the weights E_1, E_2, and E_3, added together. If A be glued to B, the resistance to motion will be increased, but E_1, E_2, and E can any one or all of them be increased till breaking takes place. Only we must remember that, when breaking of the glue occurs, instead of the block A being drawn with a slow motion it will be pulled with a rapidly increasing motion toward the pulleys D_1, D_2, and D_3, for the weights E_1, E_2, and E_2 as now increased will more than overcome the resistance offered by the friction of A on B as soon as the glue is sheared across.

Summing up the principles discovered, they are these:

1. Breaking, as here considered, is parallel to the direction of the breaking forces.

2. The distance of the breaking forces from the breaking surface does not materially affect their action.

3. The resistance to breaking is equal to the sum of the breaking forces, up to the time when the breaking takes place.

4. When once breaking takes place no further resistance remains, except that which is furnished by friction.

Suppose that the block A and the surface B with supported pulleys, be turned at right angles, as shown in Fig. 4, so that the weights E_1, E_2, and E_2 hang down freely. Then if the glue binding A to B be considered unbroken, the resistance of the glue will be a resistance to vertical shear and the shear will equal the weights of E_1, E_2, and E_2, together with the weight of the block A. When the surfaces at $a\,b$ break apart, no further resistance remains, there being no pressure on $a\,b$ to create friction, consequently the block A falls with a rapidly increasing speed and without giving any premonitory warning.

Now, instead of imagining weights E_1, E_2, and E_3, as hung from the block A, we can imagine them resting on the top of the block, as in Fig. 5. (The linear dimensions of the block, it should be noted, have been increased fourfold for greater distinctness.) The weights are there marked E_1, E_2, and E_3, as in Figs. 3 and 4, but they are drawn as circular weights, as is customary in treatises on Strength of Materials.

Imagine the block A cut and glued together just to the left of E_1, E_2, and E_3, at the surfaces represented by $a_1\,b_1$, $a_2\,b_2$, and $a_3\,b_3$. Then, neglecting the weight of the block, the shear on $a_3\,b_3$ will be the weight of E_3; on $a_2\,b_2$, the weight of E_3 increased by the weight of E_2; and on $a_1\,b_1$, the weight of E_1, E_2, and E_3, combined. We have seen this is the shear on $a\,b$. At each of these reglued cuttings must be a resistance, the strength of the glue under shear, equal to the shear at that point, or the glue will break and a part or all of the block fall. Now $a_1\,b_1$, $a_2\,b_2$, $a_3\,b_3$, or any other cuts, real or imaginary, are called "sections" or cuttings of the block A. These principles and definitions enable us to write the following important statement:

1. The shear at any section is the sum of the weights or loads (vertical external forces) to the right of the section, thus the shear on section $a_2\,b_2$ is the sum of the loads to the right of that section; namely, E_1 and E_2.

2. The shear on the section over the edge of the support is as large as any.

We do not need to imagine all these gluings. We can see that the action will be the same if A be a solid block without breaks extending to the left beyond the surface B and so disposed that it cannot topple over to the right. Nor do we need to imagine loads E_1, E_2, and E_3, but may consider them replaced by the weights of the block. For instance, let the block A (let us now imagine it as a beam extending well to the left over support B) be 6 feet long, as in Fig. 6. Let its overhanging portion weigh 6 tons. Then the weight per foot-run, as it is termed, is 1 ton, or 2,000 pounds. Let us represent it by the letter w. Let us represent the length in feet to any section by l and the shear at any section by S_s in pounds. Then we may write

$$S_s = w\,l.$$

If, as in Fig. 6, $w = 2{,}000$ pounds, and if we say that $l = 3$ feet, then S_s, as shown in the figure, $= 2{,}000 \times 3 = 3$ tons. But, it is clear that the weight of the whole beam and all that is put upon it must be supported by the upward lift of the supports or the beam would go down. This lift of the supports we call the reaction, because it opposes the natural action of the beam, which is to fall unless it is supported. Let us call the reaction R, expressing it also in pounds. Then if, as in Fig. 7, the beam be L feet long and loaded with a burden of earth e pounds per foot-run, and if the beam has a weight of w pounds per foot-run

$$R = w\,L + e\,L$$

and we write $R = S_s = w\,L + e\,L$, S_s being the shear at the support. The reaction of the supports together with the loads and weights are the external forces acting on the sections of the beam. The shears and resistances to shear are the internal forces set up in the section to balance the external forces. In Fig. 8 the internal resistances are marked R_1.

When beams are supported at both ends and of equal cross-section throughout, as well as equally loaded, and when both supports are at the same level as in Fig. 8, one support must bear as much as the other and together must uphold the whole weight of the beam. Calling the reaction at one support R_1 and at the other R_2,

$$R_1 = \frac{w\,L + e\,L}{2} = R_2 = \frac{w + e}{2} L$$

The reaction at the right-hand support, that is, equals $\frac{w+e}{2} L$.

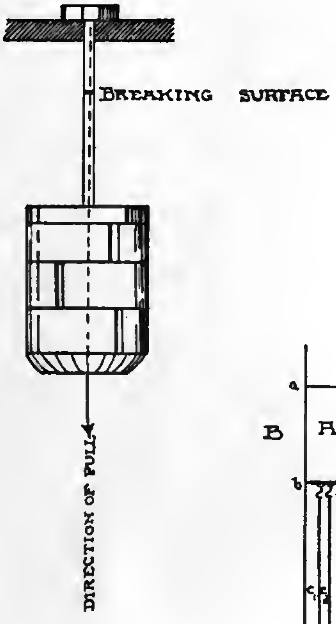

Fig. 1.

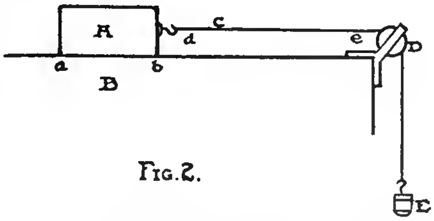

Fig. 2.

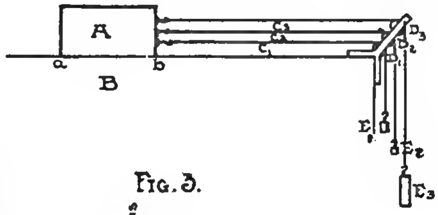

Fig. 3.

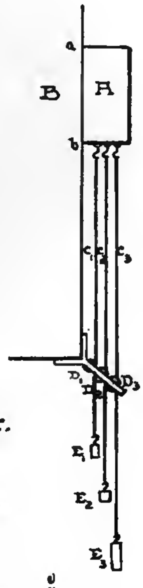

Fig. 4.

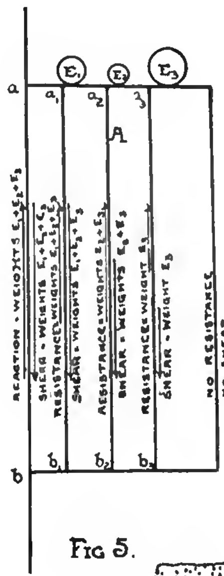

Fig. 5.

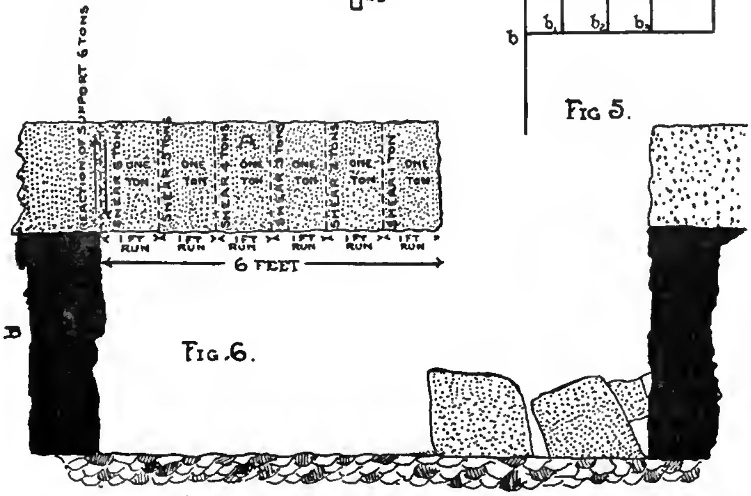

Fig. 6.

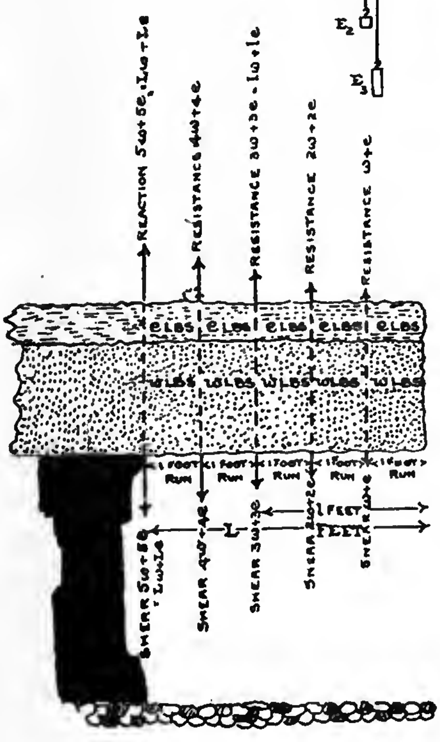

Fig. 7.

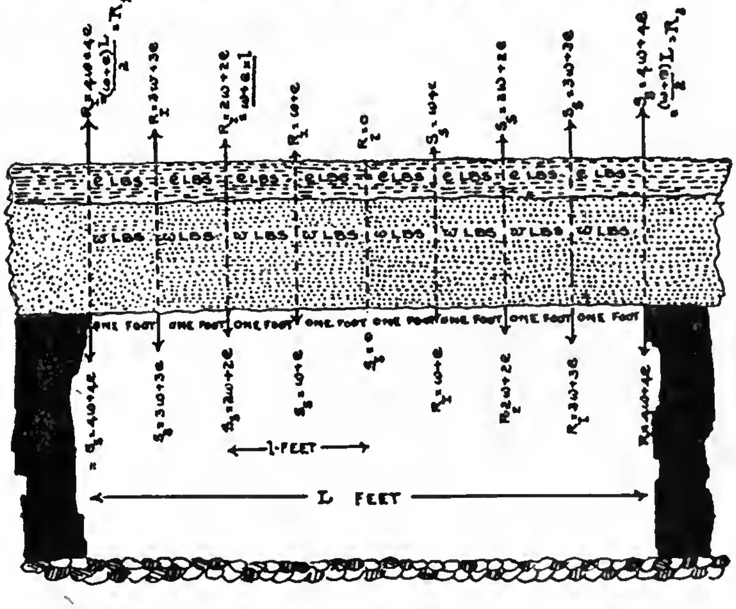

Fig. 8.

This causes a shear upward. A foot away the shear is $\frac{w+e}{2}L$ – the weight of 1 foot of rock (w) and 1 foot of overburden (e).

$$\therefore \quad S_s=\frac{w+e}{2}L-w+e=\frac{w+e}{2}(L-2).$$

The shear l feet away from the reacting support is

$$\therefore \quad S_s=\frac{w+e}{2}(L-2l)$$

when $L=2l$ or when the section considered is half-way between the supports.

Then $$S_s=\frac{w+e}{2}\times 0=0.$$

That is, at the section there is no shear. After the center is passed the shear is increased but the sign becomes "reversed" from plus to minus, the minus member in the equation becoming the larger and overpowering the plus member. To the right of the center the beam breaks so that the part of the beam to the left of any section goes down. On the other hand, to the left of the center, it breaks so that the part of the beam to the right of any section goes down. Thus the sign of the shear is changed from plus to minus. The difference is real but not very important. Restating results we have the following important rules:

1. Shear is zero at the center and at the side of a room or other working is equal to the load on the adjoining rib due to the undermined rock.

2. Shear increases proportionately from the center line of the room out to the pillar.

All this seems contrary to experience. The roof usually breaks in the center, not near the rib. But it must be remembered that only the roof of rooms where the cover is shallow will break from shear and we are now considering shear alone. But shear modifies other forces breaking up a roof mass and grows more important as the roof breaks up and therefore is no less essential a force to be studied, than those of tension and compression. Moreover, just as shear plays an important part on the manner of breaking of present-day mine roofs, so, also, it has played an important part in the fracturing and cleaving processes of past geologic ages.

PEAT BOGS OF IRELAND

Consul H. S. Culver, of Cork, reports on the difficulties that have been encountered in utilizing more extensively the peat beds of Ireland. One-seventh of the entire area of the country consists of bog lands—one bog alone, the Bog of Allen, has an area of 240 square miles and extends across the Central Plain, almost from Dublin to the Shannon.

Although peat has been for ages the fuel of the poorer classes in the remote districts of Ireland, by whom it is used in the same manner as wood in open fireplaces, no process has yet been discovered for converting it into a desirable and economical commercial fuel. Many schemes have been tried in Ireland in recent years, and extensive and well-equipped plants have been erected in different parts of the country at enormous expense in an effort to convert the peat into a profitable fuel for manufacturing purposes, but so far all efforts have been disappointing. It was thought at one time that by applying pressure to the product in its green and wet state and compressing it into a convenient shape, like briquets, it could be successfully used in the place of coal, but in most cases this process has had to be abandoned. So long as the briquets can be kept free of moisture they remain firmly intact, but the least moisture causes them to disintegrate and crumble to pieces. Numerous extensive plants are idle in the country waiting for some enterprising company to take hold of them and through some new process or through further experiments convert these bog lands into mines of wealth.

COAL NOTES

In an interview in New York, just before he sailed for Europe, General F. M. de Sousa Agular, of Rio de Janeiro, who has been in this country as a special commissioner from Brazil on a trade mission, authorized this statement: "Brazil has enormous iron deposits practically undeveloped, but no coal. I came on a special mission for the purpose of establishing closer relations with your manufacturing industries, especially with your great steel companies."

Forty-seven damage suits brought as a result of the Browder Mine explosion on February 1, have been settled. Thirty-four men lost their lives in this explosion, which was one of the most disastrous in the annals of Kentucky coal mining. The refusal of the indemnity company, in which the coal company was insured, to contribute to the settlement made it doubly hard for the Elk Valley Co. to settle; however, they did so, to the satisfaction of the lawyers at least.

Nearly 1,000,000 tons of coal was handled over the piers of the Norfolk & Western, Chesapeake & Ohio, and Virginian railways during the month of August. This tonnage broke all previous records. The Norfolk & Western shipped 391,335 tons from Lambert Point, the Virginian 116,870 tons from Sewalls Point, and the Chesapeake & Ohio 388,048 tons from Newport News, a total of 896,253 tons. Of the tonnage shipped from Norfolk 91,363 tons were foreign cargoes and 22,023 tons for bunker use of foreign vessels, a total of 113,386 tons. While the August tonnage was a surprise, it is predicted that there will soon be shipped more than 1,000,000 tons a month.

During a recent visit to the Pacific coast, William Mackenzie, of Mackenzie & Mann, told representatives of the press of notable improvements to be made at the Dunsmuir collieries, in British Columbia, which he and his associates purchased for $11,000,000 a number of months ago. It is said that $3,000,000 will be spent on development and equipment. W. L. Coulson, an American, became manager of the mines recently. The Dunsmuir collieries have been one of the chief sources of coal supply on the Pacific coast for years past and while the chief intent of the purchase was to secure a fuel supply for the Canadian Northern when it has been built through, the large trade of the present day will be exploited to the fullest extent by the provision of the most up-to-date facilities. Apparently the undertaking will rank well up with the largest companies on the continent in due course of time.

The more it is considered, the greater appears the heavy loss which the miners of Illinois sustained by reason of the late strike. Corresponding gains were made largely by the non-union miners of West Virginia, though the distribution of gains went through a number of other states.

It seems certain that the loss of wages sustained by the Illinois miners covers at least 20,000,000 tons. The annual coal production in Illinois is in round numbers 50,000,000 tons. The men have been idle practically six months. Production during the summer months is on the average considerably below that for the winter season, but a very large percentage of the Illinois product consists of steam coal, the consumption of which is fairly uniform throughout the year. And moreover the mines at the expiration of the six months' idleness are so crippled in various ways that production during the next six months will be considerably below par. One prominent operator says he doubts if much more than half the usual winter tonnage is mined in Illinois. On the whole, 20,000,000 tons is believed to be a conservative estimate of the tonnage decrease in Illinois. The wage cost of this tonnage under the increased scale, adopted at the Cincinnati convention, a wage scale which the miners might have had at the outstart, is about $1 per ton, 90 cents under the old scale and 10 cents additional granted by the Cincinnati convention, a total of $20,000,000 in wages actually lost by the Illinois miners.

To offset this loss the miners have gained for the next

18 months an average increase in wages above the Cincinnati scale of 2 cents a ton, 3 cents in Franklin and Williamson counties, 2 cents in the northern field, and $1\frac{1}{2}$ cents per ton for shot firers in other districts of the state. Assuming that the production in Illinois will be for the next six months 30,000,000 tons and that next year the high record will be reached, 50,000,000 tons, the miners' gains of 2 cents per ton on a production of 80,000,000 tons is $1,600,000, as an offset against the actual loss of $20,000,000. It would take 20 years for the men to make up that loss of $20,000,000, for their increased wages of 2 cents per ton on 50,000,000 tons annually amounts to an even $1,000,000 per year.

It is ridiculous to assume that the new scale will last that long. It certainly will not if history repeats itself. A serious loss to the Illinois miners is therefore the inevitable conclusion as a consequence of the recent strike.—*J. B. M., in Coal Trade Journal.*

A valuable seam of shale recently discovered near the Seafield works of the Pumpherston Oil Co. will be of advantage to the Scotch mineral oil industry, the expansion of which is measured only by the available supply of native oil shale and the products of which are in increasing request. Boring operations have been in progress for some time past in this district, and the shale now revealed is said to be both thick and rich. New pits will be at once opened and a considerable impetus given to local employment.

On the Thorosk estate, near Stirling, a good seam of coal, the existence of which has been known for some time, is now about to be worked, the property having been acquired by Messrs. Archibald Russell & Co., who have the neighboring Fallin collieries. Thorosk lies adjacent to the Bandeath colliery, the coal from which is steam coal. The Thorosk coal, however, is more suitable for domestic consumption.

At Pittston, Pa., the surface has been disturbed by a cave. In one location, where there was a well, "marsh gas" accumulated in such quantities that the owner covered over the top and piped the gas to his kitchen stove. In another case, a pipe which was driven in the ground about 18 inches, tapped sufficient gas to run an argand burner continuously.

The record for freight tonnage on the middle division of the Pennsylvania Railroad between Altoona and Harrisburg, Pa., established about a year ago, was broken on the afternoon of August 18, when a coal train over $1\frac{1}{4}$ miles long, consisting of 120 steel cars having an individual capacity of 100,000 pounds, was hauled over the road. The record made a year ago was 105 cars. Telephonic communication was established between the engine and the last vehicle, and the engine driver was directed by the officials at the rear end of the train. An average speed of more than 20 miles an hour was maintained over the division.

The Illinois Mine Rescue Station Commission has appointed Mr. Richard Newsam, of Peoria, manager of the three stations provided for by the law. The southern station will be located at Springfield, the northern one at La Salle, and another one at Benton. Contracts for the buildings have been let which call for the buildings to be completed not later than January 1, 1911.

The Hacklebernie coal mine about 2 miles from Mauch Chunk, Pa., was the first coal mine opened in the anthracite regions. The mine, which has been operated during the past few years by David E. Pursell and James M. Breslin, under the firm name of the Hacklebernie Coal Co., has been closed by the Lehigh Coal and Navigation Co., its owner, and will probably never be operated again. It was opened shortly after the discovery of anthracite coal by Philip Ginter, a hunter, at Summit Hill, in 1794, and it was from this mine that coal was first taken and hauled to Mauch Chunk, and there loaded in arks and sent by river to Philadelphia to market. This was long before any railroad and many years before the Lehigh canal was built. The Lehigh Coal and Navigation Co. ceased operating this mine as soon as a railroad was built throughout the Panther Creek valley, because coal in that region could be mined and transported more cheaply than at the Hacklebernie Mine, where coal had to be hauled in wagons. There is still coal to be found in abundance at this mine, but the Lehigh Coal and Navigation Co. will not operate it on account of its many collieries at other and more convenient places. This mine is crossed by the famous Switchback, about 1 mile from Mount Pisgah, and is prominently pointed out to passengers taking a ride on that famous road as the pioneer anthracite mine in the entire world.

The people in New England, New York, and New Jersey are greatly interested in the verses of the Springfield *Republican* poet. The New York *Sun* declares that his song, "Talk To Me About Coal" has not been surpassed in the interest manifested by the public since the time when "Drink To Me Only With Thine Eyes" appeared.

A miner, Joseph Tressa, fell down the shaft at the Forty Fort colliery, near Pittston, Pa., and after brushing the dust from his clothes and picking a speck or two of coal from his eye calmly proceeded back to his room in the 11-foot seam and continued his day's work. Just how far Tressa fell is not known, but the shaft is 1,000 feet deep. Tressa boarded a cage about to descend and gave the signal for the 11-foot seam. When the carriage stopped at this landing he alighted and signaled all right. The cage immediately descended toward the red-ash bed, 900 feet below. Just how it happened Tressa does not know, but the moment the cage disappeared he lost his balance, fell, and catching up with the cage held to the top just above the shield. When the bottom was reached he called to the footman and the cage was lowered so that he could jump down from his perch. This method of falling down shafts is highly recommended, besides proving that a man in an office elevator cannot bump his head on the elevator roof no matter how swift the elevator descends.

The Buck Mountain colliery, near Weatherly, which was once run by the late William Spencer, of Pottsville, is to be reopened by the Lehigh Valley Coal Co. It will be remembered that William Spencer was the first to call on the governor for troops during the "Molly McGuire" excitement. After finishing work at Buck Mountain he went to West Virginia and opened the Bottom Creek colliery, which his nephew, Mr. Samuel Patterson, now manages.

Consul Augustus E. Ingram forwards from Bradford a series of English press accounts on the extension of the Yorkshire coal fields, which indicate that they have thirty-five thousand millions more tons of coal available for mining than was supposed.

WORLD'S PANAMA EXPOSITION

The contest between New Orleans and San Francisco for the World's Panama Exposition in 1915 runs merrily on. The New Orleans Exposition Committee is distributing throughout the country a "logical point map," according to which there are 70 cities within an average distance of 900 miles from New Orleans with a combined population of 20,000,000, while within the same average distance of San Francisco there are only eight cities, having a combined population of 1,000,000 people. New Orleans' principal claim is that if the Exposition be given to San Francisco the people of this country would be penalized $200,000,000 in railroad fare over what it would cost to go to New Orleans.

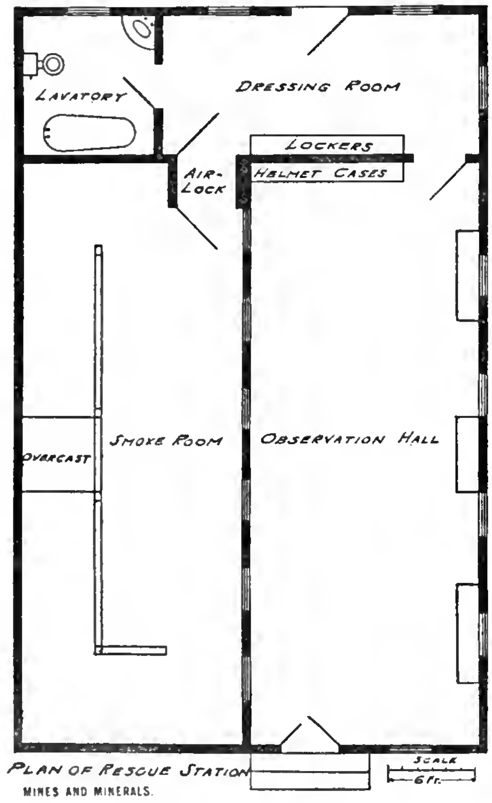
Breccia in the form of rough blocks being similar in texture and uses to marble is dutiable, under the application of the similitude provision of paragraph 481, at the same rate as marble in rough blocks, at 65 cents per cubic foot under paragraph 111, tariff act of 1909.

RESCUE STATIONS IN ILLINOIS

*By R. Y. Williams**

Design and Equipment of a Joint Rescue Station—Plan for Stations in Illinois

The discussion of any problem affecting coal-mining methods applicable to such a state as Illinois, is of considerable interest, because Illinois stands second in the list of the 27 coal-producing states, and holds in reserve more bituminous coal than any other state in the Union. It is also the second largest producer of bituminous coal. This position, however, has been attained by the sacrifice of many human lives and the loss of millions of tons of coal. The indefinite continuance of these conditions would be most unfortunate. But coal-mining engineers are facing these problems seriously. Already the explosiveness of coal dust has been demonstrated, methods of its control investigated, a list of permissible explosives has been published by the government, and a paper on some phase of the efforts now being made for the conservation of that greatest of all natural resources, human life, it is believed will be of value.



Plan of Rescue Station

The investigations in this field are proceeding along two lines—the prevention of mine accidents, and the work of mine rescue. While the first is by far the more important problem, it is nevertheless apparent that calamities such as mine explosions and fires are of such frequent occurrence as to be a constant menace to the safety of the men and of the mine. For these reasons the work of rescuing life and saving of property are urgent problems in present-day coal mining. With this in mind, the following has been written in an endeavor to present a general scheme for Joint Mine Rescue Stations in Illinois.

Early in March, 1909, the United States Survey, in cooperation with the State Geological Survey and the University of Illinois, established at Urbana, Ill., a mine-rescue investigation station, which is a branch of the Central Testing Station at Pittsburg, Pa. This substation is equipped with oxygen helmets, and has a gas-tight room resembling a coal mine, in which miners may test the efficiency of modern breathing appliances. Already this mine-rescue laboratory has been visited by many operators and inspectors; a large number of miners have been trained in the theory and practice of rescue work; and considerable assistance has been given on the occasion of several mine fires and explosions. One station, however, cannot render adequate service in a state having more than 400 large shipping mines scattered throughout an area of 275 by 180 miles. In fact, it was not the intention to establish at the Urbana station a permanent rescue corps to act in the event of mine disasters in ordinary rescue work. This station was established primarily to supply the equipment and trained assistants required for the study, by the Survey experts, of mine explosions in the Illinois-Indiana-West Kentucky coal field, and in the hope that the station would offer a means of demonstrating modern mine-rescue practice to the mining fraternity of this field.

When an explosion or fire occurs in a coal mine, conditions are usually such as to require that the men entering the mine be protected by helmets, which must be supplied as quickly as possible. It is, therefore, necessary, both for rescue and investigation work, that stations should be within easy reach of each important coal field or division of the field, so that the trained experts can reach and enter the mine promptly following the disaster. Were each mine in the state equipped with a complete rescue station and manned with a corps of trained rescuers, we would have ideal conditions for the recovery of life and preservation of property after a calamity. But, unfortunately, these stations are quite expensive; equally unfortunately, the present selling price of coal is so low that the small margin of profit is already a matter of much concern, so, unless some remedy for this condition can be found, but few individual mine owners, I fear, would feel warranted in authorizing such an expenditure of money. In order to overcome this obstacle and still obtain the benefit of the modern mine-rescue methods, the suggestion of joint rescue stations, it is believed, should be of great value.

In general, by a joint rescue station is meant one specially designed and equipped for a particular group of mines; located centrally to each of such mines by natural or special transportation facilities, and financed either on a "per ton" or a "share-and-share-alike" basis by each mine benefited. At such a station, at stated intervals, a squad of men from each mine could report for training in rescue methods under the direction of an experienced instructor, assisted if possible by a physician. From such station the rescue paraphernalia could be furnished without delay in the event of a calamity befalling any mine of the group. There are four divisions of the subject which may be amplified:

1. Design and equipment of a joint rescue station.
2. Character of the training to be given at the station.
3. General advantages that may be derived from the stations.
4. Plan for rescue stations.

Design and Equipment of a Joint Rescue Station.—Breathing appliances were invented abroad and their use established long before we in this country recognized their value. But if we study the design and equipment of these foreign stations, we might be discouraged in an endeavor to copy them. Conditions abroad and in this country are entirely different; and valuable as is a study of foreign methods, we could not afford the luxury of such structures as the Howe Bridge Station in England. There are, however, certain requirements that must be followed in design. The station building should contain a gas-tight room, 40 feet long by 20 feet wide and 10 feet high. The interior of this room should be fitted to resemble a mine and to afford opportunity for the practicing miner to do work similar to that required in the event of an actual disaster. In

* Paper presented before Western Society of Engineers, May 4, 1910.

a number of stations already built in this country, it has been the practice to divide this room longitudinally and to construct an overcast on one side, the aim being to present a passageway about the room, the travel over which would represent the journey of a rescue party through the entries of a mine. This room should be furnished with mine props and a frame consisting of four pieces of 6″×8″ timbers joined together in the shape of a square and tied with two iron rods, in which props may be set and capped with wedges; also brattice cloth, stretchers, and a canvas dummy filled with sand and sawdust so as to weigh about 165 pounds. In order that men may gain confidence in working in the presence of gas, sulphur candles may be burned in this room to form a chokedamp; charcoal may be fired in open salamanders yielding blackdamp; hydrogen disulphide may be generated producing stinkdamp, or ordinary dense smoke may be obtained by burning dampened excelsior.

Adjoining the smoke room and separated from it by a glass partition, should be an observation room where visitors may sit and view the work of the miners. Here, too, the instructor may observe and record the performance of each member of the rescue squad. In this room there should be wall cases in which the rescue apparatus may be hung and protected from dust; there should be work benches to facilitate the cleaning of instruments and the charging of electric safety lamps; and a place to store the cases in which the apparatus is shipped.

Back of the smoke room there should be a lavatory containing toilet, shower baths, and lockers for the accommodation of the miners coming to the station for practice.

The equipment of the station should include oxygen helmets, or other suitable breathing appliances furnishing a dependable supply of pure air, with the aid of which men may safely enter any kind of the foulest and most poisonous atmosphere in order to perform rescue work.

Apparatus and supplies for recharging these machines.

Portable electric safety lamps with a convenient device for recharging.

A supply of some standard make of oil-burning safety lamps.

One or more resuscitating cases for use in reviving men overcome by the afterdamp of mine fires or explosions.

Special cases or trunks, of convenient size for handling, in which the above apparatus may be quickly packed and safely transported to the scene of an accident.

The Character of the Training Given.—The character of the training given should include a general study of the conditions that obtain during and after a mine fire or explosion, with special detailed reference to concrete cases. With these actual occurrences in mind, plans should be discussed for successfully solving these problems according to modern rescue practice. The principles on which the machines used at the station are constructed and operate should be explained; and a thorough first-hand knowledge of the manipulation of the various apparatus should be acquired by the practicing miner. The actual training of the mind and body to do work similar to that required in the actual recovery of a mine and in the presence of deadly gases should be given by means of drills in the smoke room. In this way, men become acquainted with the possibilities and limitations of the machines, gain knowledge as to their own prowess as rescuers, and learn to work in squads under the leadership of one of their comrades. For mental and physical ability shown in the work, a certificate of competency should be awarded. This would tend both to keep up interest in the work of the station, and to be of especial value as a reference card when a disaster occurs.

Advantages That May Be Derived From Stations.—The advantages that would obtain from such stations are in a large measure obvious. It often happens in an explosion that the ventilation machinery is thrown out of commission or totally destroyed. Also, it is often necessary after a gas explosion to stop the fan to prevent a series of subsequent blasts and to control a mine fire by cutting off all ventilation. Previous rescue methods have afforded only a choice between two evils; either close the mine with concrete stoppings and leave it sealed indefinitely, or start the fan, send in the men, and trust to luck, with the result of the loss of many lives and much property.

With the introduction of modern practice, however, rescue work assumes a decidedly different aspect. With the aid of the breathing appliances, trained men may enter the mine at once with comparative safety and begin the task of recovery, without aid of air supply from the fan. As the work progresses, each step may be taken with a complete knowledge of the situation gained from the careful reconnaissance of the helmet men.

Not least among the advantages that would accrue from the employment of rescue stations, is that in cases of emergency there would be available squads of men trained for the undertaking, accustomed to working together and obedient to the commands of their leader.

A further advantage is that such rescue stations may become centers for the dissemination of knowledge among the men. In addition to the usual studies and lectures, local institutes could hold their meetings in the observation hall of the station; and talks and demonstrations on first-aid work could be given by the town or company physician with a view to forming first-aid corps similar to those that are meeting with such success in the anthracite fields of Pennsylvania.

Plan for Rescue Stations in Illinois.—It is clearly out of the question, in view of the destructive competition that at present exists in the coal trade of this locality, to legislate against the very life of the industry by requiring each operator to establish a rescue station or make other improvements not immediately necessary. And yet, considering all that has been and is being done by foreign and domestic stations, and remembering the advantages that would accrue from the establishment of these stations, along the lines of discipline, education, etc., we are compelled to recognize their value.

The legislature of Illinois appropriates annually $193,000 for investigation in agriculture. The mining and metallurgical industry of the state represents an output valued at approximately $150,000,000, and for the aid of these industries the state appropriates only about $25,000. In establishing and maintaining charities and schools, the state annually spends enormous sums; and while rescue stations are primarily devoted to training tending to life saving, they are or may be considered as educational centers. Moreover, the state has appropriated $2,500 for the relief of the sufferers of the Cherry disaster, and the legislature is now considering bills calling for an additional benefit appropriation of $50,000 to $150,000. In view of these facts, it seems reasonable to ask the legislature for a grant of funds sufficient to carry on work which has for its object the saving of life and property, the training of its citizens to be effective agents of a vast enterprise and the reduction of a constantly increasing number of deaths, a special appropriation of $30,000 and in addition an annual appropriation of $30,000, to be expended according to the following plan of operation:

The coal fields of Illinois would be arranged in three divisions, and in a centrally located city or town in each of these districts a central rescue station would be established. For example, LaSalle, Springfield, and Carbondale. Each of these three cities is a railroad center, enjoying exceptional railroad facilities. A station could be built for $5,000, and equipped with a complete line of apparatus for a like sum; itemized as follows: 12 oxygen helmets, or other suitable breathing appliances; 12 portable electric safety lamps; 12 oil-burning safety lamps; 6 oxygen tanks or reservoirs; 1 oxygen pump; 2 oxygen reviving outfits; 200 potash cartridges; 1 chemical cabinet for gas analysis; 15 cases or trunks for transporting the above apparatus; furniture, including chairs, tables, wall cases, etc., tools, supplies, etc.

Thus the three stations could be completely installed for the special appropriation of $30,000.

In charge of each of these three central rescue stations there should be appointed a man whose experience in coal mining has been large and varied—some one who can maintain the interest of the miners who visit the station, care for the apparatus, and keep the records. Over the entire rescue work, with power to purchase supplies, direct the course of training, and assume the entire charge in case of a mine disaster, there should be a man who is a mining engineer by profession, one who has had experience in all phases of coal mining, including mine rescue work, and one upon whom may be thrown with confidence the welfare of the whole proposition. It is proposed that such officer cooperate with the inspector in whose district a disaster may occur. It is also suggested that he report to a board of five persons to be appointed by the Governor, to consist of one inspector, one operator, one miner, the head of the Department of Mining Engineering at the University of Illinois, and one member of the Federal Inspection Force.

Each operator of the state should be asked to send a small number, say 4 per cent., of his employes to the nearest of the central rescue stations at least twice a year for training in rescue work. These men should spend at least 3 days at the station on each visit. In return for this action of the operator in bearing such expense for the safety of the lives of his miners, the men so trained should agree, in cases of emergency, to assist in the work of mine rescue, with the understanding that they are to receive only the "inside wage scale" for time devoted.

These three central stations could be made of great value to both miners and operators. But one further step is necessary

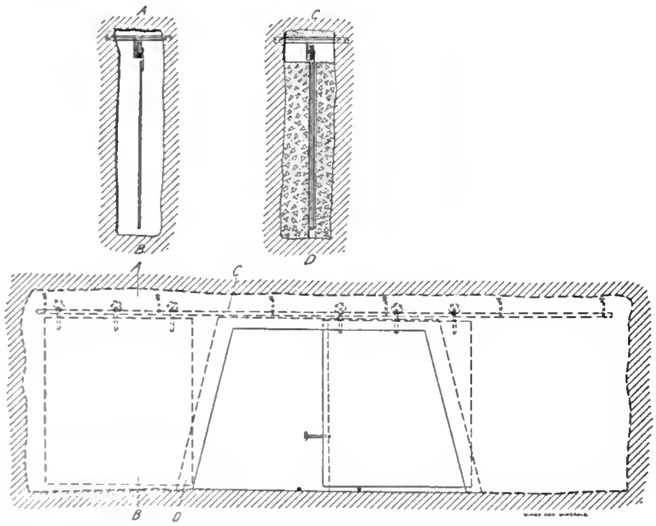


FIG. 1. PLANS AND SECTIONS OF MINE DOOR

to complete the plan and insure its entire success, because, even with the three stations thus located, there would be an appreciable lapse of time before the apparatus could be delivered to a mine in case of trouble. So to overcome this delay, the suggestion is made that all operators combine in what may be called local or private stations, consisting merely of five helmets and five electric safety lamps, charged and packed in cases, ready for transportation, in some town or a mine where there is always some one present who can deliver the helmets as needed. This local station might be in a fire department house of the town. These local stations would serve all mines within a radius of 15 miles. As the station equipment would consist of the five helmets and lamps, without any of the costly apparatus for recharging them, the expense, when divided among all mines within the 15-mile radius circle, would be very small. It would be the duty of the central rescue station people to inspect and charge these helmets periodically and see to it that they are in working condition for an emergency. This might be accomplished by having the local helmets brought to the central station by the miners when they visit it for training The object of the local stations is that the men at the mine may, in case of fire or explosion, have means at hand for preliminary work, or immediate rescue that may be necessary during the period while the men and equipment of the nearest central rescue station are journeying to the mine.

In concluding this paper I can assure you that I am urging the adoption of certain engineering principles that have been of inestimable advantage wherever used legitimately, and which have as their object the conservation of life and property.

EXTRA MINE DOORS

Written for Mines and Minerals

The Anthracite Mine Law, Article 10, Section 12, says: "An extra main door shall be so placed and kept standing open, as to be out of reach of accident, and so fixed that it can be at once closed in the event of an accident to the doors in use."

The intention of this section is to have an extra door on the main airways, so placed that in case of an explosion it will not be injured. The doors are to be kept standing open ostensibly for the purpose of allowing the blast from an explosion to pass through without injuring them. Possibly the law makers had something in their mind's eye that could stand in the way of an explosion and not be wrecked. If that be so, they should have placed a diagram in the article, for as a matter of fact when a good live explosion occurs, the mine entries are like gun barrels where all ahead of the powder moves forward. If door jambs are in a gangway or airway the chances are that if not knocked down by an explosion they would accumulate wreckage, so that the law could not be complied with and the door at once closed in case of accident to the door in use. It may be assumed further that a rock fall might occur to prevent the extra door being closed, particularly if the door frame was moved, and that, too, would prevent its being closed at once. Thomas H. Price, of Wilkes-Barre, Pa., Mine Inspector of the Seventh Anthracite District, evidently thought over this extra main door problem, for he has devised the one shown in Fig. 1, which surely comes as near to complying with the law as any so far advanced. The door frame is made flush with the walls of the entry. A space is then cut in the rib on each side, as shown in Section *A B*, Fig. 1. Suitable bearings for door hangers are then placed at the top of the openings and the forms for the concrete, shown in section *C D*, put so as to leave a space for the doors to slide back out of the entry when not in use. In the illustration, one-half of the sliding door is in the entry and the other in the recess in the rib.

Another case when this door becomes exceedingly useful is where shafts are partitioned for downcast and upcast and the partition lining becomes broken by fall in the shaft, or catches fire. By having one of these doors on each side at the foot of the shaft, and by closing the top of downcast shaft outside, the air will be conducted around the mines as before until all the men are taken out through the second opening required by the mine law of Pennsylvania.

It is evident that doors of this description could be used to advantage in case of mine fires, if judiciously placed with reference to panels and entries, so as to confine the spread of such fires by cutting out the air supply. Considerable more thought is being given to the prevention of mine fires than heretofore, owing to the Cherry Mine disaster and the decided stand the state of Illinois, through the suggestion of its mine commission, has taken to prevent a recurrence in that state. Doors of this kind could make a kind of rescue station to keep back the death-dealing gases until a rescue party reached those behind them. In the account of the Palau mine explosion in this issue of MINES AND MINERALS it is stated that several men were saved from death by a rock fall which held back the afterdamp. The records left by the Cherry Mine victims, also show the need of these doors.

MINE LABORATORY WORK AT GARY, W. VA.

*By Vitus Klier, Chemist**

Coal-mine laboratories should be supplied with samples which represent the large product reduced to small measures, that is, good average samples. If this standard is not maintained, the work in the laboratory, no matter how accurately it may be done, is useless.

Equipment of Laboratory. Methods of Sampling Coal, Coke, and Mine Air

The United States Coal and Coke Co. equipped the coal-mine laboratory, whose analytical room is shown in Fig. 1, at Gary, W. Va., in 1906, since which time 90,000 samples of coal and coke have been tested, or approximately 23,000 samples a year. This number of samples will be increased gradually as the output of the mines and ovens increases. The cost of analyzing one sample is about 10 cents, whether the analysis is for ash or a complete analysis of fireclay. The number of coal and coke analyses made in the laboratory daily varies from 120 to 150, although as many as 214 have been made in a single day. The variation in the number of analyses is due to the number of coke ovens charged and coal cars loaded for shipment.

The working force of the laboratory consists of a chemist, assistant chemist, and two laborers. The assistant chemist must be an ambitious young man with good habits and trained to the daily routine work which remains the same.

FIG. 1. ANALYTICAL ROOM, GARY LABORATORY

FIG. 2. SAMPLING ROOM, GARY LABORATORY

All coal going to the coke ovens is previously crushed. Every tenth larry that leaves the tipple is accompanied by a sampler who takes a sample at intervals, so long as fine coal runs from the larry spout into the oven. To do this he makes use of a flat wooden scoop 3 inches wide and 24 inches long. The coal he catches on this scoop he places in a bag made of some strong material and encloses a memorandum giving the name of the operation, the oven number and the date when the oven was charged. He then ties the bag up tightly and places it where it will be protected until all the ovens have been charged, when all the samples are collected and taken to the laboratory. When coal is to be shipped, the work of obtaining a good average sample is more difficult. To obtain as good a sample as possible a man is put on one side and below the end of the loading apron with a shovel, and as the coal slides into the cars the man holds his shovel under the falling coal. When one-third of the height of the car has been run in, this shovelful of coal is put on a clean steel plate 5 ft. × 5 ft. × $\frac{1}{4}$ in. When the second third of height of car has been run in, another shovelful of coal is taken and placed on the plate. As the car has to be moved three times before it is filled, nine heaping shovelfuls of coal are thus taken from the different parts at different heights of the car and a fair average sample is thus obtained. The coal on the plate naturally consists of varying sizes, from that of a lump as large as one's head down to fine slack. All lumps are broken up to the size of a walnut with a hammer, after which the coal is thoroughly mixed with a trowel; spread out in a circle and quartered down to a sample of about 10 pounds. This sample is then put in a bag marked with the name of the operation, car number, and date, after which it is sent to the laboratory. At the laboratory there is a sample preparing room the interior of which is shown in Fig. 2. This is provided with a quartering machine of the writer's design that reduces a 10-pound sample to 5 ounces in one minute.

Whenever a coke oven is to be sampled it is divided into quadrants. From each quadrant one piece of coke, whose thickness is that of the coke bed in the oven, is taken and placed in a sack which accompanies the coke-drawing machine until all ovens are drawn. The sample is then marked with the number of the operation, date the oven was drawn, and then sent to the laboratory.

To ascertain if the coke has been properly watered a bucket on a rod or a handle is held under the conveyer of the coke-drawing machine at intervals until the oven is drawn. The pieces of coke so caught are broken off and put into a can having an air-tight cover. The sample is weighed, heated in a steam bath up to 100° C., and the moisture determined. All coke samples received at the laboratory during the week are saved until Saturday, when they are combined and a complete analysis made which represents an average analysis of the coke shipped during the week. Samples reach the laboratory about 4 or 5 o'clock in the afternoon and work is commenced in the evening. By 4 o'clock the next day the certificates of analyses are ready to be distributed to the superintendents of the various plants. If this report shows any irregularity the superintendent proceeds to investigate and eliminate the causes that led up to the evil.

There are different sections in a mine and each section has a man whose business it is to see that the coal is cleaned before being loaded into mine cars. The superintendent when informed that his coal is not clean is able immediately to locate the section from which the dirty coal was loaded. In order to do this he takes samples of coal from the different sections as they are run through the crusher at the tipple. These samples he sends to the laboratory and after receiving the analyses he is posted as to which section needs special attention. As stated, all coal is crushed previous to its being sent to the coke ovens, and at the laboratory tests are made to determine the fineness of the slack

* Read at Bluefield Meeting of West Virginia Mining Institute.

in order to keep the superintendent informed as to the condition of his crusher.

The methods adopted at Gary for sampling and analyzing the mine products has up to the present time proved satisfactory. To show the accuracy of this system comparisons between the analyses made at Gary and South Chicago, for ash, are as follows:

Works Number	Difference Between Gary and Chicago	Date
	Per Cent.	
1	.58	March, 1909
2	.32	March, 1909
3	.13	March, 1909
4	.15	March, 1909
5	.32	March, 1909
6	.48	March, 1909
7	.46	March, 1909
8	.45	March, 1909
1	.36	April, 1909
2	.87	April, 1909
3	.23	April, 1909
4	.06	April, 1909
5	.08	April, 1909
6	.65	April, 1909
7	.32	April, 1909
8	.42	April, 1909

The samples at Gary were taken from the ovens and the samples at South Chicago from the cars on arrival. Fig. 3 shows the steel tipple at the Gary No. 7 mine. The lower building is for the crushed oven coal; the small addition on the left-hand side is for domestic coal used at the plant, and the chute is for loading locomotives.

In addition to testing mine products at the Gary laboratory, tests are also made for information in regard to the condition of the mines and to ascertain the quantity of gas and dust in them. This is accomplished by means of an aspirator and a sampling tube. The aspirator is made of tin and has 15 liters capacity. It is provided with a stop-cock and on the upper end is a filter tube with a filter inserted. To take a sample the apparatus is filled with water, the stop-cock is opened, and as the water is run out at the lower end the dust coming in is

Fig. 3. Steel Tipple, Gary, W. Va.

caught by the filter in the tube. The air sample is taken with a glass sampling tube which is filled with water before reaching the place where the mine air is to be sampled. This apparatus is supplied with two stop-cocks, one to permit the water to run out and the other to permit the air to enter as the water runs out. As soon as the water is all out of this tube both stop-cocks are closed and the tube is sent to the laboratory where its air contents are analyzed Air and dust samples are taken at the same time and in the same place regularly So far tests for inflammable gas have not been necessary at Gary, as the amount of gas found in samples of mine air taken at the coal face has never been over 1 per cent., and the dust determined at the same time has never exceeded 5 milligrams per cubic meter. According to Taffanel, 4,500 milligrams of dust per cubic meter will start an explosion. However, the sampling is continued at Gary as a means of precaution. Every superintendent when in doubt as to gas takes samples and checks his Pieler lamp to insure the safety of the mine. The following is the form of report used, and it shows how closely the Pieler lamp checks with analyses, the greatest difference being not quite ¼ of 1 per cent.

Date	Sample Number	Per Cent. Analysis	Pieler Lamp Per Cent.
9–1	1	.7	.50
	2		
9–10	1	.4	.50
	2	.2	.25
9–16	1	.2	.50
	2	.2	.25
	3		
9–30	1	.4	.50
	2	.3	.25
	3		

The laboratory is not only used to analyze the output of the mines and of the coke ovens, but is also used to check the materials purchased, such as miners' oil, blasting powder, brick material, etc., so as to know exactly what is being paid for and its quality.

PERSONALS

Sidney F. Walker, R. N., of Bloomfield Crescent Bath, England, has been elected President of the South Branch of the Association of Mining Electrical Engineers.

W. F. Zimmerman, M. E., is reassociated with the Pittsburg Testing Laboratory, with office at 50 Church Street, New York City.

Prof. John J. Rutledge, of the Bureau of Mines, and Dr. M. J. Shields, have been touring the southern coal-mining states lecturing to miners. Professor Rutledge lectures on mine apparatus and safety in mines, and Doctor Shields on how to render first aid to the injured.

A. E. Borie has resigned from the New Jersey Zinc Co. to accept a vice-presidency of the Taylor Iron and Steel Co., High Bridge, N. J. New York office, No. 100 Broadway.

Wm. A. Evans has been appointed superintendent of the Hartshorne group of mines of the Rock Island Coal Mining Co., vice R. J. Pickett. Mr. Evans will continue to act in the capacity of chief engineer for the mines of this company, located in Oklahoma.

Charles Enzian, Wyoming Division Engineer of the Lehigh Valley Coal Co., has been appointed mining engineer for the Anthracite Division of the United States Bureau of Mines. His duties will be to cooperate with miners and operators and state officials in safeguarding lives and property in and about the mines. He will be expected to investigate thoroughly the many mining problems and will make himself familiar with serious questions confronting the mining officials. He is to go to Pittsburg for a few weeks special work and then will be permanently stationed at Wilkes-Barre.

J. B. Tyrrell, mining engineer of Toronto, Canada, has returned from London, England.

Arthur Lakes and Arthur Lakes, Jr., have moved their offices to rooms 701-703 Gas and Electric Building, Denver, Colo., where they will continue their practice as mining and metallurgical engineers.

Eli T. Conner, Mining Engineer, has opened an additional office in the Traders Bank Building, Scranton, still retaining his office in the Real Estate Trust Building, Philadelphia.

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

(Continued from October)

NOTE.—The following questions, selected from different examinations, are here numbered consecutively. The examination from which the question is taken and the number of the question are found at the end of each.

Selected Questions of the Illinois Examinations for 1909, Held at Springfield

QUES. 1.—How is carbonic acid produced in mines, and how is its presence detected?—**Q. 4, April 12.*

ANS.—Carbon dioxide (CO_2) or carbonic acid gas is produced by the combustion of carbon in a plentiful supply of air. This combustion is called oxidation; such is the burning of lamps, powder, coal, wood, or other organic matter; breathing of men and animals, decay of timber, etc. The oxygen of the air unites with the carbon, in the proportion of two atoms of oxygen to one atom of carbon, forming carbon dioxide (CO_2). The presence of this gas in mine air is manifested by the dim burning of lamps or their complete extinction when a sufficient percentage of the gas is present.

QUES. 2.—What is the quantity of air required by law for the ventilation of a mine employing 150 miners, 21 day men, and eight mules?—**Q. 5, April 12.*

ANS.—The Illinois mining law requires 100 cubic feet of air for each man and 600 cubic feet for each animal—Section 19, (*a*)—to be circulated per minute throughout the mine. This would require in this case $100\ (150+21)+600\times 8=21{,}900$ cubic feet per minute. The mine inspector is authorized by law to require that this circulation be increased whenever, in his judgment, the conditions demand a stronger current.

QUES. 3.—If a mine is generating much firedamp and there is danger of explosion, what kind of material would you use to build overcasts—wood, stone, iron, or brick? Give reasons. **Q. 7, April 12.*

ANS.—Opinions differ in regard to the material to select for building overcasts in gassy mines where explosions are liable to occur. While it is desirable to build overcasts that will resist, ordinarily, the force of an explosion in the mine, it must be remembered that nothing but an overcast driven in the solid strata can resist the tremendous shock of many mine explosions. It is also claimed that the resistance of an overcast, preventing as it does the escape of the expanding gases, causes the destruction to extend further in the mine and penetrate workings that would otherwise not be reached. However this may be, it is a fact that the iron plates and beams used in constructing an overcast are often so badly twisted as to make it impossible to remove them or repair the damage quickly so as to reestablish the air-current. Timbers, if broken or dislodged, can be cut away and removed and a new overcast built temporarily to restore the current. For this reason it would seem advisable to build an overcast of heavy timbers and plank well braced and provide a large trap in the floor of the bridge so as to relieve the pressure and perhaps avoid the destruction of the air-crossing.

QUES. 4.—When making your rounds in the morning you find gas at the face of an entry, and after measuring it with a safety lamp you estimate its volume to be about 21 cubic feet. What volume of flame would you expect if this gas were to be ignited, the temperature of the mine being 65° F.?—**Q. 8, April 12.*

ANS.—The flame volume of marsh gas (CH_4) mixed with sufficient air to insure the complete combustion of the gas is generally assumed to be 10 times the original volume of the firedamp mixture. If it could be assumed that the body of firedamp mentioned in this question was at its most explosive point, and measured 21 cubic feet, its ignition might be expected to produce $21\times 10=210$ cubic feet of flame. This is not, however, the case in practice, since the mixture of gas and air is not uniform, but varies from nearly pure gas at the roof, near the face, to a mixture containing but a small percentage of gas at a point farther away. At the point where the gas is first detected there is probably 3 per cent. of gas, but there is much gas below this point, so that it is not possible in such a case to estimate the volume of flame that would be produced by the ignition of the gas with any degree of accuracy.

QUES. 5.—Suppose there are 10 men and 22 mules in the mine, and on your arrival in the morning you discover the tower on fire and smoke going down the shaft; the fan is running at a speed of 100 revolutions per minute. What would you do? **Q. 9, April 12.*

ANS.—Get word at once to the men, by phone or by messenger. At the same time, give orders to reverse the fan; or if this cannot be done, short-circuit the air-current by setting open the doors at the bottom of the shaft. In the meantime, do everything possible to get water on the fire; use the chemical extinguishers, which should always be at hand. When the safety of the men is insured give attention to the mules.

QUES. 6.—The long hand on an anemometer makes 3.25 revolutions in 1 minute; the airway where this reading is taken is 6.25 ft. × 8.5 ft. What is the quantity of air traveling, allowing 3 per cent. for the resistance of the instrument?—**Q. 11, April 12.*

ANS.—Assuming this is an average reading, the quantity of air passing is $(1.00-.03)\ 3.25\times 100\ (6.25\times 8.5)=16{,}747+$, say 16,750 cubic feet per minute.

QUES. 7.—If the temperature in a mine is 60° F., and the average velocity of the air-current 325 feet per minute at a point where the entry is 6.25 ft. × 8.5 ft., what weight of air is traveling per minute in the airway?—**Q. 13, April 12.*

ANS.—The weight of air passing per minute assuming a barometer reading of 30 inches is

$$325\ (6.25\times 8.5)\ \frac{1.3273\times 30}{460+60}=1{,}322+\ \text{lb.}$$

QUES. 8.—A current of 9,000 cubic feet of air per minute is passing through a regulator having an opening 25 in. × 35 in. How much air will pass through the regulator if the opening is enlarged to 45 inches square, the pressure and rubbing surface (and area of the airway) being the same in each case?—**Q. 15, April 12.*

ANS.—The question is not definite in regard to the pressure that remains the same when the opening is enlarged. If the pressure due to the regulator is the same in each case, the quantity of air passing will be increased in the same ratio as the area of the opening is increased, or $\frac{45\times 45}{25\times 35}=\frac{81}{35}$; and the quantity of air passing will then be $9{,}000\times\frac{81}{35}=20{,}828+$ cubic feet per minute. In that case, however, the ventilating pressure, which is the sum of the pressure due to friction in the airway and that due to the regulator, would have to be increased to maintain a constant pressure at the regulator.

The question probably intends to make the total ventilating pressure constant. In this case, as the opening in the regulator is enlarged the pressure due to the regulator decreases, which causes more air to flow through the entry and incidentally increases the friction and the pressure required to overcome friction. Without knowing the sectional area and rubbing surface of the airway, it is not possible to determine the quantity of air that will pass through the larger opening under the same ventilating pressure. The original area of the opening in the regulator was $(25\times 35)\div 144=6.076$ square feet; and the enlarged area is $(45\times 45)\div 144=14.062$ square feet. Then, assuming the sectional area of the airway as 50 square feet, and the rubbing surface as 100,000 square feet, the quantity of air that will flow through the larger opening, under the same ventilating pressure, is found by the formula

* Mine Examiners' Examination.

$$\frac{q_2}{q_1}=\frac{A_2}{A_1}\sqrt{\frac{a^3+.026\ s\ A_1^2}{a^3+.026\ s\ A_2^2}}$$

or in this case,

$$q_2=9{,}000\left(\frac{14.062}{6.076}\right)\sqrt{\frac{50^2+.026\times 100{,}000\times 6.076^2}{50^2+.026\times 100{,}000\times 14.062^2}}$$

= say, 12,250 cu. ft. per min.

Ques. 9.—If an air-current passing in a mine is divided into two or more equal splits, will the resistance of the mine be diminished or increased, or does it remain the same after splitting as before, the power upon the air being constant? Explain fully.—†*Q. 4, July 12.*

Ans.—Considering primary splits only, or splits starting from one point in the mine, if the power on the air remains constant at this point, the velocity will be unchanged by splitting the current, because the rubbing surface is constant. This is easily seen by observing the formula for power, $u=k\ s\ v^3$. Also, the mine resistance is not altered, in this case, as shown by the formula for resistance $R=k\ s\ v^2$. In all cases, however, where the air-current travels through a deep shaft or main airway before reaching the point of split, if the power is constant at the mouth of the shaft or main airway, the effect of splitting the air-current at some point in the mine is to increase the quantity of air in circulation. The result is an increase of velocity in the shaft or main airway and likewise an increase in resistance here. As a result the power on the air at the point of split is decreased, which causes a decrease in velocity and resistance in the splits. The decrease of resistance in the splits is always greater than the increase of the same in the shaft or main airway, so that in this case splitting the air produces a decrease in the mine resistance. This is always true for all secondary splits.

Ques. 10.—A mine is ventilated by a furnace that consumes 5 tons of coal each 12 hours. The water gauge gives a reading of 1.5 inches. What will be the increase of pressure caused by increasing the amount of coal consumed to 10 tons each 12 hours?—†*Q. 5, July 12.*

Ans.—In furnace ventilation, the power developed is proportional to the coal burned per hour; and, for the same mine or airway, the square root of the pressure varies as the cube root of the power. Hence, in this case, since the coal burned per hour is doubled, the fuel ratio is 2, and the power ratio is also 2. Then, calling the pressure ratio x, we have $\sqrt{x}=\sqrt[3]{2}=1.26$; and $x=1.26^2=1.58+$. If the water gauge reads 1.5 inches the pressure due to burning 5 tons of coal in 12 hours, in this mine, is $1.5\times 5.2=7.8$ pounds per square foot; and the pressure caused by burning 10 tons of coal in 12 hours, in the same shaft, would be $7.8\times 1.58=12.32+$ pounds per square foot. The increase in pressure is therefore $12.32-7.8=4.52$ pounds per square foot.

Ques. 11.—A current of 50,000 cubic feet of an explosive mixture of air and marsh gas is passing in a mine per minute; what is the quantity of gas given off?—†*Q. 6, July 12.*

Ans.—The question as it reads is unintelligible, as the explosive range of marsh gas extends from 7.14 per cent. to 16.67 per cent. of gas in the firedamp mixture when no other gases are present. The presence of carbon dioxide in the firedamp decreases this explosive range, while the presence of dust or carbon monoxide increases the same. Assuming, however, that the question refers to pure marsh gas mixed with air in such proportion that the firedamp mixture is at its most explosive point, or contains 9.46 per cent. of gas, the quantity of gas carried in this air-current, and which is being generated per minute in the mine, is $50{,}000\times .0946=4{,}730$ cubic feet.

Ques. 12.—What do you understand by ascensional ventilation?—†*Q. 7, July 12.*

Ans.—The ventilation of a mine is ascensional when the air is conducted to the lowest point of the workings in an inclined seam first, and from there continues, in general, to rise in its circulation throughout the mine. As far as practicable the circulation in every mine should be so arranged, in order to take advantage of the air-column due to the natural heat of the mine wherever there are rise or dip workings.

Ques. 13.—What is the velocity of air under the following conditions: water gauge 1.577 inches, barometer 29.5 inches, temperature 64° F.?—†*Q. 8, July 12.*

Ans.—From a practical mining standpoint this question is wholly unintelligible, since the velocity of air-currents in mines depends on data not given and is not appreciably altered (except in furnace ventilation) by the barometric pressure or the temperature of the mine. In mine ventilation, velocity depends on the power on the air and the resisting power of the mine as determined by the relation of its rubbing surface to the area of passage; or, in other words the mine potential $X=a\sqrt{\frac{a}{k\ s}}=\frac{Q}{\sqrt{p}}$; whence $Q=X\sqrt{p}$, or $v=X\frac{\sqrt{p}}{a}$. When the water gauge or the ventilating pressure, or power on the air is known, and the size and length of the airways are given, the velocity can be calculated, but these data are necessary in mining practice. The flow of air into a vacuum under a given pressure is calculated by the formula

$$v=\sqrt{2\ g\ h}=\sqrt{\frac{2\ g\ p}{w}}$$

in which, v = velocity of air (feet per second);
g = force of gravity (32.16 feet per second);
p = pressure on air (pounds per square foot);
w = weight of air (pounds per cubic foot).

This formula, however, cannot be used in this case, because the mention of water gauge precludes the idea of a vacuum, as the water gauge always measures the difference between two pressures, or the ventilating pressure. The question cannot be answered.

Ques. 14.—A fan is producing 150,000 cubic feet of air per minute when the mine resistance produces 1.5 inches of water gauge. If the area of inlet of this fan is 100 square feet and the area of the discharge orifice 70 square feet, what is the manometric efficiency of the fan?—†*Q. 9, July 12.*

Ans.—In order to calculate the so-called manometric efficiency of this fan under the given conditions, it would be necessary to know the depression that causes the air to enter the fan, or that which expels the air from the fan, either of which are not given. It has been suggested that the pressure created by the action of a centrifugal fan may be divided into three distinct pressures; namely, the pressure required to blow the air into the fan, that required to blow the same air out of the fan, and that caused by the mine resistance. Since the pressure due to the mine resistance is the effective pressure, the ratio of this pressure to the sum of all the pressures is what has been called the manometric efficiency of the fan. The ratio of the blowing-in to the blowing-out pressure is equal to the square of the ratio of the discharge to the intake area. Hence, it is necessary to know one of these pressures, from which the other can then be calculated, and the manometrical efficiency of the fan determined. Without this, however, the question cannot be answered.

Note.—The manometric efficiency is clearly of no practical value, since it only relates to pressure (not power), and that in reference to a particular mine or circulation where a given quantity of air is passing under a certain pressure. It is practically impossible to measure either the blowing-in or blowing-out pressure required to calculate manometrical efficiency. Again, since it is the mine resistance that causes the pressure it is evident that the same fan working on another mine or airway will present an entirely different efficiency, depending upon the resisting power of the mine. The true efficiency of a fan is the mechanical efficiency which is expressed by the ratio of the power on the air to the indicated power of the engine, making due allowance for the power absorbed by the engine itself.

Ques. 15.—There is 150,000 cubic feet of air per minute passing through an airway 8 ft. × 10 ft.; what would be the

† Mine Managers' Examination.

horsepower of the circulation apart from friction? The temperature of the air is 60° F., barometer 30 inches.—†*Q. 10, July 12.*

ANS.—Ignoring friction in the circulation of an air-current in a mine or airway, there is no pressure, and therefore no power; no work is done aside from the work of overcoming friction.

QUES. 16.—What must be the area of an airway to pass 10,000 cubic feet of air per minute, with a water gauge of 1.7 inches, the length of the airway being 5,000 feet.—†*Q. 12, July 12.*

ANS.—The question should state the form of the airway, as being circular, square, or rectangular; and if rectangular the ratio of the height to the width of the airway should be given; otherwise the question cannot be worked. The following formulas apply to each one of these types of airways:

Circular airway $a=\sqrt[5]{4\pi\left(\frac{k\,l\,q^2}{p}\right)^2}$

Square airway $a=\sqrt[5]{16\left(\frac{k\,l\,q^2}{p}\right)^2}$

Rectangular airway $a=\sqrt[5]{\frac{4(1+r)^2}{r}\left(\frac{k\,l\,q^2}{p}\right)^2}$

For a circular airway 5,000 feet long the sectional area would be 27.62 square feet; for a square airway, 28.95 square feet; and for a rectangular airway in which the width is twice the height of the airway the area would be 29.68 square feet. The diameter of the first airway would be 5.9 feet; the side of the second (square) airway would be 5 47 feet; and the rectangular airway would be 3.85 ft. × 7.7 ft.

QUES. 17.—There is 20,000 cubic feet of air per minute passing into a mine, which becomes charged with 2.5 per cent. of marsh gas (CH_4); what will be the volume of the return current?—†*Q. 13, July 12.*

ANS.—The meaning of this question would be more clearly expressed if it asked, "what will be the volume of the return current if charged with 2.5 per cent. of gas, the temperature remaining the same?" The gas is 2.5 per cent. of the return current, whereas, the reading of the question would lead one to think it was 2.5 per cent. of the intake volume. The gas being 2.5 per cent., the air (20,000 cubic feet) is $100-2.5=97.5$ per cent. of the return current, which is therefore $20{,}000\div.975=20{,}512+$ cubic feet, at the same temperature.

QUES. 18.—Find the motive column that would produce a pressure of 3,906 pounds when the temperature of the upcast is 70° F. and that of the downcast 42° F., the barometer being 30 inches.—†*Q. 14, July 12.*

ANS.—This question is wholly unintelligible. It is difficult to understand what is the true meaning. A motive column in mine ventilation is an imaginary air column, 1 square foot in section and of such height that its weight will produce a given pressure, which is stated in pounds per square foot. The pressure, 3,906 pounds, is too great to be understood as being the pressure per square foot. It is evidently the total pressure due to the difference in weight of air in the two shafts. But the size of the shafts is not given and without this and the depth of the shafts the question cannot be worked. Moreover, the question should state whether the height of the motive column is to be found in terms of the upcast or the downcast air, as the answer will be different in each case The formulas for height of motive column are as follows:

Downcast air, $M=D\,\frac{T-t}{460+T}$

Upcast air, $M=D\,\frac{T-t}{460+t}$

QUES. 19.—If on a pitch of 25 degrees there is a pitch distance of 300 feet between two seams of coal, what would be the pitch distance if the pitch (of the connecting slope) was increased to 55 degrees?—†*Q. 17, July 12.*

ANS.—Assuming the two seams of coal are horizontal, the vertical distance between the seams is $300\times\sin 25°=300\times.42262=126.786$ feet. The pitch distance then for 55 degrees would be $126.786\div\sin 55°=126.786\div.81915=154.7$ feet.

QUES. 20.—With the entry running due east and rooms running N 45° E, what distance apart (center to center) would you mark off rooms on the entry in order to provide for a width of 30 feet in the rooms, and pillars 15 feet wide?—†*Q. 18, July 12.*

ANS.—The distance between room centers, measured on the entry should be $(30+15)\div\sin 45°=45\div.7071=63.64$ feet.

QUES. 21.—What is the angle included between two lines whose bearings are, respectively, N 47° W and S 32° W?—†*Q. 19, July 12.*

ANS.—The included angle is $180-(47+32)=101°$.

QUES. 22.—How tightly should props be wedged when first stood in a room or entry to support the roof?—†*Q. 20, July 12.*

ANS.—The wedging should be only tight enough to hold the post in position and prevent its being accidentally knocked out or displaced by an ordinary jar. This will allow for the initial and irresistible settlement of the roof due to the extraction of the coal and which will tighten the post without breaking it.

QUES. 23.—In wedging a post in a room with a cap piece sharpened 1 inch in 12 inches, or one sharpened 3 inches in 12 inches; which of these would cause the greater pressure on the post?—†*Q. 21, July 12.*

ANS.—The cap sharpened 1 in 12 would cause a greater pressure on the post than the one sharpened 3 in 12, because it is a sharper edge and is more easily driven up.

QUES. 24.—How much blasting powder would you use in a dead hole that was 2 feet on the solid?—†*Q. 24, July 12.*

ANS.—None. The hole is a dangerous hole.

COST OF MINING AND MARKETING ALASKA COAL

The Bering River and Mantanuska fields of the Pacific coast province furnish high-grade steaming and coking coals as well as anthracite, but these fields have not yet been reached by railways, and these will require large investments of capital. The conditions in both fields are in many ways similar. The Mantanuska field will probably have a slight advantage in a lower cost of mining, but this advantage will be more than offset by a greater railway haul. The bituminous coal of the Bering River field can probably be mined for about $2 a ton, and when a railroad to tide water is built should be delivered at Seattle for little more than $4 a ton. The anthracite of this field can probably be delivered at Seattle for $5 a ton. These coals could probably be delivered at Oregon and California ports at an additional cost of not more than 50 cents a ton.—*United States Geological Survey.*

The Heroult electric iron smelter has demonstrated its commercial practicability and is producing about 20 tons of high-grade pig iron per day in California. The Noble Electric Steel Co. has decided to add five more furnaces to the plant, to bring the production up to 100 tons per day. The smelter has demonstrated its ability to produce pig iron at a total cost of $12 per ton, and, as eastern pig iron costs about $30 per ton on the Pacific coast, the success of the Heroult plant means considerable to the industrial enterprises in California. Deposits of iron ore have been discovered in Shasta and other counties, but the absence of coal has prevented the production of pig iron. Now that it can be produced electrically, the iron-ore beds will receive attention. The Noble Electric Steel Co. is mining ore at a short distance from the smelter, and sufficient ore is developed to insure the operation of the enlarged plant for a long term of years. The company has booked extensive orders for the product, most of it going to San Francisco iron works.

BLASTING SUPPLIES

*By F. H. Gunsolus**

Although the explosive naturally demands first consideration when blasting is to be done, the fact is not to be overlooked that it cannot be properly exploded without certain materials and appliances, especially designed for the purpose, known as "blasting supplies." In addition to those articles necessary to develop the energy of a charge of explosive, there are other devices which, although they may not be absolutely requisite, contribute to safety, certainty, and economy in the use of explosives, and these are also included in the category of blasting supplies.

Importance of Proper Apparatus for Firing or Detonating Explosives. Right Methods of Using

The importance of keeping blasting supplies up to the highest standard in every respect cannot be overestimated, for the very best grades cost but a trifle in comparison with the charge of explosives in connection with which they are used. It is poor economy to attempt to detonate an explosive with an inferior article, for it always results in a considerable waste of the value of the explosive. More than a hundred years' experience in the manufacture, sale, and use of all kinds of explosives has taught that the popularity depends entirely on the results which consumers have with them, and with this in view and from a standpoint of "good business," only a high quality of blasting supplies are recommended.

When a high explosive, such as dynamite, is the blasting agent the "electric fuse" is the detonator used when firing by electricity. It consists of a copper shell containing a detonating charge surrounding a fine platinum wire "bridge," which joins the tips of two insulated copper wires of various lengths. The ends of the copper wires are secured in the copper shell by a composition plug which also serves to keep moisture and water away from the charge. The electric fuse is detonated when sufficient electric current is passed through the copper wires and across the platinum bridge to heat the latter to a temperature high enough to ignite the charge surrounding it.

Fig. 1. Series Connection

In certain classes of tunnel or shaft excavating, "delay-action" fuses have been used to advantage. These are made so that a very short space of time intervenes between their ignition by the electric current and their detonation. Two kinds are manufactured: One kind, called first-period delay-action fuses, detonates a little before the other kind, called second-period delay-action fuses, when both are connected in the same blasting circuit. When they are used in conjunction with regular electric fuses, the latter will detonate at the instant the electric current passes through the circuit; the first period delay-action fuses will follow these, and the second period delay-action fuses will detonate a little later. By their use it is possible to fire one section of a blast, sufficiently ahead of the following section, for the material blasted by the charges in the first section to be blown out of the way when the next section is blasted.

* Manager Technical Division E. I. duPont de Nemours Powder Co.

When several charges of explosives are to be detonated at one time with electric fuses, it is necessary (unless the electric fuse wires are long enough to reach between the bore holes) to join them with connecting wire. Insulated copper wire is used for this purpose.

Leading wire, which is also insulated, and in order to reduce resistance is of a larger size than connecting wire, connects the electric fuses in the first and in the last bore hole with the source of the electric current.

The current for electric blasting is sometimes taken from a power or lighting system, but the source of current commonly used is known as a blasting machine. Although manufactured in several sizes and styles, they are usually designed on the same general principle.

For electric blasting in coal mines or other work where not more than three or four shots are to be fired at one time, the pocket battery is used instead of the blasting machine, because it is smaller and more convenient.

In order to have the maximum amount of electric current pass through the electric fuses, all connections must be carefully made and insulated to prevent leakage, insulating tape being used for this purpose.

Owing to the many difficulties generally attending blasting, such as wet or cold weather, water in drill holes, necessity for hurry and so on, it not infrequently happens that electric fuse wires are stripped or broken in tamping; connections are improperly made, poorly insulated and leaky, or the circuit is interrupted in some other way which results in the misfire of the explosives in some or all of the bore holes, causing serious loss and delay. In order to eliminate this trouble as far as possible, a galvanometer has been designed for testing the blasting circuit before firing. It is possible with this instrument to detect a break or a leak of any considerable extent in the blasting circuit; it will also detect leaks of any considerable extent, or serious defects in the electric fuses, rendering it possible to locate the point at which the trouble exists.

The kind of work on which blasting machines are used is largely responsible for rough and careless handling, which often wears them out rapidly. The rheostat is a simple but effective instrument which should be used from time to time to test the capacity of blasting machines, so that there will be no danger of overloading them.

If leading wire is to be kept in good condition and handled easily and quickly a leading-wire reel is necessary.

When blasting powder is the explosive used, electric squibs may take the place of electric fuses. They are made on the same principle as the electric fuses, but cost less, as a heavy paper shell replaces the copper cap of the electric fuse. As the charge in electric squibs does not detonate but burns or flashes, they will not detonate dynamite or other high explosives.

Blasting caps are often used to detonate high explosives, when it is not necessary to fire more than one charge at a time, or when for some other reason electric firing is not feasible. They consist of a copper shell similar to that of the electric fuse which contains the same kind of a charge. The charge in the

blasting cap, however, is not ignited electrically, but by safety fuse on the end of which the blasting cap must be crimped.

Safety fuse consists of a small train of fine grain black powder which forms the core of a rope of hemp, cotton, or tape, generally covered with waterproofing mixture. It is used for detonating blasting caps as described above, or for igniting directly charges of blasting powder into which it carries a spark.

The cap crimper is a very convenient and serviceable little tool, which is used to attach the blasting cap securely to the safety fuse. Some styles are equipped with a fuse cutter.

Most high explosives containing nitroglycerine freeze and become insensitive at temperatures from 45° F. to 50° F., consequently they cannot be used effectively in cold weather, unless they are thoroughly thawed and kept warm until they are loaded in the bore hole. Thawing kettles are used for this purpose. There are several different designs, but all are constructed on the principle of a warm-water jacket surrounding the compartment which holds the explosive.

Tamping bags are paper containers for sand, clay, or other material with which horizontal or pitching bore holes, or uppers are to be tamped. They are also used when making blasting powder cartridges for use in similar bore holes.

Blasting mats are woven mats of rope which are spread on the ground above the bore holes when blasting is done where flying pieces of rock will be dangerous. If heavy charges of explosives are used it is the custom to place logs or railroad ties directly over the bore holes, and the blasting mats on top of these.

Blasting by electricity is generally conceded to be the most effectual and economical system, and to surpass any other in safety, expedition, and certainty. In work where it is possible to blast more than one charge at a time it will nearly always be found advantageous to do so, and this can only be accomplished by electric firing. When several charges are fired simultaneously each tends to help the other, both in turning out and in breaking up the material blasted, with the result that a greater amount of work is done by a given quantity of explosive than if the several charges were fired successively. In addition, it is possible to better protect against water and other causes of misfire the appliances used in electric blasting, thus insuring greater certainty. As delayed explosions or "hang fires" are hardly possible, and as the blaster can always be a considerable distance away from the explosive when it detonates, this system reduces the possibility of accident to a minimum.

No method of blasting in gaseous or dusty coal mines, other than the electrical one, deserves consideration, because in all others the ignition in the open of some burning substance is necessary, even though a device be used whereby the safety fuse or squib can be ignited without exposing an open light or flame in a gaseous place.

It is believed by many authorities that disastrous explosions in coal mines have been caused by a blown-out shot occurring shortly after a number of other blasts have been fired. This cannot happen if the firing is done by electricity, when as many shots as desired are fired simultaneously. In submarine or other very wet work, no other system is feasible. In underground work, where ventilation is not good, burning safety fuse increases the smoke and fumes very materially. It is not uncommon in its use for the fire to break through the side of the fuse and ignite the charge of explosives before detonating the blasting cap, resulting in poor execution and increase in fumes. This cannot occur when the blasting is done by electricity.

The equipment necessary for electric blasting is as follows: Electric fuses, connecting wire, leading wire, blasting machine.

In addition, the following will prove of much assistance and saving: Insulating tape, rheostat, galvanometer, leading-wire reel.

If the explosive used is blasting powder, electric squibs, which are less expensive, should replace electric fuses in the above list.

When the source of the electric current is a blasting machine of the usual type, connect the bore holes in series, Fig. 1, that is, join one wire of the electric fuse in the first bore hole (if necessary, using connecting wire), to one wire of the electric fuse in the second bore hole and the other wire of this electric fuse to one wire of the electric fuse in the third bore hole, and so on until all of the bore holes are connected together with a free electric-fuse wire in the first and the last bore hole, each of which is to be connected by one of the leading wires to the blasting machine.

Blasting machines and pocket batteries are commonly made for series connecting only and connections should not be made in parallel, or any modification thereof, except machines are especially designed for such connections.

When making connections, care must be taken to see that all metal parts joining each other are scraped bright and clean. Another point of particular importance is, that no part of the circuit which is not thoroughly insulated should come in contact with any other uninsulated part of the circuit, or with water, or with wet or damp ground. In order to accomplish this, all bare joints should be covered with insulating tape.

FIG. 2. LOOPED WIRES—WRONG WAY

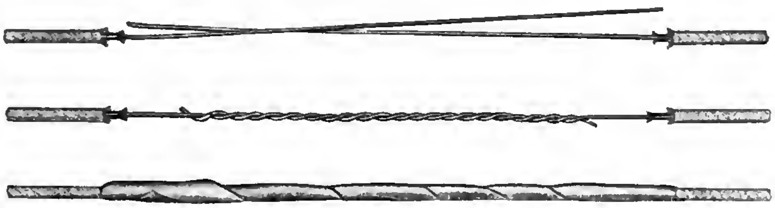

FIG. 3. TWISTED WIRES—RIGHT WAY

When making connections do not loop the wires, but twist them tightly together.

The attempt to use old and damaged leading wire, or connecting wire, is a great mistake and is often the cause of misfires. One of the principal objections to their use is that the wire itself will frequently break inside of the insulation, which will remain intact. When this occurs, the ends of the wire may touch and the circuit appear all right when tested, but a very slight movement of the wires afterwards may pull these ends apart, breaking the circuit, and causing a misfire. A break of this kind is not easily located, and sometimes is responsible for the loss of the time of many workmen waiting for the shot to be fired.

Victor electric fuses are made in four different strengths, No. 4, single strength, No. 6, double strength, No. 7 and No. 8, each of which is put up with insulated copper wires of the following lengths in feet: 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30. Special lengths are manufactured to order. The following table describes fully Victor electric fuses of different strengths:

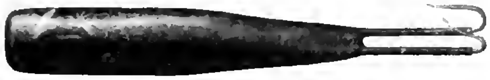
Grade	No. 4 Single Strength	No. 6 Double Strength	No. 7	No. 8
Dimensions of cap	1.25 × .273	1.56 × .273	1.75 × .273	2 × .273
Color of carton	Yellow	Red	Brown	Green

Victor No. 4, single-strength, electric fuses may be used to detonate straight nitroglycerine dynamite, but results are

better with Victor No. 6, double-strength. Nothing weaker than Victor No. 6, double-strength, electric fuses should be used with ammonia dynamite, Red Cross explosives, Semigelatin, gelatin dynamite, blasting gelatin, Judson powder, or the permissible explosives.

The No. 6 double-strength, No. 7 and No. 8 grades, are furnished when so desired for submarine work with a special gutta-percha covering, which is water resisting, Figs. 4 and 5.

SECTION OF GUTTAPERCHA COVERED (FOR SUBMARINE WORK)
Fig. 4



GUTTAPERCHA COVERED (FOR SUBMARINE WORK)
Fig. 5

Fig. 6. Section of Electric Fuse

Fig. 6 shows, in section, an electric fuse. *A* is the shell of copper, having a corrugation thrown out from the inside, which holds the composition plug more firmly in place; *B* is the chamber containing the explosive charge; *C* the copper wires entering the cap, having a cotton covering which is an insulator sufficient for ordinary purposes; *D* the bare ends of the copper wires, projecting through the cement into the charge; *E* the small platinum wire, or bridge, soldered to, and connecting the two ends of the copper wires, which is heated by the electric current; *F* the composition plug holding the fuse wires firmly in place; the bare ends of the wires are tinned to prevent corroding.

Electric fuses are packed in pasteboard cartons which are enclosed in heavy wooden cases. The cartons contain either 25 or 50, depending on the length of the wires. Electric fuses with wires from 4 feet to 16 feet long are packed for domestic trade, 500 to the case, while those with longer wires are packed 250 to the case. The number of electric fuses with wires of different lengths to the case, dimensions, and gross and net weight of case for domestic shipment, are given in Table 2.

Table 2. Electric Fuses

Quantity in Case	Length of Wires in Feet	Gross Weight Pounds	Net Weight In Cartons Pounds
500	4	25	17½
500	6	31	23½
500	8	39	30
500	10	46	37
500	12	54	43½
500	14	61	50½
500	16	68	57½
250	18	45	32½
250	20	48	37½
250	22	52	39½
250	24	55	42½
250	26	58	45½
250	28	61	48½
250	30	64	51½

Outside dimensions of cases are 9½ in. × 17½ in. × 22¾ in.

The storage of electric fuses should always be given careful attention by the consumer. If they are permitted to remain, for a considerable period, in a very warm place, the waterproofing material in the insulation dries out to such an extent that the insulation may break when the wires are bent, and misfires occur if an attempt is made to use them in wet work. The explosive charge in the electric fuses is very easily affected by moisture and if they are stored in a damp or wet place they may deteriorate. As the charge which electric fuses contain is very sensitive, and they may be exploded by a moderately hard knock or jar, they should be handled carefully. Careful handling is also necessary on account of the delicate bridge wire, which may be broken, and when broken it renders the electric fuse absolutely useless. The wires must not be bent sharply, or forcibly separated at the point where they enter the copper cap, as this may break or loosen the sulphur cement and permit water to come in contact with the charge in the electric fuse.

The correct way to prime a high explosive cartridge with an electric fuse is to insert the fuse cap in the center of one end of the cartridge, pointing it directly toward the opposite end, then bring the two wires together up one side of the cartridge, tying them in place with string, an inch or two from each end of the cartridge. The common custom, Figs. 7 and 8, of taking one or more loops or half-hitches around the cartridge with the wires themselves after inserting the fuse cap in a hole made diagonally in the side of the cartridge near one end, is always to be condemned. The principal objection is that the looping of the wires may break the insulation, causing short circuits or leakage of current in wet work, or may even break the wires. In addition, when a fuse cap from 1¼ inches to 2 inches long is pushed into the side of a cartridge 1 inch, 1¼ inches, or even 1½ inches in diameter, it very often occurs that the point where the principal part of the detonating charge is located goes entirely through the explosive, even though it may not penetrate the paper. As it is always the custom when priming in this way to point the fuse cap diagonally toward the end of the cartridge, which will be nearest the outside or top of the charge, it can be readily seen that any pull on the wires hard enough

Fig. 7

Fig. 8

to affect the position of the cap, will tend to bring it more to a right angle with the long axis of the cartridge and thus force the point still farther out of the opposite side. While this does not always cause a failure, it is quite possible that lost shots may be attributed to it, especially when a cartridge of small diameter is used. To make a primer properly with an electric fuse may take a little longer, but the reduction of misfires will more than pay for the trouble.

Can Water Vapor Be Resolved Into Its Gases in an Explosion?

Editor Mines and Minerals:

Sir:—I would like to know the degree of heat, Fahrenheit, required to resolve steam or aqueous vapor, H_2O, into its original gases? This point of temperature is known as the point of dissociation, and in the study of the effects of moisture upon a mine explosion it would be interesting to know whether or not the moisture or humidity of the air-current plays any important part in the composition of the explosive mixture. The temperature of a firedamp mixture is estimated at about 6,600° F. upon combustion. The question is, whether the hydrogen and oxygen contained in the steam or vapor (H_2O), and mixed with the air of the mine, could combine with any other elements of the same, so as to have an accelerating effect upon the explosion? Could it be possible for the hydrogen of the vapor to become dissociated from its oxygen element in a flame of great intensity in time to combine with something else, such for instance, as the carbon of coal dust, and what would become of the oxygen contained in the vapor in such an event?

Do the resulting gases of an explosion, or the afterdamp, preclude the possibility of such a conclusion?

Montcalm, W. Va. E. W. Bailey

Black Powder

Editor Mines and Minerals:

Sir:—I note the exception taken to my answer to a recent examination question, by "J. S., West Pittston," page 165, October issue. I wish J. S. had given his full name so that I could have written him personally. The reference is to the answer to the second part of Question No. 8, page 52, of the Anthracite Mine Inspector's Examination, Mines and Minerals, August, 1910. The question reads: (*a*) What kind of explosives are used in the anthracite mines? (*b*) What powders are best adapted to various conditions of mining? (*c*) etc.; (*d*) etc. The answer to this question, for lack of space, was not made as full as would be possible in a discussion of this important matter; but was aimed to bring out the chief points of difference between the two general classes of explosives used in coal mining; namely, black powder and dynamite, mentioned in answer to (*a*). The question (*b*) draws attention to the well known "various conditions of mining," with the intent, we presume, of ascertaining a candidate's knowledge of how these two classes of explosives differ the one from the other, and how these differences adapt each class to certain conditions in mining. The question does not require that the candidate subdivide the two general classes of explosives, as such subdivisions are almost endless in their application to various coals.

Powder manufacturers have for several years now been studying to produce powders particularly adapted to coal in different sections. The aim has constantly been to conserve the strength of black powder by uniformity in grinding, mixing, and sorting, and by compression of the mass. Little change has been made in the general formula, but by nitration and other similar means, the various forms of permissible explosives of the black-powder class have been developed. In like manner, also, by varying the dope and the character of the absorbent in the dynamite or nitroglycerine class, the action of this powerful class of explosives has been modified so as to make it of great value in the blasting of the harder coals. In the working of the thin seams of hard bony coal, referred to by our correspondent, "the grade and strength of the powder," as our answer states, "should be adapted to the hardness of the coal." Our correspondent seems to understand the term permissible explosive as describing a different class from the two general types mentioned, whereas the term relates to special powders belonging to each of these classes. We are glad to explain our answer in this respect and hope we have made the same clear.

Scranton, Pa., October 3, 1910. J. T. Beard

The "Howell-White" Furnace

George W. White, son of the inventor of the so-called Howell–White furnace, writes as follows:

"The name was probably copied from the circular and pattern list of the Pacific Iron Works, in 1880, Rankin & Brayton, proprietors. My father, George W. White, of New York City, in 1860 conceived the value of a furnace that would desulphurize, oxidize, and chloridize the base ores, and left for California soon after. A patent was granted him August 23, 1864, also February 7, 1865. A patent was also secured in the Republic of Mexico, 1876. When he reached San Francisco in 1860 he found that base ores were not generally worked, as then there was plenty of free milling ore in sight with placer diggings in plenty. Nothing was done therefore to introduce the furnace until the year 1870, when my father located at the Aetna Foundry, on Fremont Street, where the furnaces were cast, set up, and shipped. The Pacific Iron Works, located nearby, recognizing the value of the White furnace, attempted to secure a one-fourth interest through an agent of the name of Thompson, but before the final payment was made my father learned that they were trying to secure a patent in Mexico without his knowledge. Then suit was commenced against said Thompson and won, and as Thompson was merely an agent of the Pacific Iron Works and had nothing, suit was brought against the Pacific Iron Works and won. It was carried to Superior Court in Equity, and before final decision was reached my father died. At that time mining was on the ebb. Mining-machinery manufacturers were going out of business; the Pacific Iron Works with the rest. My father's lawyer was approached by the Pacific people to settle the suit for $2,000, and as Brayton, the only member of the firm alive, was to make over his possessions to his wife, my lawyer advised settlement. This I agreed to, and the suit, which had been in the courts almost the life of the patent, was settled.

"The name Howell is a myth. Owing to litigation neither the Pacific Iron Works nor my father could collect from the users of the furnace in full, and at the time of his death $60,000 was outstanding which the users of the furnace would not pay, saying that if they did so the other would also try to collect. It seems a pity that the furnace should not be called by its right name—White–Howell Furnace—instead of by the mythical name, Howell–White furnace."

RUST-PROOF FINISH FOR IRON

The so-called "Coslettising" process for producing a rust-proof finish on iron is referred to in a recent issue of the *Brass World*. This process consists in boiling the iron or steel article to be treated in a solution of 1 gallon of water, 4 ounces of phosphoric acid, and 1 ounce of iron filings. By this means a black coating is produced on the iron or steel, which protects it from atmospheric and other corrosive influences. This formula gives good results when care is used, but when carelessly handled a certain amount of undissolved iron filings may be left on the surface of the article being treated. As far as the protection of the coating against corrosion is concerned, it is stated that a piece of steel treated by the process and immersed in salt water for nearly a year has resisted its attacks so that it is practically free from corrosion, while a similar piece untreated has become badly rusted.

Mines and Minerals

ESTABLISHED 1881

PUBLISHED MONTHLY AT SCRANTON, PA.

WESTERN EDITORIAL OFFICE: 728 Equitable Building, Denver, Colo.
CHICAGO OFFICE: 309-311 Michigan Ave.

Entered at the Post Office at Scranton, Pa., as second-class matter

Address all business communications to MINES AND MINERALS, Scranton, Pa.

SUBSCRIPTION RATES

Single Copies..25 cents
Yearly Subscriptions, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines $2.00
To Canada.. 2.50
To all other Countries..................................... 3.00

Remittances should be made by P. O. Order, Express Money Order, Bank Check or Draft, or Registered Letter.

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

THE AMERICAN MINING CONGRESS

In common with all meetings of the American Mining Congress held at long distances from the center of population, the attendance at the Los Angeles meeting, just closed, was drawn largely from the surrounding country. While the official figures are lacking, a study of the names of the members present, published in the Los Angeles *Examiner*, indicates that about 50 per cent. of them came from the convention city or within a radius of 50 or 100 miles; some 35 per cent. from other parts of California, from Nevada and Arizona; about 10 per cent. from other states west of Colorado and about 5 per cent. from the farther East. Probably not over 1 per cent. of the attendance was drawn from points east of the Mississippi River, and less than that if the heads of departments and other officials of the Mining Bureau and the United States Geological Survey are omitted. At the last minute many "oil men" came into the convention and took an active part in the proceedings. The policy of admitting oil producers to the Congress is open to discussion and if the expression of opinion voiced by the few members of that calling who spoke publicly is to be followed, they do not care for membership. Although oil is classed as a mineral under our laws, its method of production and handling is so different from any other mineral that the oil producer and miner have little in common except that, for the purposes of acquisition, oil and placer lands are classed together. This unequal distribution of the delegates and members present was not due to any fault of the Congress or the city of Los Angeles, but would have happened had the meeting been held in New York or Philadelphia, and is brought about by the average man having neither the time nor the means to make the round trip of about 5,000 miles required to reach the seat of the convention. The convention at Los Angeles was particularly a western one and largely in the interests of the oil producer; the next, if held in, say, Philadelphia, would reflect the sentiments of the bituminous and anthracite coal operators and of the iron men. Thus, no convention can be considered strictly national in character, and this is contrary to the spirit of the Congress, which is supposed to reflect the opinion of mining men from all sections of the country.

But notwithstanding this, the Congress annually places itself on record as reflecting the sentiment of all the mining men, whereas the fact is that each convention properly reflects the opinion of those nearest the city in which that particular convention is held. It is evident that something should be done to give the deliberations of the American Mining Congress more of a national and less of a local color. It has been suggested that each state in which the mining industry is of sufficient importance to warrant national recognition, shall organize a local chapter which shall elect one delegate to the Congress. This delegate shall be instructed to cast the vote of that state upon all questions of suggested legislation, and by requiring all resolutions to be

presented to the central resolutions committee sufficiently far in advance of the national meeting, each state and its delegate will be able to vote intelligently upon, at least, the most important questions likely to come before the Congress. While members would be welcome at all times and should attend the national convention, they would not be allowed to vote. This seems to us a most excellent plan as placing the more distant states upon an equality so far as voting power is concerned with those within easy traveling distance of the convention hall, and will tend to stimulate interest in the Congress by bringing together in each state a body of men whose interests are essentially identical. But we would go a step beyond this and give each state, not a single vote, but a vote in proportion to the value of its mineral production as determined by the report of the Director of the United States Geological Survey. In this way the vote of Pennsylvania or Colorado would be larger than that of Alabama or New Mexico. By limiting the voting power to those appointed by the state chapters and proportioning the delegates according to the importance of each state as a producer of metals or coal, the affairs of the Congress would be conducted with more dignity and be calculated to inspire more respect as the sentiment of the mining men of the entire nation, and not as now, of those who by nearness to the place of meeting are alone able to attend.

Had some such system as the above been in force at the date of the Los Angeles meeting it is not believed that the Congress would have placed itself on record as opposed to conservation. It is our opinion that a strictly representative congress would have indorsed the opinions of Doctor Pinchot and not repudiated them as did the session at Los Angeles. Engineers are by training unconscious conservationists and we are sure that those who are members of the American Mining Congress will not feel pleased, to put it mildly, at being placed in the position of repudiating themselves.

So much has been said for and against conservation that it is useless to repeat the arguments in the case. There is a strong and growing national sentiment in favor of true conservation, and, as not infrequently included therein, a revision of the federal mining laws whereby all the citizens may profit from the exploitation of the mineral resources.

ACCIDENTS TO WORKING MEN

THE American Museum of Safety, with exhibit hall for accident prevention in the Engineering Building, 29 West 39th Street, New York, issues a monthly bulletin. In the September issue Dr. Ira S. Wile, New York, in an article on "Accidents and the Surgeons," states that while the figures on the prevention of industrial accidents are scarce, it is noteworthy that the investigation of the State Commissioner of Labor in Minnesota revealed the startling fact that 60 per cent. of the killed and injured were working men under thirty years of age. The same Commissioner of Labor declares that one-half of all industrial accidents are preventable. The waste of human life at the period of youth, vigor, and enthusiasm, demands correction. Waving aside all figures showing the economic loss to the working men, their families and the community, losing sight of the immense loss through liability insurance and the costs of damage suits, even dismissing from thought the actual cost in hospital and dispensary expenditures, surgical fees and surgical supplies, it is not too much to ask for the sake of the working man that adequate protection be given to lessen his surgical burden of preventable accidents.

Prevention of accidents is as essential to the welfare of the nation as the prevention of tuberculosis, yellow fever, or typhoid fever, which are occupying the attention of sociologists and humanitarians.

IN the last issue of Mines and Minerals the article appearing under the title "Power Production at Collieries," should have been credited to W. S. Meyers, and not Howard N. Eavenson.

BOOK REVIEW

Esperanto Grammar. Arthur Baker, 700 East 40th Street, Chicago, Ill., has prepared 100,000 brief grammars of Esperanto, and to permit every thinker an opportunity to judge as to the merits of the language, will send one free to any one sufficiently interested to ask for it, enclosing stamp for reply.

Twentieth Century Sheet-Metal Worker is a modern treatise on modern sheet-metal work. The book, which costs $1, bound in cloth, has 86 pages but no index. It contains 76 diagrams explanatory of the sheet-metal workers' art, and numerous practical examples. The book is published by the American Artisan, Chicago, Ill.

Practical Data for the Cyanide Plant, by Herbert A. Megraw, 93 pages, 4¼ in. × 6¾ in., flexible cover, price $2. Published by the McGraw-Hill Book Co. The inspiration for the publication of this volume was in the realization that, while theory and practice of the cyanide process has been ably explained in the standard works on the subject, no attempt has yet been made to collect the practical data, formula tables, usual methods, etc., in one small and convenient volume which might be carried about by the "Man on Shift." As a $2 proposition the book is a joke. E. B. W.

The Third Edition of "Economic Geology," by Heinrich Ries, Professor of Economic Geology at Cornell University, has been issued by the MacMillan Company. The preface states: "Although it is but little more than 4 years since the first edition of this work appeared, our knowledge of the subject of economic geology has expanded to such an extent it was deemed advisable to make a somewhat complete revision of the book." The book is an interesting one on the subject and furnishes book references on the minerals described. There are 589 pages, 237 figures, and 46 plates. The method followed in treating the subjects is as follows: Properties and Occurrence; Analysis; Distributions; Origin; Uses; Production; Bibliography. The price of this book is $3.50. E. B. W.

The Minnesota Iron Ranges, is the subject of an article by G. O. Virtue, Ph. D., published in Bulletin No. 84 of the Bureau of Labor, Department of Commerce and Labor. This article is a study of the iron ore mines of Minnesota, and deals with the history of the development of the mines, the amount of ore produced, and the transportation facilities, together with a more detailed discussion of the economic condition of the employes of the mines, a large percentage of whom are of foreign birth. According to figures furnished by the Oliver Iron Mining Co., the principal producer of iron ore in Minnesota, only 23.2 per cent. of the employes of that company, on June 1, 1909, were Americans. The principal foreign-born employes numerically were Austrians, who constituted 32.5 per cent.; Finns, 15.9 per cent.; Italians, 11.1 per cent.; and Scandinavians, 10.2 per cent. Tables are given for 1907 showing the conjugal condition of the foreign-born employes, length of residence in the United States, ability to speak English, and number naturalized. Only 48.6 per cent. of the foreign-born employes could speak English, and 42.9 per cent. of those who had been in the United States 5 years were naturalized; of those over 21 years old reporting their conjugal condition, 51.6 per cent. were married.

The article discusses the characteristics of the various nationalities employed, wages and cost of living, housing conditions, home ownership, educational facilities, and labor organizations. The various methods of mining the ore and the working conditions are described, and statistics are given of fatal and nonfatal accidents, with a discussion of their causes and the provisions made for mine inspection. A brief account is also given of the hospital service and the aid funds and insurance systems provided by the companies.

SAG AND STRETCH OF POWER TRANSMISSION ROPE

The sag and stretch of manila rope cannot be determined to any exact amount, as it varies with the load carried, the speed run, and the initial tension in the rope. In the multiple system, when slack comes on top, the rope is allowed to sag until parts running in opposite directions would nearly touch. It then has to be shortened. The sag on tight side may be determined quite closely if the exact power to be carried is known. Likewise, in the continuous system, where it is possible to keep a uniform tension on rope, the sag may be closely approximated. In general, a rope should be allowed to run as slack as possible without slipping.

The sag of rope takes nearly the form of a parabola. The amount may be approximated by multiplying the weight of 1 foot of rope by the square of the distance from sheave to sheave where the rope leaves, and dividing by eight times the tension on rope. For example, 2-inch diameter rope with supports 90 feet apart, running at 4,200 feet per minute, $\frac{1.34 \text{ pounds} \times 8,100}{8 \times 800} = 1.7$ feet sag on driving side, which would be the same at all speeds. The slack side sag may be determined after the same method, by adding to the initial tension the tension from centrifugal force. Thus, with the same rope as before $\frac{1.34 \times 8,100}{8 \times 199 \text{ pounds initial} + 205 \text{ centrifugal tension}} = 3.3$ feet.

A new rope will stretch considerably for a short time, but after the parts of the rope are firmly bedded together further stretch is slow. The total stretch should not exceed 5 per cent. under reasonable conditions. In cutting the slack out of continuous drives, it must be borne in mind to allow some movement of tightener sheave to guard against shrink caused by atmospheric conditions, and also to allow for future resplicing.

MINING CEMENT GRAVEL AT ALTAR

Written for Mines and Minerals, by Aloysius Coll

Old and New Methods of Recovering Gold from Cemented Gravel in Absence of Water

The success of the recently invented Quenner dry pulverizing machine in the treatment of the gold cement in the Altar gold district of Western Sonora, Mex., has revived operations in a field which was worked more than 100 years ago. Strangely enough, after numerous attempts to mine the conglomerate at a profit, the methods now adopted go back to those employed in the days of the district's supremacy.

Following the discovery of gold in the Altar district by a band of soldiers in 1799, thousands of people flocked into the region from Hermosillo, Chihuahua, Durango, and Sinaloa, establishing camps at Cienega, San Francisco, and other places. Altar is the most arid province in Mexico, and on this account the placers could not often be worked with water. But the ground was so rich in gold that with dry panning, using the Mexican "batea," the operations were profitable. Ten years ago a big stamp mill was erected at El Tiro by Epes Randolph and others, at a cost of $1,000,000, and an attempt was made to extract the gold in the conglomerate by means of the stamp mill, but without profit.

The natives have, year after year, continued to work over the surface of the vast gold field, which extends from a point well up in Arizona to the Yaqui River, in Sonora, rushing into the district after each rainy season, when the gold is found in the top sands.

The richest gold-bearing material is in the lower stratum of the conglomerate, and although gold is almost anywhere, it is only found in profitable quantities in the ancient channels, which are for the most part covered by the wash of centuries of erosion. The field is one requiring prospecting, but when one of these channels is discovered a fortune is in sight. Once found these channels can be followed, whether on bed rock or above, and so far the new operations have failed to discover the petering out of any one of these channel deposits.

The most extensive operations since the success of the dry pulverizer has been established have been those of the American Ore Milling Co., which is working what is known as the Bray lease, a tract of proven ground near Baludo, 60 miles west of Santa Anna, on the Southern Pacific Railroad. A stage line is in operation between the railroad and the camp.

Fig. 1. Monuments for Mining Claims in Mexico

Fig. 2. Old Furnaces at Cienega

The American Ore Milling Co. sank a shaft 130 feet to bed rock, where there is a stratum of gold-bearing cement in a channel that is 3 feet thick and 10 feet wide. The gold in this stratum averages $12 to the ton.

Twenty feet above this is another stratum 20 feet wide and 8 feet thick which averages $10 in gold to the ton. Eight feet above this a third stratum 12 feet thick and 40 feet wide carries $8 in gold to the ton. From the shaft, tunnels follow each stratum. A second shaft has been sunk, up which the material taken from the top stratum is hoisted. The company has now on the dump 14,000 tons of the underground material which averages $8 in gold a ton. This is mixed with the material hoisted from the two shafts, and fed into the dry placer machine, which is now pulverizing 150 tons a day, half from the dump and half from the tunnels.

Labor in this field costs $1 a day gold, and it requires a crew of 60 men and boys to operate one machine and the dry washers used to complete the treatment. The machine eliminates the pebbles and pieces of broken rock, leaving only the dust and black sand with the gold for treatment on the dry washers. It requires six dry washers to handle the pulverized material turned out by one machine. Boys are employed to carry this material from the machine to the dry washers. One man cleans up the dry washers, brushing off the gold and black sand left by the bellows into a common gold pan. The hand panner sits upon a duck sheet and blows off the black sand, which still carries fine particles of gold. It is therefore caught on the sheet and saved for shipment as concentrate.

One of the strange features, is that though the dry-pulverizer had been in operation more than a year, not even those along the borderland in Arizona knew of the operations. As soon as it became known there was the usual rush into the field and during the month of April of this year there were more denouncements made in the Altar district than in all the other districts of Mexico combined. It is now hot in Altar, but the denouncements go on day after day, and the region is swarming with prospectors, who pick out what seems to them promising locations. The Mexican mining laws are so simple and direct that this feature greatly influences activity in the district. When a man finds a piece of ground not already denounced, which he thinks contains gold, he merely has to pay 5 pesos a pertinencia, or unit of mine location, equal to 2.47 acres, or $2.50 in United States currency, and is given his denouncement certificate. He then has a year in which to put up monuments, which must be 50 centimeters square at the base, of

masonry or concrete, and within sight of each other, as in Fig. 1. He may do this work at once, and in 6 months obtain title to the ground. It is then his so long as he pays the taxes upon the land. There is not the same hardship imposed in work upon the claim, as in the United States, nor is there the fear of having the claim jumped because of technical points.

Most of the denouncements so far made have been in and around Baludo, where Quenner has worked his machine, and at Cienega where mining was carried on from 1799 up till 1844. The whole country around Baludo, Cienega, and other villages, is so torn up and gutted out on the surface that a horse cannot be ridden over the ground. It will be understood from Fig. 2 that the district is not new in any sense of the term, and if new mines have not been recorded in years, the loose sand at the surface has been worked summer after summer by the natives. Since the natives had no method of crushing the lower stratum of cement gravel, they contented themselves with screening the surface dirt, as in Fig. 3, and working over the sand and gold particles in it by the dry washer shown in Fig. 4.

Fig. 3. Using Primitive Grizzly Preparatory to Dry Washing

Fig. 4. Primitive Dry Washer Used in Mexico

It is not permitted to work the ground denounced until the expiration of 6 months after putting up monuments, with proper marks, so that there can be no great activity in operations till this fall, by which time most of the ground will have been taken up. Much of the ground has been denounced by persons who have not the capital to install the Quenner plant, simple as it is, and this gives rise to the impression that by the autumn Altar and Hermosillo will witness many stirring scenes in mining deals. Much of the ground is held by men in Douglas and Bisbee, Ariz.

The main body of the machine, Fig. 5, is a screen in the form of a drum which revolves on small wheels set under it, at the rate of 28 revolutions per minute. This drum is made of steel bars 1 inch thick, 2 inches wide, by 6 feet long. The arrangement of the bars, with a small opening between them, makes the drum a revolving screen as well as the body of the pulverizer. Through the center of this drum is a shaft, to which are attached 36 chains of three links each, at the ends of which are suspended manganese hammers. When the machine is in motion these revolve in the same direction as the drum at the rate of 400 revolutions per minute. The hammers, when whirled about the shaft strike a blow of 1,800 pounds and have the advantage over rigid hammers in that if they strike rocks and must give, there is no breakage. The hammers attached to the shaft are set so that they strike edgewise against the material and when new, clear the inside curve of the drum about ½ of an inch. The mill is 6 feet long, and the diameter of the drum 40 inches. It requires 16 horsepower to operate the mill when set to crush to 8 mesh.

One of the successful features of the machine is the arrangement of the chains and hammers on the inside shaft. Quenner's first machine had the hammers arranged in regular order around the shaft, and when the material was fed into the hopper at the end of the drum, the material had a tendency to fly around in circles, with no tendency toward a discharge of the worthless rock in the gold cement. He then solved this problem by setting the hammers in spiral form on the shaft, and these in rotation have the power of passing the pebbles and broken fragments of rock from the feed end to the discharge end of the drum. By reducing the spiral trend, the machine can be made to crush all the material fed into the hopper. The fines drop under the drum, and are then ready for treatment on the dry washers. These are operated by hand. The fines are fed into a hopper, which regulates the flow. The bellows in the dry washers, Fig. 4, blows off the light dust and leaves the black sand and gold ready for hand panning.

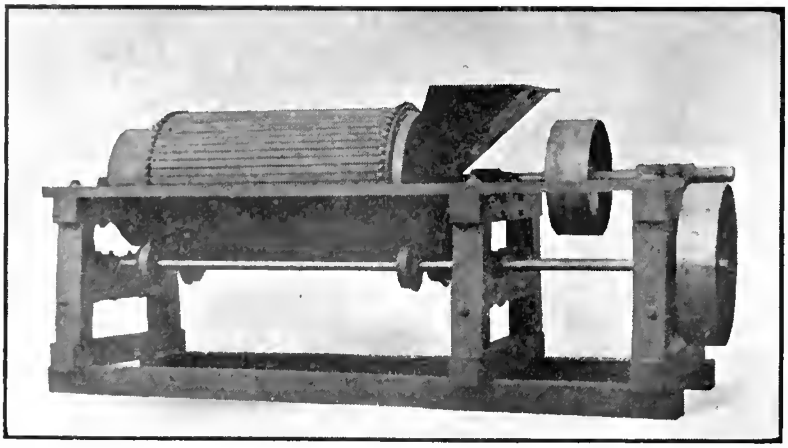

Fig. 5. The Quenner Dry Pulverizer

Tungsten powder, heretofore rarely sent from the Plauen district, was shipped to the United States in 1909 to the value of $34,996. This metal, produced from wolfram ore found in that district, has been used in Germany in a process for hardening steel. It promises to become an important item of export as it is used extensively in American steel works.

THE AMERICAN MINING CONGRESS

Written for Mines and Minerals

Probably the most important meeting ever held by the American Mining Congress was that which commenced September 26, in Los Angeles, and ended October 1.

Report of the Meeting Held at Los Angeles, September 26, to October 1, 1910

Early conventions were not attractive, principally because they were dominated by lawyers, politicians, colonels, boomers, and mining experts who learned their mining from prospectuses and prospectors. Those interested in mining could not afford the time to associate with these people and be regaled with noise. The writer attended one of the early conventions where the effusive outbursts of hot air were possibly never exceeded even at a political convention.

President Buckley in his opening address called attention to former conditions and congratulated the Congress on the beneficial changes that had occurred; hardly had he finished, however, before the lawyers, politicians, corporation henchmen, and promoters commenced the old tactics.

Gifford Pinchot made a few remarks on conservation which were not sufficiently lucid to flag the outbursts of the Antis. He urged that mining men of all classes cooperate with the other people of the country in eliminating waste and control by large interests and in accomplishing the restoration to the people of large areas that through former bad legislation were permitted to slip from the control of the government. He said: "The early grants of the Southern Pacific Railway in the state of California, containing oil, should not permit the people to despair of conservation of the remaining lands of the government. The government will not be doing its duty unless it attacks the title of the Southern Pacific to the lands included in those grants and by legislation or otherwise restores them to the people of the United States."

"Before you condemn conservation find out what the friends of this policy assert and do not condemn upon what the enemies of conservation declare or dispute."

"The fundamental principle of conservation is that natural resources belong to the people of the United States and should be protected for their benefit."

"In the past the few have been benefited. The people of the nation wish to change this condition and they will."

"The rights of state and nation in regard to conservation have been the cause of division among some, but this should not be, for the several states and the nation can work in harmony, as they labored in the past in all great problems concerning the people."

"Every acre should be put to use by the greatest number of people, and excessive holdings by individuals should not be tolerated."

"Settlement of land must be encouraged and the land disposed of in fee simple, but separate from mineral beneath the surface which comes under a different head." (In this clause Mr. Pinchot had reference to agricultural land underlaid with coal.)

"The object of conservation is not to tie up development but to prevent the present generation wasting the natural resources."

"The coming generations have a right to some of the benefits."

"Mining men should accept the proposition and urge it."

"We believe in developing and not in speculation and monopoly."

"The people should supervise regulations concerning the natural resources, and seek to prevent the loss of life, fires, and accidents in mines. That is fair to all mining men."

"The forest service has never attempted to interfere with mining, but as a fundamental fact has endeavored to beat the man who was trying to get control of land under pretense of legitimate mining."

Speaking of the leasing system he said: "Conservation must not and will not interfere with the prospector. Any system that did so would not be sound."

"All that conservationists are trying to do is to make the prospector's work easier, to facilitate and not check his progress."

"Conservation is here to stay whether mining men like it or not."

Mr. Pinchot in his address stated that the attack upon the conservationists is based for the most part upon misunderstanding. The conservationists are working for all the people and the policy of conservation must eventually benefit all the people. He said: "The conservationists want cooperation between state and nation and not discord. Both should work together. He is an enemy to both state and nation who fixes difference between them. The conservationists are striving for the good of all and should receive the support of all the people, and national control or state control should not enter into a controversy. What is needed is both a national conservation commission and a state conservation commission and they should work together in this way. All the resources should be handled equitably and harm will be done to no man."

"Oil lands not now located should remain so. Legislation should be made for the development of these lands, say for 3 years, and if oil is found the government should give a permit to develop for a period of many years, say for 25 years, and the operator should pay a royalty, but small enough not to hamper his development of the land."

Mr. Pinchot, in Pueblo, had more to say on this subject. He said: "There is only one enemy to fight. It is the man in politics to feather his own nest. The loudest cries against the new policy and the most bitter fight against it have come from those individuals and organizations who see their individual profits are in danger."

"The basic principle of this fight of yours and mine is that it is better to help the small man make a living than to help the big man make a profit; to indorse the idea that the natural resources do not belong to a few men, mainly in Wall Street, but they belong, and must be kept, in the possession of the people."

"I believe the contest of states' rights and federal, so prominently before this Congress, would never have arisen if the government had not undertaken to control some of the special interests which believe they could avoid all control by taking refuge behind the states."

E. W. Parker, of the United States Geological Survey, was one of the speakers at Wednesday's session, his subject being "Conservation as it Affects Coal Lands." He voiced the arguments for conservation saying that the people should be protected. He said that in former years coal lands were given away at from $2 to $3 an acre, but that now through the suggestions of the Geological Survey such lands were being sold at from $300 to $400 per acre and this has not retarded development. Following up the argument that the East is seeking to take away that which belongs to the West, he said: "All money that has been obtained thus far from the sale of public lands has been put back immediately into the reclamation service for the development of lands in the West, therefore the West obtains all the benefits of conservation so far as applied and not the East."

Judge Short in his address attacking the policy of conservation claimed in substance that the northern, southern, and eastern sections of the country have had their share of the national wealth, wasted it in riotous living, and now seek to rob the West of its heritage.

Others who opposed the Pinchot policies have also used this extravagant figure.

The chief stumbling block was conservation, and from the various ideas advanced each one had his own. Doctor Buckley said: "There appears to have been some confusion of the

question of conservation with that of ownership of the public domain. They undoubtedly have some relation to each other, but in their fundamental natures they are distinct problems."

"Dr. T. C. Chamberlin, of the University of Chicago, has recently made the point, and rightly, 'I believe that conservation of our natural resources centers in the scientific and technical while the right of ownership and the most desirable distribution of ownership centers in the political and sociological This means that whenever it shall have been determined whether the lands of the public domain shall be owned or leased by the individual, company, or corporation, we will still be confronted with the question of conservation. As far as the conservation of our mineral resources are concerned, it must be conceded that such ownership or distribution of ownership as will result in the least waste, is theoretically the most desirable. Whether the government should use the lands of the public domain as a source of revenue, regardless of whether or not the result should be less waste, is a question involving other fundamental principles for its settlement.'

"Four things appear to be perfectly clear in a consideration of the conservation problem: We cannot afford to have the government enact legislation which will make the occupation of mining more hazardous. That nothing shall be done that will in any way retard the development of our manufacturing industries that depend on the products of the mines for their business. That everything possible be done to increase the percentage of metals that can be recovered from the ore bodies and from deposits of coal, oil, and gas. To bring about as quickly as possible the use of substitutes for the present sources of power and for metals which are supposed to be limited in quantity. If it is desired to bring about a decrease in the consumption of mineral fuels without lessening the growth of our manufacturing commodities, one of two things must happen. Either the efficiency of the mineral fuels must be increased or substitutes for the mineral fuels must be made available.

"The waste in mining is said to approximate 50 per cent. This waste, however, cannot be decreased beyond a point where mining becomes profitable. Under present conditions of the industry there appears to be five ways in which this waste may be lessened; viz., by improved methods of mining, by decreasing the profits; by increasing the price of coal to the consumers; by reducing the price of labor; and by securing markets for the poorer grades of coal."

On Tuesday morning a list of resolutions was offered as follows: Charles F. Potter, Colorado, recognizing conservation and providing for a leasing system for the disposition of oil lands; Colonel E. F. Brown, Colorado, providing for more simple means of location of claims in forest reserves, and again a resolution protesting against the segregation of surface and mineral; C. P. Fox, California, recommending that the American Mining Congress refuse to commit itself on any policy of handling public oil lands. The remaining portion of the morning was devoted to a discussion of the Federal Government in the oil industry. S. C. Graham, Los Angeles, strongly favored conservation and believed in such legislation as would secure for the government as large a revenue as possible consistent with the prevention of monopoly. T. A. O'Donnell, Los Angeles, favored a return to the laws that have been in force for the past 30 years, characterizing as ruinous the handling of affairs of the West from Washington by the leasing system. The former was an individual operator on patented land; the latter manager for a large corporation working on unpatented government land.

In the afternoon J. W. Dawson, West Virginia, recommended such changes in the Sherman Anti-Trust Law as would provide for the conservation of coal lands. George E. Baker, Bakersfield, Cal., urged that the Mining Congress take action on the subject, set forth the injustice of recent decisions by the land office, and express the belief that the situation could be cleared by simple amendments of present laws governing the disposition of oil lands. F. H. Short, Fresno, Cal., spoke in favor of leaving public lands open to entry and location. T. E. Gibbon, Los Angeles, spoke in favor of conservation that will give the government the benefit of lands still owned by it, but that will not withdraw land that has already been entered upon in good faith. W. E. Clark, Arizona, read the report of the Committee on the Revision of Mineral Land Laws as follows:

REPORT OF COMMITTEE ON MINERAL LAND LAWS

General Revision of Mineral Land Laws.—Submitted by E. B. Kerby, Chairman; Frank G. Tyrrell, Los Angeles; Will L. Clark, Jerome, Ariz.; W. H. Dickson, Salt Lake City, Utah; M. Baumgartner, Spokane, Wash.

Your Committee on General Revision of the Mineral Land Laws begs leave to report as follows:

Our work has been carried on with some difficulty, owing to the impossibility of having a meeting of the committee. But by telegraph and mail various matters have been discussed and agreed upon.

With few individual exceptions, the feeling is general among mining men, that a general revision of our mineral land laws is imperative. A generation has passed since the subject was last dealt with in any comprehensive fashion, and conditions and methods have radically changed.

On June 13, 1910, your committee sent the following message to Secretary Callbreath, who was then at Washington, D. C.:

"San Francisco, June 13, 1910.—Committee recommends that our President ask Congress to undertake promptly a general revision of the Mineral Land Laws which, in view of the difficult problems presented, should be in cooperation with the mining industry. The plan adopted for this cooperation should give all sections opportunity for public hearing and discussion of remedies. Mining Congress will suggest a practicable plan later on, if desired."

It was hoped to secure favorable action by Congress at once; this, however, was impossible, but your committe has seen no reason to modify this recommendation, and now reports to your honorable body, again recommending:

That we appeal to the Congress of the United States to undertake promptly a general revision of the Mineral Land Laws; that a Committee or Commission of Congress be appointed, and properly supported to enable them to carry out the work, and instructed to hold public hearing in the various mineral land sections of the country, and cooperate as closely as possible with the people actually engaged in the mining and oil industries in framing amendments, new legislation, etc.; that whatever be the general plan of the Commission, all sections be given opportunities for public hearing and discussion of remedies.

The reasons for this recommendation are:

1. The Mineral Land Laws of the United States and Alaska framed in 1872, and interwoven with a mass of supplementary state legislation, differing more or less in every state, fail to meet the present requirements of the industry. Moreover, evils have developed, the injurious effects of which are steadily increasing. These have become so serious as to create great dissatisfaction and complaint everywhere, and it is confidently believed that a general revision will be welcomed and supported by all the mining communities.

2. Of the numerous evils due to the present inadequate code, those most generally recognized are: The monopolization of valuable mineral land, and its speculative holding, without any effort at utilization, to the consequent exclusion of prospectors and miners. The result is a paralysis of productive industry, and the indefinite postponement of the development and settlement of the country. Among the many points that will come up for consideration in a general revision of the laws are the following:

1. The apex law, with its vexatious uncertainties and costly litigation. Here we shall have to consider, not only the

conflicts due to the extra-lateral right, but also those occasioned by the resulting contours of claims, and the overlapping of lines.

2. The present non-enforcement of the law of discovery.

3. The partial, or complete, evasion, by various ingenious expedients, of the law of assessment.

4. A clear, definite, and practicable procedure for acquiring rights to those mineral claims on which, from the nature of the deposit, discovery must be long deferred.

5. The problem of tunnel locations, and the uncertainties of title caused in neighboring claims.

6. The location of an unlimited number of claims by one person.

7. Location by proxy.

At almost every session of the American Mining Congress the prevailing dissatisfaction has found expression in various resolutions, asking for the correction of this or that or the other feature of the existing law. Such resolutions have been altogether resultless, for two reasons: In the first place, the United States Congress has paid no attention to them. In the second place, those who study the matter closely, find that the laws are interdependent, and it is difficult, and in some cases impossible, to correct one fault without going through the entire code. We must abandon the idea of patchwork, and concentrate our efforts upon the task of securing a general revision.

As the problems involved are peculiarly difficult, a revised code will not be satisfactory, unless it be the result of the most experienced judgment, and of full discussion by the mining communities. It is believed that the National Congress will welcome the active cooperation of the mining and oil men of the country, upon any practicable plan.

Congress must first assent to the general proposition, and agree to undertake a general revision; to do it with the cooperation of the industry and to give all sections an opportunity to be heard upon the problems involved. As to the details of the plan to bring this about, your committee is of the opinion that they can and should be left to the National Congress itself, with the understanding that this body is ready at all times to assist if desired. We further recommend

That the president and other officers of the American Mining Congress, and its members and committees, exercise every effort to secure the prompt attention and favorable action of the National Congress; and

That the people of every mining state and territory be requested to bring the matter before their Senators and Representatives, and enlist their active support.

A motion was carried that the report be referred to the Resolutions Committee.

A resolution approving the holding of a Panama Canal Exposition at San Francisco in 1915, was submitted and adopted.

The resolution providing for the investigation of freight rates on ores was reported favorably. As a part of the discussion on the motion for the adoption of this resolution, T. C. Becker, of Los Angeles, read his address entitled "Railroads and Mining Development." Mr. Becker went fully into the matter of rates and pointed out the injustice of the present basis of charges. He stated that the rates were based on what the carrier thought the traffic would bear, and that long and short haul features were given little thought. The resolution was adopted.

The following is the report of the Committee on Resolutions:

REPORT OF THE COMMITTEE ON RESOLUTIONS

Your Subcommittee on Conservation, having had under consideration the various resolutions referred to it, do respectfully make the following report:

We recommend the adoption of the following resolutions:

As a substitute for Resolution No. 10:

Resolved—That, in common with citizens of the United States engaged in other industries, we approve the theory and practice of true conservation, which means utilization and developing with the least possible waste the natural resources of our country.

We recognize, as men engaged in one of the most important industries of our country, the value of true conservation and its intimate relation to the mining interests, and recommend the enactment of such legislation, both state and national, as will bring about a beneficial development of the mines, the public lands, the public water rights, and the timber contained within our great western country for the best interests of the present and future generations without unnecessary waste.

We condemn, however, as unwise, as opposed to the best interests of the American people, and as wholly unnecessary to the success of any plan of true conservation, legislation or proposed legislation which tends to make the miners and other citizens of the public land states who invest their time, labor, and capital in the development of the natural resources contained within such states, lessees of, or tribute payers to the national government.

We believe that every legitimate means should be adopted in the control of public lands to eradicate or lessen the evils of monopoly, but fail to find in any of the remedies suggested by the advocates of the leasing system how this can be accomplished by changing the present laws so as to take from the citizen a clear title and substitute therefor a lease.

As a substitute for Resolution No. 12:

WHEREAS—The laws relating to forest reserves provide that nothing therein contained shall prohibit any person from entering upon such forest reservations for all proper and lawful purposes, including that of prospecting, locating, and developing the mineral resources thereof, and

WHEREAS—Reports have been made from time to time to this Congress that in the administration of the rules and regulations of the Forest Service in many instances, mining and prospecting have been discouraged within the forest reserves and miners and prospectors have been hampered and interfered with in the exercise of their lawful vocation, and

WHEREAS—Assurances have been made to this Congress by representatives of the Forest Service that in their administration of the laws relating to the public lands under their jurisdiction they will in no manner discriminate against but will aid and assist them in the development of the mineral resources within the Forest Reserves. Therefore,

Resolved—That in reaffirming the right of every prospector who is a citizen of the United States, or who has declared his intentions of becoming such, to enter upon and prospect every part of the public domain, we suggest and recommend a spirit of greater harmony and cooperation between the prospector and miner upon one side, and the officials of the government on the other.

We further recommend that the laws relating to the public domain and particularly that part of the public domain lying within the forest reservations, be administered without burdensome and discouraging departmental rules and regulations and in such a manner as to foster and encourage the mining industry.

We condemn the actions of any class of citizens who go upon the forest reserves, or other public lands, for the purpose of locating fictitious mining claims in order to obtain the timber contained thereon, but we ask Congress to protect the miner and prospector in the development of the mineral resources by the enactment and enforcement of such laws as will give them the right to use such timber and other products of the soil from the public domain as may be necessary in the proper development of their mines.

As a substitute for Resolution No. 30:

Resolved—That, recognizing the right to appropriate to a beneficial use, waters upon the public lands, is fully recognized by Congress and the courts to be wholly governed by the laws of the state wherein such waters are located, and

That the development of mines and the mining industry in many sections of our country is largely dependent upon the

use of water-power, and that there are large amounts of undeveloped water-power now running to waste on the public domain which in the interest of true conservation should be utilized and put to a beneficial use, and

Recognizing further, that the National Government is the owner of large quantities of lands bordering upon and adjacent to streams, the waters of which belong to and are under the control of the states, and that by reason of such diversity of ownership and the different constructions placed upon existing laws relating thereto, water-power development in the West has practically ceased, and

Recognizing further the great expense necessarily incurred in the construction of water-power plants in the mining region, which involves in most cases an expenditure of several million dollars; the uncertain markets for power presented by the mining districts; and the great benefits derived by the mining industry by the construction of such plants,

We therefore recommend that laws be speedily enacted which shall definitely and accurately define the rights of citizens to utilize and put to a beneficial use the waters of the streams and the rights-of-way on public lands adjacent thereto for water-power purposes, and that such laws provide for the concurrent use of the rights of way so long as the water rights are put to a beneficial use under the laws of the state, or for a sufficient length of time to enable those who engage in their development to secure a reasonable return upon their investment.

We believe and therefore recommend that for the purpose of harmonizing all interests and bringing about a proper development of water-power freed from monopolistic influences, all water-power sites upon the public domain should be under the control and supervision of the respective states, wherein said sites are located.

As a substitute for Resolution No. 32:

Resolved—That any conservation policy which places obstacles or restrictions in the way of the free and unrestricted prospecting and location of metalliferous mineral lands, or which favors any lease or royalty upon the future tenure and production of such locations, is inimical to the development of our country's resources, represents a step backward, and strikes directly at the welfare and prosperity of the entire mining industry.

Resolved—That we indorse the work of the Forest Service in its efforts to preserve and maintain a national consumption of the nation's timber resources, but we are unqualifiedly opposed to any and all withdrawals of metalliferous mineral lands from public entry, and to any legislation which will in any way interfere with the free prospecting, location of or production of mining claims.

As a substitute for Resolution No. 33:

Resolved—That this Congress believes that the best interests of all the people will be conserved by state regulation and control of all natural resources within the boundaries of each and every state, in the very largest measure compatible with present Federal statutes.

We have had under consideration Resolutions Nos. 11, 13, and 16 and do respectfully recommend that the same do not pass.

Respectfully submitted,

Charles F. Potter, Chairman, Subcommittee on Conservation.

Edward F. Benjamin, Chairman, Subcommittee on Oil.

The Chairman announced that 10 minutes would be allowed each delegate in discussing these resolutions. Charles F. Potter, chairman of the Conservation Subcommittee, spoke in favor of Resolution No. 10. He reviewed the practice of conservation since the days of early ancient history. He condemned the leasing system; showed that the plan of making the miner a tenant and tribute payer to the government is not a new one, and furthermore that it has been a failure in most of the cases where practiced. He quoted President Polk, who in 1845 condemned the leasing system then in force.

At noon adjournment was taken until 2 P. M.

THURSDAY AFTERNOON

Resolution No. 42 was read, providing for the establishment of government smelters in various mining districts.

The 10-minute discussions of Resolution No. 10 were resumed. Dr. H. Foster Bain, California, speaking in favor of some form of leasing system, pointed out that such systems are now in force, and with great success, in the Mississippi Valley; Missouri has a system of leasing and it does not discourage prospecting. T. W. Hull, Arizona, made a strong appeal for a continuation of the old way of acquiring mineral ground—by location and patent. After remarks by several other delegates, chiefly unfavorable to conservation, Resolution No. 10 was put to a vote and was passed. The substitute for Resolution No. 12 was then taken up and passed without discussion. Substitutes for Resolutions Nos. 30 and 33 were adopted after short discussions.

In the adoption of the report of its Committee on Resolutions the Congress puts itself on record as follows:

While indorsing the policy of conservation in general terms, it is opposed to the leasing of mineral lands by the Federal Government.

Less burdensome restrictions in connection with forest reserves are demanded so that prospectors may have greater freedom in going on to forest reserves to prospect for minerals.

State control of water-power sites on the public domain is urged as tending to more rapid development of the various states.

Withdrawal of metalliferous mineral lands from public entry is condemned.

State regulation and control of all natural resources to the largest degree compatible with Federal statutes is urged.

After the reading of Resolutions Nos. 42, 43, and 44, the Secretary read the report of the Credentials Committee. This was adopted without comment. The report of the Committee on Standardization of Electrical Equipment in Coal Mines was read.

ELECTION OF OFFICERS

The newly-constituted Board of Directors held a meeting at 3 o'clock on Friday afternoon and elected the following officers for the ensuing year: Mr. John Dern, Salt Lake City, Utah, president; Mr. Samuel A. Taylor, Pittsburg, Pa., first vice-president; Mr. D. W. Brunton, Denver Colo., second vice-president; Mr. E. A. Montgomery, Los Angeles, Cal., third vice-president; Mr. James F. Callbreath, Jr., Denver, Colo, was re-elected secretary.

A resolution was passed that the next meeting of the Congress should be held at either Phœnix or Douglas, Arizona.

In the evening the Congress resolved itself into a "smoker," given under the auspices of the Sierra Madre Club, held on the roof of the Hamburger Building.

VANADIUM STEEL

For axles, the superiority of vanadium steel over other alloyed and plain steel, is due to its high elastic ratio (which is the real strength of steel), its wonderful ductility with this increased strength, and its resistance to failure under repeated alternation stresses. The full advantage of vanadium steel is obtained only after heat treating. To demonstrate the ductility of vanadium steel axles: it is possible to bend double without cracking a vanadium axle treated to show an elastic limit of 85,000 pounds per square inch with 19 per cent. elongation in 2 inches, while a plain axle treated to this high elastic limit will invariably break in attempting to bend double. Vanadium bits specially treated for coal-cutting purposes have under actual test cut two-thirds more coal than ordinary cutting bits.

EL COBRE COPPER MINE*

By Benjamin B. Lawrence, New York

It may surprise many to learn that the first copper mined in quantity by civilized man on the Western Hemisphere came from the El Cobre copper mines, at Santiago de Cuba; and much information of historical interest relative to this property may be found in the government archives at Santiago.

History of the Oldest Copper Mine in America. Rich Ore Mined Under Difficulties

It seems that the first discovery of copper was made by Spanish adventurers in 1544, 9 years after the founding of the town now called Cobre. The mine lies 12 miles northwest of Santiago Bay in the valley of Rio del Cobre, in the Sierra Maestre Mountains, 400 feet above sea level.

In the early days, this town lay in the center of rich coffee and sugar plantations, and the mountains in which El Cobre Mine is situated were the summer resort, as it were, of merchants residing in Santiago.

In these days El Cobre was by far the most important town in Oriente Province. From the time of its discovery the mine attracted wide attention in Spain, and the Crown was richer by vast sums from its operations, the Queen of Spain herself being personally interested in the railway which was subsequently built to bring the ore to the coast. The property was worked for a century by the Spaniards, who employed for the purpose slaves, both African and Chinese

The most important feature of El Cobre and one that has made it widely known throughout the world, is the Sanctuary of the Virgin of Cobre. This stands upon the very apex of the Cobre vein, and its pink dome and square blue towers may be seen from any point in the mountains for miles around. The incident of its erection forms a part of the history of the mine itself.

Alonzo Ojeda, from San Domingo, wrecked upon the shores of Cuba early in the fifteenth century, was saved from death by an Indian chief, Cacique by name. Ojeda had with him an image of the virgin, and, in fulfilment of a vow conditional on the saving of his life, built a chapel to her in the town of Cuieba. This was the first christian chapel in the island of Cuba. The Indian chief, however, stole the image to try the Lady's charm against his enemies, and it is said that so great was her power that he never lost a battle while he had the image in his possession.

In 1600, so legend has it, Juan de Joyos and Rodrigo de Joyos, Indians, and Juan Moreno, a negro, found the image floating in the bay. On a board upon the image was written: "Yo soy la Virgin de la Caridad"—"I am Our Lady of Charity." These three men took the image to Hato, where the mayor erected an altar for her, at the same time notifying the manager of the Royal Mines at El Cobre, Don Francisco Sanchez de Moya, that he had done so. Francisco built a chapel for the Virgin, first at Hato, and afterwards she was brought to Cobre, and a chapel was built for her in the town.

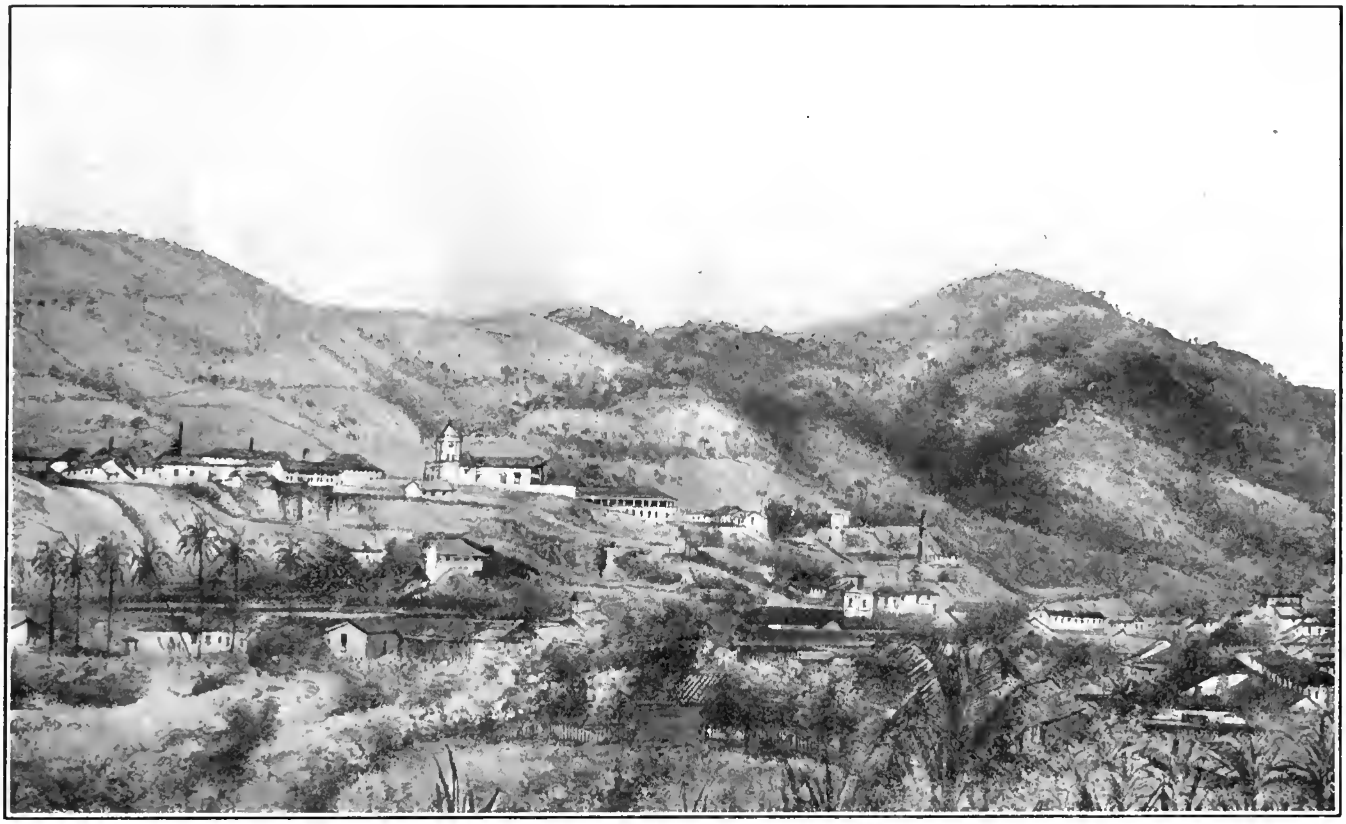

Fig. 1. Part of Town of El Cobre

As the mine prospered, Our Lady of Caridad became, as it were, the patron saint of the mine, and the sanctuary was built for her protection on the present site. It is a handsome building, 150 ft. × 90 ft., supported by massive columns, and is reached by 430 steps from the village below. Up these steps on their knees the pilgrims passed in thousands to pay their "promesas" to the Mother of Charity, and many wonderful cures of the sick are mentioned. Back of the chancel is a pile of crutches and canes, testifying to the fact that cripples had left the sanctuary without these aids to locomotion.

Heroic figures of the saints stand on either side of the entrance to guard the Virgin, who, in her cloth of gold, stands on the altar under the great dome. The figure is about the size of a

*Journal of the Canadian Mining Institute. Part of Vol. XIII, "Two Cuban Mines."

child's doll, and holds a small image of the Holy Infant in her left hand, who in turn holds a sphere symbolizing the world. The Virgin's right hand is raised in benediction.

Today Our Lady of Caridad reigns disconsolately in the old station of the Cobre railway, at the foot of the old steps. The sanctuary, however, still stands as a monument to days gone by.*

Fig. 2. Modern Boiler Plant, El Cobre Mine

In 1700, Francisco Sanchez de Moya was succeeded at the mines by Juan de Equilus, who obtained a concession from the Spanish Crown, agreeing to pay 200 tons of copper yearly to the Arsenal in Havana. Failing to pay his tribute, he was put in jail, and his successor fared no better. The mines were then worked by the Crown until 1830.

As early as 1623 the English displayed much interest in the yield of copper Spain enjoyed from the island of Cuba, and had already cast somewhat longing eyes in this direction. It is recorded that Oliver Cromwell sent a commission to Cuba to investigate this deposit; but there is no record concerning the report of such a commission.

The first appearance of the English on the scene was in 1830 when the Consolidated Company, an English syndicate, purchased some of the claims from the Crown of Spain, and mined actively until the necessary suspension of operations occasioned by the 10-years' war in 1869. Meanwhile this period of 39 years of operation seems to have been the most active in the history of the mine. Tall chimneys of rounded stone rise from among the rusted shells of old Cornish boilers, and the great low-pressure cylinders of the Cornish pumps are still on the ground, testifying to the energy which characterizes the English race. Even block houses were built to defend the operators from attack. There is still on the ground a cast-iron pump bob weighing 60 tons, made in Glasgow, which it is alleged occupied the energies of 500 men for 6 months to transport it from the coast to the mine.

Forty old shafts are recorded, and remnants of old hoisting machinery litter the ground. One flat woven wire rope, 6 inches wide and 1,000 feet long still remains upon the reel.

* The sanctuary was injured by the mine cave in 1906.

Many of the buildings were of massive stone, and provided with port holes indicating that they were used not only for dwellings, but for defense purposes in cases of attack.

On the topmost point of one of the highest hills, known as Hardy Hill, are the remains of the former manager's house, to which a zig zag trail leads. At this height a magnificent panorama presents itself of Santiago Bay, the entrance guarded by Morro Castle, and beyond the sweep of ocean. From this height the stirring events of the Fourth of July, 1898, could have been watched, when Cervera's fleet was defeated and captured just outside Santiago Bay.

The underground labor during English operations was performed by black slaves and Chinese, supervised by Cornish mine captains. Much in the records with reference to the operations at this time is tragic in the extreme, for the mine managers had under their command a corps of armed men, and the treatment of the slaves is said to have been cruel. Slaves were paid $15 per month, and an old letter from one mine manager mentions that more Chinese labor must be introduced since slaves were scarce and free labor commanded the prohibitive wage of $24 per month. Such a wage nowadays would certainly not appear excessive.

Rock and ore were hoisted in buckets and stull timbering was exclusively used. Much ore was in consequence left in the mine, since no method was devised for mining the ore under conditions when the ore body bulged.

When the mine was pumped out, many handsome mahogany stulls of large size were found, and these beautiful stulls, 24 in. × 24 in., 30 to 40 feet in length, were again used in retimbering dangerous places. A wooden pump rod 18 in. × 20 in., and 63 feet long, was removed from the shaft. These timbers were perfectly preserved by the copper sulphate waters, and, as already remarked, were used again after an interval of 50 years.

In 1869, as the mines became deeper, greater difficulty was experienced in keeping the workings dry, especially in the rainy season. The breaking of the Cornish pumps caused serious delays, out of which lawsuits arose between the Spanish and English companies operating the mines. A very complete history of this litigation is given by one Quintana, a mine inspector employed by the Spanish government.

Fig. 3. Old Stack at El Cobre, Sanctuary in Distance

As shown in Fig. 6, much of the surface of the property is covered by fine tailing dumps, the result of hand jigging. There are also the remains of an old stamp mill, Fig. 4, all of which is proof that much of the ore was concentrated before shipping. And indeed the concentration of this ore was necessary, as the freight rate to the coast and to England was excessively high.

Previous to the year 1844, when the railroad was built, the ore was "packed" to the coast on mules, and camels were also for a time employed, but in such a rocky country proved to be of little use.

In 1844 the Cobre Railway, shown on the right in Fig. 7, 8 miles in length, and replacing the use of 2,000 mules, was built. The Queen of Spain was the principal stockholder in this railway, and a freight rate of $6 per ton for down and $4.50 for up freight, was established. The railway was built, as our manager, Mr. Emerson, says: "with a fear of curves and a disregard of grades, which necessitated five important bridges and one incline, up which the trains were hoisted by cable!" The railway became, from its commanding position, the controlling feature of the property, and ultimately such high freight rates were charged as to leave no margin of profit to encourage the reopening of the mine at the conclusion of the 10-years' war. For example, no ore carrying less than 13 per cent. copper could be shipped with profit.

In these days the ore was sent to Swansea, Wales, and was treated in reverberating furnaces.

The old companies had the advantage of a high price for copper and cheap labor, but were handicapped by inadequate pumping machinery, inferior methods of mining, and high freight and treatment charges. In 1869-70 all operations were suspended, chiefly by reason of the war which centered around Santiago. Some 30 years later, in 1901, after the conclusion of the war with Spain, a New York syndicate was organized for the purpose of unwatering the mines.

In order to install modern machinery in the mines it was first necessary to rebuild the railroad. As it had been entirely destroyed, this was no light undertaking. The mine was equipped with heavy pumps, and the first difficulty encountered was occasioned by the copper in the water, which had a disastrous effect on the pipes and pumps. Again, the shafts proved to be full of miscellaneous debris—old pump rods, timber, boxes of cartridges, cannon balls, and human bones

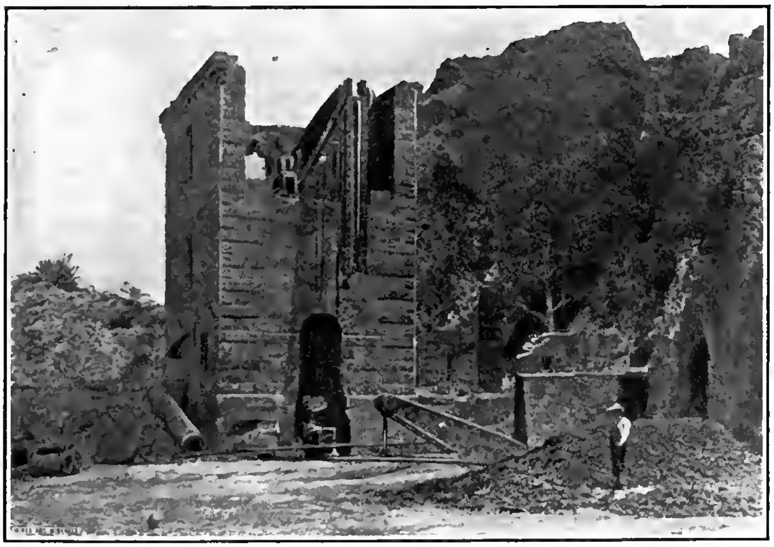

Fig. 5. Old Cornish Pump—El Cobre

were removed. These difficulties delayed the unwatering for more than 2 years; and when, finally, a depth of some 200 feet was reached, the company had the misfortune to experience an exceptionally rainy season accompanied by unprecedented floods, which latter carried away a large part of the town of Cobre and five railway bridges, while some 35 people were drowned.

The following year, 1903, the 500-foot level was reached, and some mining was commenced in the unwatered area. The railway was repaired, and a 250-ton smelter and 400-ton concentrator built at Punta Sal, the port. The company smelted and concentrated some 85,000 tons of ore, averaging 7 per cent. copper in this year. The water taken from the mine for the first

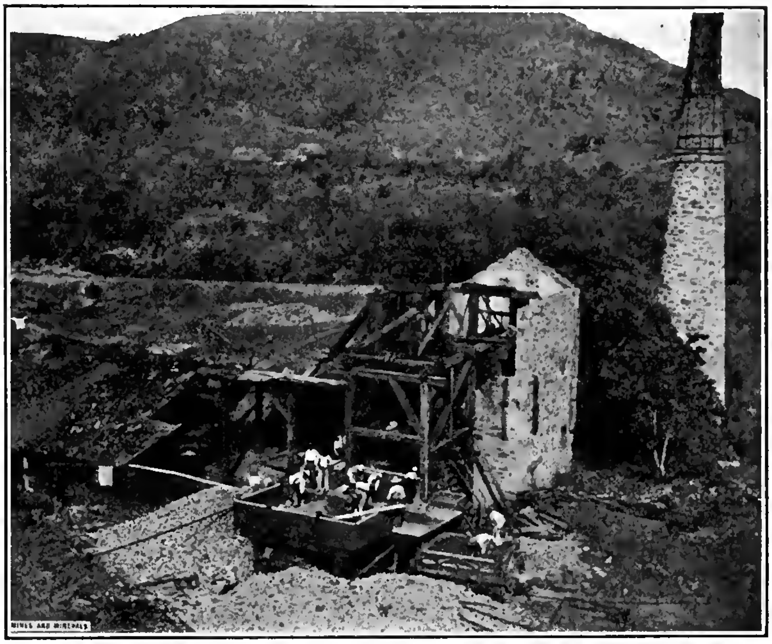

Fig. 4. A Modern Head-Frame in an Old Shaft House

6 or 8 months contained some 400 grams of copper per cubic meter. This water was run over Californias, as is the practice today. After the first year, however, the copper contents in the water rapidly decreased, and now only about 50 grams of copper per cubic meter is recovered.

The large quantity of low-grade oxide ore in and about the surface workings led to the erection of a leaching plant using sulphuric acid; but owing to the loss of acid and heavy cost of transportation, this undertaking was unprofitable.

As greater depth was obtained the old workings were found to be badly in need of timbering. They were, moreover, filled with a soft mud, and it proved a most dangerous and expensive task to lower to the 800 feet. Bad air from rotting timber and sulphides caused much annoyance and some deaths, and caves of old stopes were a constant menace.

In spite of all these difficulties, work was continued at enormous cost, and a considerable production was being maintained, when in May, 1906, a cave-in occurred which for a time practically rendered the lower portions of the mine inaccessible. At the time of this disaster 60 miners were confined in stopes filled with bad air; but through the heroic work of the superintendent, M. B. Yung, and his assistant, who is now superintendent of the mine, Edward B. Nagle, only two men lost their lives.

The pumps were pulled and the old mine temporarily abandoned. This was in 1906.

The management of the company now gave attention to working the upper portion of the property and to the outlying or adjoining property, which they thoroughly prospected. In the latter part of 1906 a huge blow-out, or surface deposit of copper ore was found, from which 64,000 tons of 6 per cent. ore was mined and shipped to New York. In addition, systematic exploration resulted in the mining of 100,000 tons of 8.7 per cent.

ore from the area above the 200-foot level. This ore has all been shipped to the United States for smelting, where remarkably good rates were secured and substantial profits made.

The mine is at present producing from 3,000 to 4,000 tons of ore per month, and exploration is once more being actively prosecuted with the object of again attempting to unwater this wonderful old mine in order to reach the 1,200-foot level, supposed to be the lowest level in the property.

The character of the ore deposit has been very fully described in an excellent paper written by the manager of the property, Mr. E. H. Emerson, and this description I present as a part of this paper.

Character of the Ore Deposit.—The strike of the ore bodies is with the valley, northeast and southwest. A series of rocks, from a coarse agglomerate to a fine-grained rhyolite without definite boundaries, constitutes the country rock of the deposit. The entire region is volcanic, traces of sediments occurring only on the summits of the surrounding mountains. One main fault, with several lesser parallel faults, striking with the formation, is responsible for the deposit. The main fault dips slightly to the south and carries a mud seam 3 inches to 5 feet in width. It presents a straight, smooth surface in many places in the mine. Another nearly parallel fault 300 feet to the north, called the

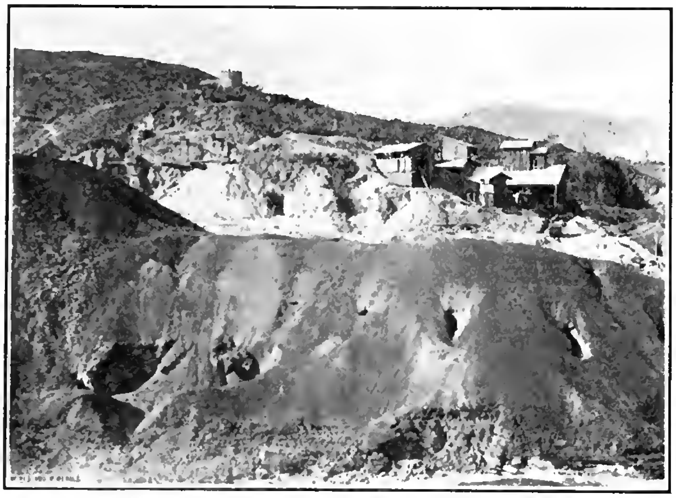

Fig. 6. Old Dumps, El Cobre

North vein, dips to meet the main fault at 1,000 feet in depth. To the south is a series of lesser faults that diverge from the main formation at the east end of the property, and extend along the side of the mountain range for a mile.

The main fault formed what has been called the Middle vein. This is a series of lenses of ore in brecciated zones on both sides of the fault, sometimes touching it and sometimes separated from it by many feet of rock. These lenses are irregular and are cut off by slips and joints without presenting regular walls, while the other faults have produced veins with clean walls, though varying greatly in width. A transverse fault zone has caused a 50-foot throw of the Middle and North veins. Along this zone, and near it, occur the greatest bodies in both veins. The widest lense is 125 feet, and they are almost continuous for a half mile with varying widths.

The veins, with clean walls and rarely exceeding 20 feet in width, were well worked by the stull timber; but caving and slice filling have recovered much ore lost by the old methods in the lenses.

The gossan extends, pretty generally, to a depth of 100 feet, carrying pockets of very rich oxides; but it is noticeable that there is a barren zone of gossan for 10 to 30 feet above the rich sulphides.

Near the surface, and close to the transverse fault between the veins, a brecciated zone was found in the agglomerate. This was filled with oxides, cracks being filled with a network of criss-cross stringers averaging an inch in width, and the mineral also impregnated the leached, almost kaolinized, agglomerate. The rotted rock was easily separated from the harder stringers of oxides, and 10 to 15 tons of barren rock was handled and hand picked, producing 1 ton of 10 to 12 per cent. ore at a good margin of profit. This was worked from open cut and by slice-filling from below.

Pyrite, in perfect separate crystals, is common in great areas of the agglomerate, and much of the country rock shows stringers of gypsum.

The North vein, to the east of the transverse fault and at the 500-foot level, showed a very abrupt change, from the enriched tarnished chalcopyrite with silicious gangue, to a clean bright chalcopyrite with a pure gypsum gangue. Extending with lessening values to the 700-foot level, the vein became pure white gypsum with only an occasional piece of ore. At the same time the lenses along the main fault continued with enriched sulphides and quartz without a trace of gypsum, and the North vein, to the west of the transverse fault, showed no gypsum.

The depth of the enriched zone of the sulphides has never been determined. It occupies at least the area from the 100-foot level to below the 650-foot level. In this area large lenses of fresh 3½ per cent. ore contain chutes of very rich sulphides. A stope on the 550-foot level was supplying 22 per cent. ore at the time of the cave-in. The depth of the lowest workings of the old companies is variously estimated at from 1,000 feet to 1,200 feet, and, as only rich ore could be handled at that time it may be assumed that the enriched zone extends to that depth.

All ores of copper are found, from the red and black oxides and native copper in the gossan, through native copper in considerable quantities in the top of the sulphides, and all the sulphides down to clean chalcopyrite.

The ore is highly silicious (from 45 per cent. to 65 per cent. excess insoluble) carrying only 20 cents gold and ½ ounce silver. It is very free from impurities.

The veins become tight to the east, and although joined by the southern veins of the Santiago Hill, have shown no values of importance to the east of the Cobre River. At the west end they are cut off by a massive igneous intrusion. Two agglomerate hills extend, with the same strike, to the west as though the vein formation has been faulted to the north. Pyrite is very prevalent; but no copper of importance is met with.

The Santiago veins are narrow and appeared to pinch in depth. The only important ore on the Santiago Hill, worked by the Cuba Copper Co., was a peculiar pocket of ore formed by the intersection of the Santiago vein with a band of leached pyrite in the porphyry. The deposition of copper oxides and carbonates followed the spherical lines of weathering of the porphyry, forming an unusual and striking ore of spotted and striped black, red, and green in a white weathered porphyry matrix, which was well called "Tiger ore" at the smelters.

It is peculiar that at the west end of the main Cobre veins, which show only a trace of gold and no impurities, a small vein of zinc blende, chalcocite, and pyrite, carrying $15 in gold, should occur. This vein has the general direction of the others and is only 175 feet deep, 200 feet long, and about 10 feet wide in its widest place. It is a little to the north of the main veins and cut off, as they are, to the west.

The total production of the property can only be approximated. It is, however, known that a million tons of ore and 140,000 tons of copper have been shipped from the property since 1830.

El Cobre has always been handicapped by the extremely silicious character of its ore. A systematic attempt is now being made to develop a basic ore on the island, for utilization in conjunction with the Cobre ores. Should this attempt be successful, El Cobre may again take her place among the important

producing mines and add another page to her varied history, which already covers a period of 375 years.

ROCKS OF EL COBRE

Agglomerate.—Sharp angular pieces from pebble to fist size, cemented by a bluish material very silicious. Blocks have the appearance of concrete. Easily rotted and changed to kaolin near surface.

Breccia.—Rhyolite and porphyry breccia, occurring throughout the agglomerate without defined boundaries. Fine grained, light gray and reddish.

Rhyolite.—Gray, fine grained, and in depth glassy.

Tuff.—Rhyolite, tuff occurring with the rhyolite. Easily rotted to white near surface.

Massive Intrusive.—A coarse-grained porphyry. Iron-stained in weathering from contained pyrite.

DISCUSSION

Dr. Douglas.—Mr. Lawrence has touched on the recent history of copper mining. I think he might have gone back to even pre-Columbian time in his story of this interesting old copper mine. There is every reason to suppose that these copper ores were utilized before the discovery of America. Mr. Clarence Moore, who had been doing a great deal of archeological work in Florida and elsewhere, wrote to me some years ago to ask if I knew anything of a native alloy of lead and copper in New Mexico. I told him I did not think there was any such thing in the world—I was very sure that there was no such thing in New Mexico. He said that he had been informed that such a native alloy existed only in New Mexico; adding that he had discovered some copper implements in the mounds of Florida, that had been made from such an alloy of lead and copper; hence the deduction that there was a commerce in those pre-Columbian days between New Mexico and Florida. I told him I thought it was a mistake, and that his chemist had somehow or other blundered, and I advised him to send his samples to Doctor Ledoux, who would probably form some other theory to account for the copper found in those mounds. He sent the samples to Doctor Ledoux, and Doctor Ledoux of course found that there was absolutely no lead in the copper, but that it was remarkably pure copper.

The question, therefore, was where did the copper come from? I told Mr. Moore that I thought the copper came from whatever region produced copper of exactly that description. It was extremely free from arsenic, and free from antimony. If it had come from the lakes it would contain a certain amount of gold and silver. Of course we all know that copper was mined in Michigan by the natives before the discovery of America, and that it was transported almost over the continent. I suggested to Mr. Moore that possibly the copper may have come from those old Cuban mines, because Columbus on, I think, his third journey, mentioned having seen some natives, from what he supposed to be Asia, who were navigating a very large canoe and carrying on some commerce between the island of Cuba and the Asiatic shore. I advised Mr. Moore to get some samples of native copper if he could from the outcrop of this Cuban mine at Cobre. He did so, and Doctor Ledoux found that the analysis corresponded absolutely with the copper that he had exhumed from these old mounds.

The conclusion, therefore, I belive, is that these mines were worked in pre-Columbian time, and that there was a commerce in copper between the island of Cuba and the continent of America and that now, after so many vicissitudes—political and economical—we are only reviving an old industry that was active more than three centuries ago.

Dr. J. D. Irving.—Mr. Lawrence's reference to these mines has been very interesting to me—the first reference particularly, because it deals with a question to which I have lately devoted considerable thought and concerning which Mr. Ransome read a paper—that is, in regard to secondary enrichment of ore deposits in their relation to climatic conditions.

In the course of some experimental work that I had an opportunity of doing in Alaska, I found that a great many outcrops of cupriferous pyrite were absolutely unoxidized at the surface. The waters of that northern climate were so cold that there had apparently been no opportunity for deep oxidation to occur. Sulphides extended actually to the surface, and there had been apparently no opportunity for leaching to go to any depth. Even in the stream beds themselves there were present particles of sulphides of iron and to some extent cupriferous pyrites, that were not oxidized by the running water of the streams.

Coming farther south to a region of temperate climate, we find a great contrast in the deep secondary enrichment at Butte, Mont. Finally, in tropical countries such as Cuba, we find the conditions that Mr. Lawrence has encountered in the mine which he has just described. I am especially anxious to know the details of oxidation here because it has been very difficult for many of us geologists to get much information as to the depth of oxidation under tropical conditions. Generally the chemical changes may be assumed to extend to much greater depths than farther north, provided the level of standing water is itself sufficiently deep. I should like to ask Mr. Lawrence if he can give me any details on the level of ground water in the mine at the

Fig. 7. The Old and the New at El Cobre Mine

time it was pumped out and the relation in depth, of oxide, secondary sulphide, and primary sulphide zones to this line.

Mr. Lawrence.—I suppose the effect of climatic conditions upon copper ore in Cuba can best be illustrated by one of the numerous catastrophes that seem to have followed the operations there.

A stock pile of copper amounting to some 35,000 tons was placed at the harbor. The stock pile was uncovered and subjected to action of rains for a year. It was partly oxidized ore and partly sulphide ore. Some of the ore that came from the lower levels was clean chalcopyrite, and some from the upper levels was oxidized. When the ore was finally shipped to New York it showed that it had lost ½ of 1 per cent. in copper. We found on investigation that oxidation had been going on in this stock pile rapidly all the time. On digging a hole in the stock pile you could hardly hold your hand in it on account of the heat generated by oxidation. Every rain that fell on that stock pile carried away a substantial amount of copper.

The same operation, I think, happened in the upper portions of this copper mine, and the oxidized area extends approximately 200 feet to the enrichment zone. The gossan extends generally to a depth of 100 feet, carrying pockets of very rich oxide, and it is noticeable that there is a barren zone of gossan 10 to 30 feet from the surface above the rich zone.

The geology of this mine has still to be studied from its lower levels and as yet this history has not been written.

Doctor Irving.—There is just one point on which I should like information: What was the average level of the surface of the water as it stood in the mine when you commenced operations?

Mr. Lawrence.—Well, I cannot positively say as to that. They have been holding the water at the 200-feet level for many years, and that would have been fairly well up in the oxidized zone.

CUBAN GOLD MINES

Written for Mines and Minerals, by E. B. Wilson

Santiago Province, Cuba, is undoubtedly the mineral spot on the island, for it contains workable deposits of copper, iron, manganese, and gold, not all of which by any means have been developed. About 20 miles south of Gibara, in the vicinity of Holguin, gold is said to have been mined off and on since the island was discovered, mostly by washing, although there are four places where shafts indicate more progressive mining. Tradition states that royal grafters took tolls from the miners which were excessive, and that between buccaneers, wars, and official grafters, there was no incentive to mine. It appears, however, that a French apothecary living at Holguin found a vein-like deposit of magnesium carbonate at Agua Claras, which was about 18 inches wide, between serpentine walls. To manufacture some kind of product he calcined the material, slacked and floated it. In the residue he found considerable gold, of which he made no mention to the authorities. It was not long, however, before he was suspected of being an alchemist, and to avoid complications he withdrew from the island. The writer, under philanthropic emotionalism for "Cuba libre" and as a collector of curios, took one-quarter interest in this magnesium carbonate deposit.

About 4 miles south of Agua Claras, J. S. Black, who had prospected from the Yukon to Panama and Cuba, by systematic research discovered a rich deposit at what is now termed the Santiago Mine. According to the mineral laws of Cuba, when one finds minerals he may denounce a claim even though it be on another's land, and as no work is demanded, the ownership trails along from generation to generation and then some, when an outsider from the States starts to work. The Santiago land was held by well-to-do Cuban people who readily agreed that Black could mine on a 20-per-cent. gross royalty basis. Black thought his place was so rich he could afford this, and taking a quart fruit jar of coarse gold under his arm he sought capitalists that would help him develop. He found a young New Yorker who agreed to furnish $75,000 for a mill and for development provided Black would give him about four-fifths of the company stock. The young man had a friend in the mining machinery business who knew just what was needed and the mill was equipped as follows: Crusher, Chilean mill, shaking plates, and tables, all of a kind which a practical metallurgist would not have ordered, and, with the exception of possibly the tables, unsuited to the ore. The mill, which would not have cost $20,000 in New Jersey, cost $60,000 in Cuba; and with the waterworks, pumps, hoists, and developed work, absorbed all the money and more, so that when the mill did start there was a big debt to overcome. No arrangements were made to empound the tailing, consequently the people on the next lower properties were able to make good wages by washing the waste. In fact far better returns than the stockholders.

The rock carrying the gold has been leached beyond any semblance to the original, which judging from adjacent properties, approximates a quartz-felsite porphyry. This gray rock has been intruded between walls of serpentine wherever in the vicinity the rock had been shattered. Although subsequent movements have faulted the felsite dyke locally, the line along which the gold is found for several miles is practically northeast and southwest.

In the gold belt in the vicinity of the gold-bearing outcrops and in ditches after each rainstorm, gold colors can be obtained. The soil is sharp, and wide areas of talus cover the fields, so that beyond grass and shrubs vegetation does not flourish. If the ground in this vicinity was colored reddish brown the formation could be termed "laterite." Mining men have undoubtedly noticed that near gold deposits there is a gritty feeling on the shoe soles, and in the Santiago gold field this geological peculiarity is properly developed. While $250,000 has been taken from the Santiago Mine in a short time, the combination of debt, royalty, dry weather, high-priced fuel, mine timber, supplies, and labor, absorbed the proposed dividends. There are those who believe that with suitable machinery and systematic mining, the gold deposits in this vicinity could be worked at an exceedingly good profit. The locality is healthy, Holguin being about 500 feet above sea level and one of the oldest towns on the island. Asbestos of the variety known as chrysotile was found near the mines. The life of the material had been sapped from it by the climate and solutions so that it was reconverted into brittle rock at the outcrop, although it retained the fibrous appearance.

COMBINATION ASSAY OF COPPER BULLION

Written for Mines and Minerals, by S. M. Scott, Jr.

Weigh 1 assay ton of ground or sawed sample of copper bullion into a 24-ounce beaker, add 25 cubic centimeters of mercuric nitrate solution, made by dissolving 12 grams of metallic mercury in nitric acid and diluting to 2 liters with water. This is to prevent the solution from climbing on the sides of the beaker. Then add 75 cubic centimeters of sulphuric acid, 1.84 specific gravity; and place the beaker covered on a hot plate or sand bath until it goes down to fumes. Take off, allow to cool. Dilute to about 500 cubic centimeters and stir up the heavy precipitate of copper sulphate in the bottom of the beaker to prevent bumping; add enough salt to precipitate the silver, then boil to get the copper sulphate into solution. Now take off the bath and dilute until the beaker is about full. Allow to stand until cold and filter through double thickness (2) 597 filter paper, using a corrugated funnel to hasten filtering. Wash precipitate four or five times and place papers and precipitate into 10-gram crucible. Burn paper at low heat and flux as follows: 15 grams soda; 7½ grams potash; 1½ grams borax glass; 1½ grams silica; 1½ grams flour; 30 grams litharge. Place the crucible in a muffler at low heat to start and finish at high heat. Fusion should take from 20 to 25 minutes. Cupel, weigh silver, and part for gold in usual way.

THE PANAMA CANAL

Written for Mines and Minerals, by G. H. Mee

The efforts made to discover a waterway across the continent date back as far as 1515, at which time Balboa and other adventurous Spaniards succeeded in crossing the dense jungles and swamps and reaching the Pacific Ocean. The first roadway across the isthmus was constructed in 1521 during the reign of Charles the Fifth, the Atlantic terminal being Nombre de Dios, and on the Pacific, Old Panama. This roadway was constructed with almost insurmountable difficulties, and was completed entirely by manual labor and whilst there was no other permanent line of communication; it was finally abandoned owing to the turbulent condition of the country.

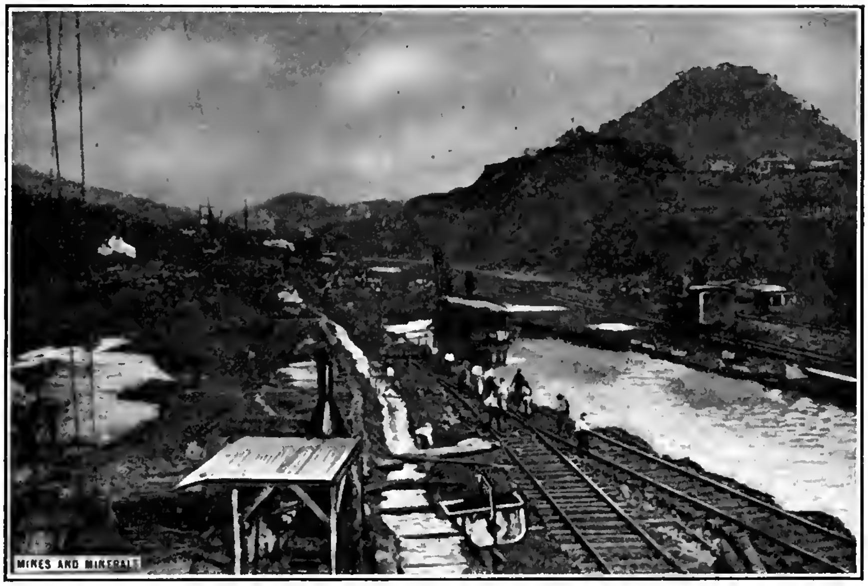
Early Plans and Attempts at Construction. Modern Methods and Conditions

Portions of this wonderful road still exist and can be followed for many miles, although it is overgrown with dense jungle growth.

The Republic of Central America, in 1825, requested the cooperation of the United States in the construction of a waterway through Nicaragua.

This route was favorably considered and the scheme thoroughly investigated, but the project seems to have been tied up on account of inability to secure sufficient funds at that time.

In 1826 a British corporation sent a Mr. J. Bailey to Nicaragua to secure a concession with the government there, which concession he failed to arrange, and it was shortly following this attempt that the Colon-Panama route was again under consideration. Very little of the geology of the Isthmus was known in 1827; in fact, the heights of the tides and the altitudes of the mountains had never been ascertained, and it was at this time that a Mr. J. A. Lloyd was commissioned by President Bolivar to survey the Isthmus of Panama, with a view to discovering the possibilities of rail or water communication. In 1831 the Republic of Colombia was again disrupted and the canal regions became part of New Grenada, and no action was taken on the plans made by Mr. Lloyd.



PEDRO MIGUEL CUT AFTER HEAVY RAIN

The Republic of New Grenada then granted a concession to a French company in the year 1838, which company made an extensive examination of the region and presented the project as a comparatively easy undertaking.

Five years afterwards the statements made by the company were rigidly investigated by the French Government and the claims made were then heavily discounted and led to its failure.

The United States Minister in Nicaragua negotiated a treaty with that Republic in 1849 by which Nicaragua agreed to confer upon our government the exclusive right to construct and operate roads and canals between the two oceans.

A concession was then granted to the American, Atlantic and Pacific Ship Canal Co. (of which Cornelius Vanderbilt was a member) and in 1852 Colonel Orville Childs completed a thorough instrumental survey of the entire region, on behalf of this company, and the plan was pronounced entirely practicable. Nothing became of this work and from 1852 until 1872 practically nothing was done toward opening up this line of communication.

In 1872 the Interoceanic Canal Commission was established, by whom explorations were conducted in various parts of the Isthmus, and following all the ineffectual attempts, the concession was transferred to La Compagnie Universelle de Canal Interoceanique de Panama, or more generally known as the Panama Canal Company, promoted in May, 1879, by Ferdinand De Lesseps.

The colossal failure of this concern is too well known, and it could hardly have been otherwise in view of the mismanagement and insane extravagance of its officers. The residence of one of the engineers is said to have cost some $100,000 and the salary of this gentleman was $50,000 per annum. A Pullman car that cost $42,000 was assigned to his use when on tours of inspection, whilst another man built a private bath house that cost the company the small sum of $40,000. Graft, or rather wholesale robbery, existed everywhere in forms too numerous to mention, and it is said that some of the foremen arranged to have their gangs meet the pay cars in two different places each month and receive double pay, and no check or tally seems to have been kept of either stores or equipment, and that half the names on the pay roll were of persons who never existed. An effort was made to reorganize the company without success.

In 1899, the Congress of the United States authorized the President to make an exhaustive investigation as to the most feasible isthmian route, and the work was placed in the hands of a body known as the Isthmian Canal Commission. The report of the Commission resulted in the taking over of the canal from the French. The remnants of their equipment were also taken over, and although the bulk of the machinery was entirely unsuitable for the work, some parts of it have been used to advantage and the remainder can be seen today rusted and decaying, almost hidden with jungle growth. In 1906 the United States was engaged in active operations on the Isthmus. The question of a sea-level or lock canal was not settled for some time afterwards, and a lock canal was finally decided upon.

The necessity of owning the Panama Railroad was recognized by the French company as an essential to conducting the work, and the road was purchased by the United States Government at the onset. The Panama Railroad Co., composed of William Henry Aspinwall, John Lloyd Stephens, Henry Chauncey, and others, obtained the exclusive right of building a railroad in 1849. The engineers were on the ground in the fall of 1849 and worked waist deep in mud and water, making surveys and cutting trails. The construction was practically completed in 1857 at a cost of $8,000,000; it is now 45 miles long and has a double track. Nothing but the indomitable will and grit of Americans could have ever overcome the terrible difficulties

encountered at every step. The whole Isthmus was a wilderness, pestilential and death dealing, the jungles and swamps were alive with poisonous snakes and insects. It was reported that in some of the swamps the engineers under the late Colonel George M. Totten failed to find bottom at 180 feet, which report was verified by the trouble had later in the Black Swamp, where it is said that in some parts no bottom can be found. It has cost thousands of dollars to maintain the right of way across this swamp, and sometime in 1907 the trestle sank some 20 feet without warning and was entirely submerged. A number of trains had passed over during the day and it was a marvel that no accident occurred when a passenger or freight train was crossing. Hundreds of old French cars and machinery were dumped into this hole and piled over with rock until a solid foundation was laid and piles were then driven in. The greater the quantity of rock and junk dumped into the swamp, the higher the mud oozed up out of the water on each side.

A great lesson on the labor question was learned during the building of the Panama Railroad, when it was found that the natives could not be counted on to any great extent. A large number of Chinamen were introduced with very poor results; they fell sick almost immediately after their arrival, and within a few weeks hundreds were unfit for work. They finally began to destroy themselves by whatever means came nearest at hand, and today the town known as Matachin derived its name from the fact that hundreds of Chinamen hung and otherwise killed themselves to put an end to the misery and suffering caused by unfitness for the climate, and lack of opium and suitable food and accommodations.

Bas Obispo Rock-Crushing Plant and Steam Shovel During Flood

Irish laborers were imported at a big expense, and although the mortality among them was less than that experienced with the Chinamen, it is reported that the company failed to get a good day's work out of any one of them. A great number died on the Isthmus and the remainder were shipped to the States, where many more died from fevers contracted.

The late Colonel George M. Totten, engineer of the road, always discredited the statement made as to the excessive mortality, and said that at no time the number of employes exceeded 7,000, and that the total mortality in the 5 years of construction was not over 1,200. It has frequently been stated that the Panama Railroad cost a life for every tie laid, which is untrue, although thousands of lives have been lost since the first attempt was made to run the canal through.

The Panama Railroad was completed with the labor of some 3,000 men of mixed races, chiefly negroes from Jamaica and West Indies.

The working force on the canal at present consists of Spaniards from the agricultural districts in Spain, Panamaians, and Colombians, the greater part of the laborers being recruited from Jamaica and Barbados; and although the negroes do not seem to be so susceptible to fever as the Spaniards, it is thought that the Spaniards are by far the superior class of laborers.

The total cost of the canal, including the $50,000,000 paid to the French company and Republic of Panama, is now estimated at $375,200,000. This figure is considerably larger than the original estimate, but the results obtained have justified the expenditure.

One of the most important stations on the Zone is Gatun, where the great lake will cover a space of 165 square miles in area. The dam extends between two hills and measures 9,040 feet along the crest, including the spillway or overflow, and is 1,900 feet wide at its base.

The crest of this dam is 115 feet above sea level and is 100 feet broad and will be some 30 feet above the normal level of the lake.

The entire structure has been made 16 times stronger than was originally recommended by the engineers.

The spillway has a channel 300 feet wide over which some 140,000 cubic feet of water from Chagres River will flow every second.

The present sea-level canal from Cristobal to Gatun is about 6 miles in length and was commenced by the French company and will enter the locks at Gatun.

These locks consist of three pairs, each 1,000 feet long by 110 feet wide, and all west-bound vessels will be lifted 85 feet to the surface of the lake. The locks are reinforced by scrap steel rails set in a horizontal position in the concrete.

The cement sheds are located on the banks of the old French canal, and the crushed rock and sand from Nombre de Dios and Porto Bello are stored nearby where they are easily handled at the mixer. The mixed concrete is loaded on little cars operated in trains by electricity from a third rail and is distributed by the cableway conveyers to the locks. These concrete trains move in a constant chain for 10 hours each day distributing the mixture to the conveyers.

Another important station is Culebra, where the big cut extends for a distance of 9 miles and follows the route of the old French survey.

The cut passes between Gold Hill and Contractors Hill some 650 feet high, and on to Paraiso, and will be about 300 feet wide.

The French dumps, which are immediately on top of the banks of the canal at Culebra, have caused considerable trouble owing to the soil descending into the prism in the wet season, and to prevent this as much as possible a large amount of the old dumps has had to be removed a second time by shovels. This action was also necessary, due to the widening of the canal at that point.

During 1908 some 37,000,000 yards of dirt was taken out and 35,000,000 cubic yards in 1909, being an average of some 3,000,000 cubic yards per month in the last 2 years.

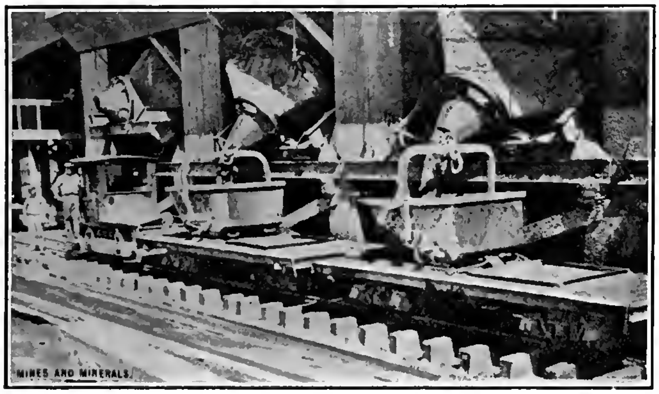
The other important locality is Pedro Miguel where the locks on the Pacific side are being constructed. Miraflores is the town adjoining.

These locks have a chamber 1,000 feet long by 110 feet wide

and are being constructed somewhat upon the same lines as the Gatun locks, except that the lock is single. Vessels passing through this lock from the Pacific will be lowered 30 feet into a a basin 1 mile wide, which is 55 feet above sea level on the Pacific side. This lock is 5 miles from the Pacific entrance at Balboa and the entrance is naturally protected.

An interesting feature at Corozal are some concrete barges, made to carry hydraulic pumps for excavating on the Pacific Division.

These barges are 64 feet long and of a 24-foot beam, being 5 feet 8 inches in draft. The walls are built of ½-inch mesh No. 12 wire cloth, which is stretched on ½-inch iron rods that are placed 8 inches apart. The concrete in the form of a plaster was applied to the frames, and the interior of the hulls suitably protected. This form of barge was experimented with by the Italian Government some years ago with great success.



Concrete Mixers Dumping into Buckets, Gatun Locks

On the Pacific entrance the channel is completed almost up to the lock site at Pedro Miguel and vessels from the west have plenty of water, and at Gatun in the big lake there will be anchorage for the whole navy. All west-bound vessels will be able to travel some 32 miles at a fair rate of speed from the Gatun lake to the Pedro Miguel basin.

The Atlantic entrance is at sea level and has an average depth of 41 feet of water and an average tide of about 12 inches. On the Pacific the tides range from 22 feet and the channel is dredged to 45 feet of water.

When at full tide the Pacific is 10 feet above the Atlantic, which was one of the reasons why it was impossible to have a sea-level canal. The Chagres River now partly flows into the Gatun lake and when the present barriers are removed and the river permitted to flood the lake bed, its waters will fill the entire canal, the surplus leaving by the Gatun spillways.

The area between Gatun and Gorgona, on account of low ground, will be entirely submerged and will become part of the Gatun lake, and very little excavation is required in comparison with the higher altitudes. A channel has of course been excavated the entire distance, and when the lake district is flooded, the towns of Tabernilla, Bohio, and Lion Hill will be deep under water.

An enterprise of this character is not free from accidents, but in consideration of the conditions under which the work is carried on and the large number of different nationalities employed, the casualties are very small.

Abandoned French Bucket Dredge, Showing Jungle Growth

Every day hundreds of tons of dynamite are used, the traffic on the railroads being exceptionally heavy, land slides, floods, and a hundred and one other causes make the work hazardous. The total working force is about 37,500 men throughout the various divisions, each of whom completes an average of 8 hours per day, with the exception of the Fire and Police Departments who are always on duty. Little improvement could be made in the organization of the force, and each division cooperates together and all runs like machinery.

Much credit is due to the Sanitary Department, under which the Medical Division, consisting of hospitals, dispensaries, etc. are operated, and the Inspectors Division that maintains a system of sanitary regulations, and sees that they are properly enforced. This department employs a large corps of men engaged in the extermination of the mosquito, and thousands of gallons of crude oil are expended for this purpose.

Handling Concrete Buckets, Gatun Locks

The following table of distances via Colon will show the number of miles that will be saved by using the Panama Canal:

From	Via Cape Horn	Via Canal	Distance Saved
Pensacola to Panama	11,421	1,401	10,020
Gulfport to Panama	11,443	1,423	10,020
Mobile to Panama	11,452	1,432	10,020
New Orleans to Panama	11,461	1,441	10,020
Galveston to Panama	11,477	1,457	10,020
Charleston to Panama	11,576	1,556	10,020
Savannah to Panama	11,582	1,562	10,020
New York to Panama	11,977	1,957	10,020
Philadelphia to Panama	11,956	1,936	10,020
Boston to Panama	12,161	2,143	10,020
Norfolk to Panama	11,775	1,755	10,020

A great factor toward keeping up the good health of the employes is the Cristobal ice plant operated by the Subsistence Department, without which it would be almost impossible to carry on the work, especially in a climate as unhealthy as this one. An ice plant is really as much an essential to the success of a mining or railroad venture in these climes as is any part of the equipment.

The great migration to the Pacific coast in 1849, following the discovery of gold in California, acted as a strong incentive to the immediate establishment of an isthmian route to avoid the long and hazardous journey across the western territories.

Thousands of persons made their way across the Isthmus on foot to Panama and from thence up the coast

to the gold fields. Few if any of the old time prospectors seemed to have tarried along the Isthmus, although deep in the heart of the jungles there can be found a few ancient workings, such as shallow vertical shafts. It is thought that most of these are Indian workings but none of them have ever been thoroughly examined, as the parties who ran across them were unable to spend much time in that vicinity.

It was thought that the exploration of the canal would uncover an extensive mineral field, but so far no minerals have been discovered in such quantity as to be of any commercial value. Gold, copper, manganese, and iron are known to exist in small quantities, also large beds of lignite. The country is yet to undergo a thorough geological survey.

On the island of Muerto, near David, on the Pacific coast, is said to be almost a solid mass of coal covered with a clay stratum. In 1851 a geologist by the name of Whiting made a report of this deposit which was published in London, England.

It is thought that the regions out beyond the 10-mile boundaries will be worthy of examination as soon as the canal is completed and the necessary transportation thus provided. Prospecting in such rank undergrowth is frightfully unhealthy and otherwise dangerous, it also being necessary for parties to cut their way through every step they take, and travel is therefore very slow.

As stated in the July issue of Mines and Minerals, the country is nothing but a big volcanic outburst and in many instances is bottomside up. The views accompanying this article, many of which are quite recent, will give a better idea of what is being accomplished here at the present time.

A MEXICAN RIVAL TO THE PANAMA CANAL

The *South American Journal* (London) reports that the new transport route across the Isthmus of Tehuantepec is proving successful beyond all expectation, and that those connected with its administration are now hopeful that by the time the Panama Canal is completed the Mexican line will have secured a preeminence in certain trades which it will be somewhat difficult to overthrow.

"Since the railway was opened 2 years ago, the traffic between the Atlantic and the Pacific coasts has steadily increased, as goods are handled at through rates for transport between the United Kingdom and continent, the United States, Canada, South America, and the Orient.

"To and from Salina Cruz, the Pacific terminal of the line, no fewer than seven steamship companies operate, while from Puerto Mexico, the Atlantic terminal, there are eight steamship lines, including the Hamburg-American, Royal Mail Steam Packet, Leyland, Harrison, and French transatlantics running, and arrangements are being made for others. At both these ports the most up-to-date facilities for handling cargo are now in operation, and so successful have been the results that work is about to be taken in hand for the doubling of the railroad track under an arrangement with the Government of Mexico. Transport from Seattle and San Francisco to Europe is now done in about 6 weeks, which is practically as fast time as that via the United States railways, and then across the North Atlantic by express steamer.

"With a view to saving the expense of passing through the Suez Canal, it is said that one of the leading Japanese steamship companies intends to take advantage of the Tehuantepec route—a course which, while avoiding the long journey around India and through the Mediterranean, will, however, necessitate connections on the Atlantic."

Assuming that the *South American Journal* knows what it is printing, it seems strange that an American railroad 48 miles in length across the Isthmus could not compete with the Mexican railroad across Tehuantepec approximately 175 miles long. May be it is a political utility.

CUBAN MINING DEVELOPMENT

Minister John B. Jackson, under date of June 25, 1910, reports from the American legation at Habana, the following measure designed to stimulate the exploitation of Cuban mineral resources:

The Committee on Agriculture, Industry, and Commerce, of the Cuban House of Representatives, has reported favorably a bill exempting mining claims and properties, under exploitation or not, from all national, provincial, and municipal taxes for a period of 10 years, and extending this exemption for a full 10 years to all mining claims and properties put in operation at any time within the original 10-year period. During a period of 30 years all vessels entering Cuban ports in ballast, coming from any foreign or Cuban port, and which clear with cargo of minerals or other products of national mines, are to be entitled to the remission of one-half of the port and tonnage dues paid on entry, and during a similar period minerals and mineral products are to be exempt from payment of export duties. During a period of 10 years, machinery, apparatus, and railway material imported into Cuba for use in mining and metallurgical industries are to pay no more than the minimum duty prescribed for similar articles when imported for use in the most favored Cuban industry.

In the preamble to this bill reference is made to the fact that Cuba is to a great extent dependent upon her export of sugar and tobacco, and attention is called to the desirability of "pluralizing" her production, especially by facilitating the development of her mineral wealth.

The following table by Francisco I. de Vildosola, Secretary pro tem of Agriculture, Labor, and Commerce, gives an idea of the number and area of the Cuban mines, with concessions in force on December 31, 1907:

Mineral	Pinar del Rio		Habana		Matanzas	
	Number	Area Hectares*	Number	Area Hectares*	Number	Area Hectares*
Asphalt	28	911	29	956	30	1,459
Coal	6	578	8	859		
Copper	23	1,206	5	413	3	97
Gold	(†)	(†)	1	64	1	125
Iron	31	2,140	4	189	3	500
Manganese					1	110
Petroleum	4	274	2	108	3	632
All other minerals	4	76				
Total	96	5,185	49	2,589	41	2,983

Mineral	Santa Clara		Camaguey		Oriente	
	Number	Area Hectares*	Number	Area Hectares*	Number	Area Hectares*
Asphalt	12	189	16	218	7	253
Coal	2	52			9	521
Copper	24	459	27	1,274	223	7,745
Gold	(†)	(†)			20	537
Iron	14	500	51	4,100	271	44,999
Manganese					218	11,364
Petroleum					3	405
All other minerals	39	2,828	3	54	106	6,843
Total	91	4,028	97	5,646	857	72,667

* Hectare = 2.471 acres.
† Included in "All other minerals."

There are other mineral riches absolutely neglected which are no less important than those mentioned, and which will prove great sources of wealth. Thus vast deposits of iron of very good quality remain unexploited, and there are extensive peat beds which at some future day will be utilized as fuel and in the production of nitrate.

The Cuba Railway runs from Matanzas to Santiago and is the backbone of Cuban development. From the backbone ribs extend wherever the developments will warrant. The latest rib is from Marti to Bayamo and Manzanillo.

IRON ORES OF SANTIAGO, CUBA

*By E. B. Wilson**

In Volume 13, page 613, of the Transactions of the American Institute of Mining Engineers, will be found an able paper on the Iron Ore Range of the Santiago District of Cuba.

Location and Extent of the Deposits, Methods of Mining and Transportation

It was written by Prof James P. Kimball, who introduced the comparatively new theory of the formation of ore deposits as the results of epigenesis and the circulation of meteoric waters. The paper was also the first public one on the structural geology of that part of Cuba, and this article is largely an abstract of the Kimball, Souders,† and Lawrence‡ papers.

The Sierra Maestra extends east and west along the southern coast of Oriente Province, Cuba. West of the Bay of Santiago the metallic minerals are copper and possibly others; to the east as far as the Bay of Guantanamo they are iron and manganese oxides.

The south slope of the mountain range for a distance of at least 30 miles is made up of eruptive syenite, covered with a massive flow of epidotic diorite. The serrated crest of this range of mountains within the 30 miles appears at a distance to be uniformly denuded of diorite, as are also the foot-hills of the coast. Along the coast are submerged coral reefs, and in the interior mountain district are emerged coral reefs resting directly on the syenite. The Bay of Santiago is excavated from coralline, having a thickness of 300 feet. The so-called Juragua Hills are the culmination of the foot-hills of the Sierra, and are in four parallel ranges, successively declining in elevation from the north toward the sea, on a general slope. The summits of the first range of the Juragua Hills reach an elevation of 2,000 feet above sea level and are mainly eroded of diorite down to the syenite.

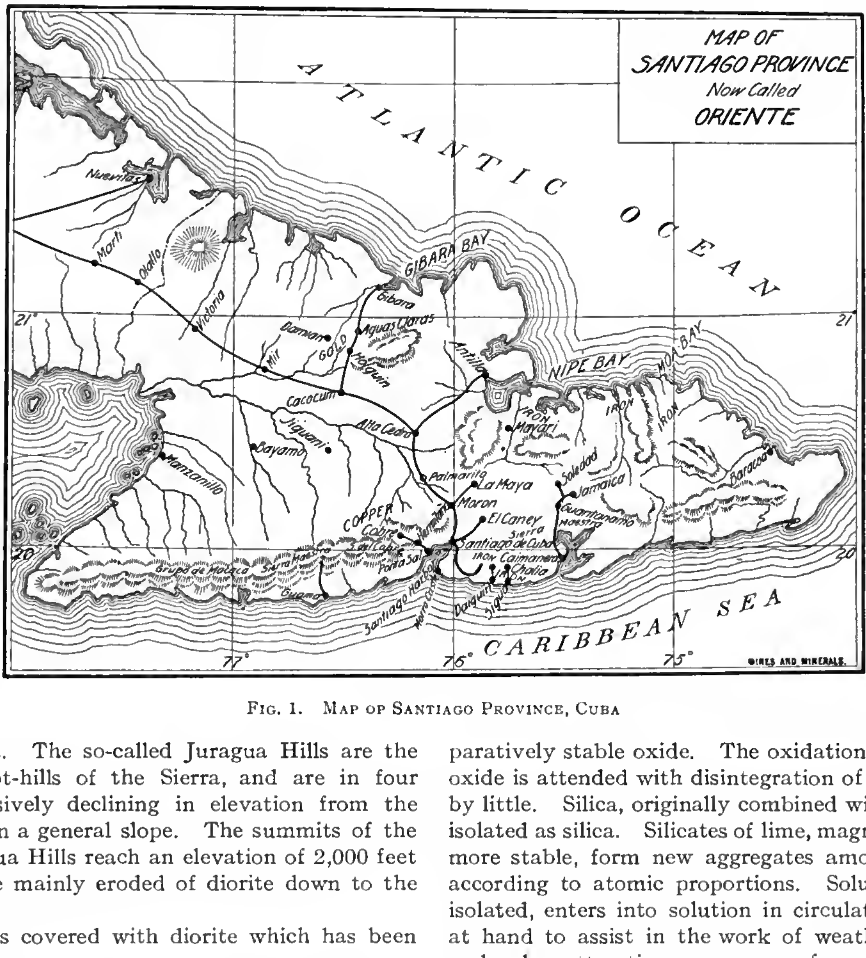


FIG. 1. MAP OF SANTIAGO PROVINCE, CUBA

The second range is covered with diorite which has been eroded into the syenite.

The third and fourth ranges are completely denuded of diorite if they were ever covered with it. These latter hills form the syenite coast margin, conspicuous features of which are the numerous dikes of epidotic diorite.

The first and second ranges present the more favorable conditions both for the original development and for the preservation of iron-ore deposits. The Lola and Berraco Hills to the eastward are an extension of the second range under changed structural conditions due to erosion, and contain undeveloped ore bodies, as do the Sigua hills still further to the east.

The second range of hills contains the best ore bodies, as is exemplified in the East and West mines of the Juragua Iron Co., and this Mr. Kimball terms "the second or lower iron-ore belt," to distinguish it from the iron-ore belt of the first or upper range.

The lower iron-ore belt contains large bodies of hematite, associated ferruginous aggregates—in part of magnetic oxide, which are secondary products from the decomposition of basic eruptive rocks now represented by epidotic diorite which has penetrated and overflowed the syenitic base of this part of the Sierra Maestra.

The iron oxide deposits are the result of the alteration of highly basic, and therefore unstable rock aggregates, and of their resolution into new aggregates, with the aid of surface agencies in subordination to the new conditions met with at and near the surface.

Thus the presence of atmospheric oxygen and of alkaline and earthy bicarbonates from decomposing silicates has rendered unstable the highly ferriferous material from deep-seated sources. These aggregates were basic from excess of protoxide bases and especially protoxide of iron.

Such eruptive material cannot long resist further oxidation at the surface, with the result of more or less complete disintegration of the original aggregate and its recomposition into new compounds.

The eruptive material which gave origin to the iron ore consisted of protosilicates, or silica combined with the protoxide bases iron, lime, and magnesia, and with alumina. Under the new conditions and in circulating waters charged with oxygen, bicarbonates of the alkalies and alkaline earths, the protoxide of iron became further oxidized into ferric oxide, which is a comparatively stable oxide. The oxidation of the ferrous to ferric oxide is attended with disintegration of the eruptive rock little by little. Silica, originally combined with the ferrous oxide, is isolated as silica. Silicates of lime, magnesia and alumina, being more stable, form new aggregates among themselves, in part according to atomic proportions. Soluble material, as fast as isolated, enters into solution in circulating waters, and is thus at hand to assist in the work of weathering. By the law of molecular attraction a process of concentration has gone on simultaneously with weathering.

Homogeneous material, such as ferric oxide, has collected by itself to a degree far greater than the other earthy residues, because in the process of conversion from ferrous to ferric oxide it has been in solution, and so in circulation, and hence becomes finally deposited. This explanation will be completed by the following observation:

The best of the iron-ore deposits are mainly, if not indeed wholly, replacements of coralline limestone.

The eruptive flow, which probably took place in part below the sea level, involved masses of littoral coralline limestone and of coral reef. The final elevation of the Sierra Maestra was a subsequent event. It is these masses of coralline limestone that have been replaced by the concentrated ferric oxide. Thus,

*Compiled for MINES AND MINERALS.
† Mineral Deposits, Santiago, Vol. XXXV, T. A. I. M. E., June, 1910.
‡ Two Cuban Mines, Canadian Mining Institute.

the outline of the iron-ore bodies, as well as their dimensions, corresponds to those of the original limestone masses.

The process of the replacement of limestone by ferric oxide is explained as follows:

Meteoric water circulating within the weathering zone of rock takes up enough carbon dioxide from the atmosphere and other sources, also sulphuric acid from the oxidation of pyrite,

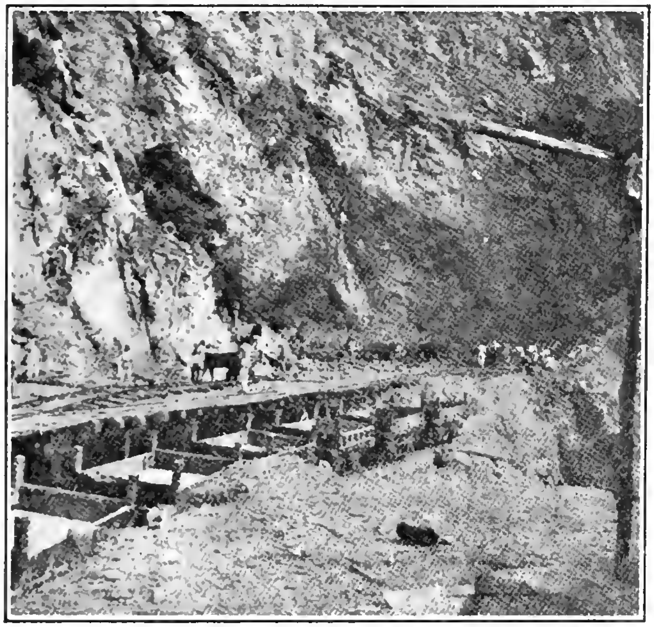

Fig. 2. Ore Face, East Mine, Juragua Iron Co.

to impart to it solvent effects, especially in its action on limestone. Coralline limestone before consolidation yields readily to such solvents. As particles enter into solution their places are taken by any available substance in the process of precipitation from the circulating water.

Lime becomes dissolved in water that has taken up ferrous oxide as a bicarbonate and that is precipitating ferric oxide. Or again, through the mediation of sulphuric acid, ferrous carbonate results from the reaction of ferrous sulphate upon limestone, and by exchanging acids and bases with alkaline carbonates also upon dioritic and syenitic rocks which supply these carbonates including carbonate of magnesia. Or still further, carbon dioxide with ferrous sulphide may follow from the reduction of ferrous sulphate by decaying organic matter.

Proof of the replacement of coralline limestone is afforded by fragments of ore still retaining the structure of coral. Other indications also quoted to establish the proof of this theory are incorporated in the paper, among which it is stated: "The presence of organic life is indicated by the pyritous ore possessing the structure of corallum at the northeast mine, which is near the contact of one of the ore bodies with the syenite."

The Sierra Maestra ores are derived without intermediate stages of development from basic silicated aggregates rich in ferrous oxide, an important portion of which has been preserved as ferric oxide in places below the surface near its source, without ever reaching the channels of drainage.

The ore deposits, so far as known in 1885, extended from Sigua, on the east, to Sevilla, on the west, a distance of some 18 miles; in 1909 they reached to Guam, 40 miles west of Santiago. The ore occurs in all forms of red hematite, including micaceous, amorphous granular, and subcrystalline varieties, the last named having minute crystals of magnetite and martite.

At Camorones, 56 miles from Santiago, near Guantanamo Bay, there is said to be a deposit of 68 per cent. magnetite. In the northern part of Oriente Province there are large deposits of brown iron ores which, however, have not been worked.

Variations in the color of drillings from red to black imply unequal distribution of altered hematite or of unaltered magnetite with water of hydration and manganic oxide.

Proximate analyses of these ores are as follows:

Moisture	.240	.810
Silica	5.000	10.500
Iron	61.000	68.500
Phosphorus	.009	.065
Sulphur	.045	.248

Mr. Kimball next theorizes on the causes which produce a lenticular outline to the ore deposits and says:

"All sections of ore bodies, whether longitudinal, transverse, or oblique, if projected to terminal outlines, result in approximately elliptical figures."

There is a second kind of ore that has been formed in prismatic blocks, the genesis of which he explains as follows:

The concentration of ferric oxide *in situ* from basic traps differs from the process of replacement of limestone from external sources chiefly in point of time required in the two cases. The circulation of chalybeate waters through dense trappean rocks would be so retarded as to induce the peroxidation of the ferrous oxide *in situ*, or at least soon after entering into solution. Its greater insolubility as compared with the protosilicates when liberated from their original bond and especially with quartz under certain conditions of temperature and pressure, ultimately leads to the elimination of all but difficultly soluble silicates. These still remain as earthy impurities of this imperfectly concentrated mixture of ferric and magnetic oxides. Magnetic oxide as a stable or difficultly

Fig. 3. Tramming in Cuba

soluble mineral originally present as such in basic eruptives has likewise been left as a residuum. This occurs in a mixture with ferric oxide. The occurrence of iron oxide in both types of deposits mainly as ferric oxide, and not as ferric hydrate, is the result of gradual dehydration more or less complete.

The first range of iron-ore deposits occurs within the foothills next below the summit of the Sierra Maestra. The ore

bodies here are ferric oxide, more or less magnetic from admixture with magnetic oxide. Nothing has been done to explore any of these ore bodies. The bulk of the specimens from the surface indicate they are inferior to the second-class ore of the Juragua East and West mines.

The first iron mine in Cuba was denounced in 1861, although mining did not commence until 1883. In 1884 the Juragua Iron Co., Ltd., exported 25,295 tons of ore, and in 1908, 366,580 tons.* The mines, which are situated northeast of Siboney, are connected by 24 miles of narrow-gauge railroad with a steel dock in Santiago harbor. The railroad runs southeast to

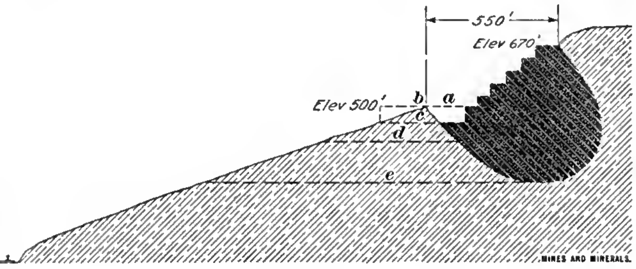

Fig. 4

Siboney, then skirts the shore to Fort Aguadores, thence a northwesterly course to the docks in Santiago harbor. The ore is mined in open cuts by benches 40 to 50 feet high, though at the East Mine of the company, Fig. 2, the face is 200 feet high. The ore in this case is loaded in cars, trammed, as shown in Fig. 3, to the loading plant and dumped into the cars that take it to the dock.

The Juragua Iron Co. owns or leases the Sevilla, Juranasito, and Firmeza deposits, besides the East, West, Columbia and Colon mines.

While the ore is shot down from the benches so as to fall by gravity to the bench beneath, it will be noted from the cross-section, Fig. 4,† that when the step *a* is excavated below the brow of the incline *b*, the ore must be hoisted or *b* tunneled as at *c*. The objection to tunneling is that with each excavation the tunnels become longer, as shown at *d* and *e*, and more expensive to drive. The method adopted in working these side-hill ore deposits is best shown by Figs. 5 and 6, which are taken from photographs loaned by Benjamin Lawrence, to illustrate this article. The ore is trammed from the floor of the steps to bins on the incline. From the bins the ore goes by gravity to the railroad bins at the foot of the incline. This mining is done by powder and steam shovels, the tramming by mules, and is apparently easy and economical mining on the lower steps shown. At the top of the hill the steps above the brow of the incline are worked the same as those on the side hill and the ore is sent by gravity to the inclines. Below the brow a much different state of affairs is found to exist as shown, in the relief cut, Fig. 6, which without doubt depicts open-cut mining more intelligently and forcefully than it could be described in words. Where the ore has been excavated below the brow of the deposit the slope up which the material is hoisted is shown. On this slope is shown an ore bin into which the ore from the bench above, but still below the brow of the deposit, is dumped prior to being loaded in a skip and hoisted up the slope. On the bench next above, mule haulage takes the ore to the ore bin on the incline. On the next bench above, a steam shovel is shown loading cars which are trammed around the hill to the incline, and so on work progresses to the top benches from which ore is lowered to the level of the incline.

The Sigua Iron Co. mine, about 36 miles east of Santiago, was opened in 1892, and connected with Playa, the sea port, by rail. According to the United States Geological Survey reports the company shipped 20,438 tons in two years and closed down. Harrison Souder‡ says "the ore is reported to be 'red specular hematite' containing 58.40 per cent. of metallic iron; 13.36 per cent. of silica, and .02 per cent phosphorus."

The Spanish American Iron Ore Co. made a shipment of 74,991 tons of iron ore in 1895. It operates the Lola, Magdalena, Providencia, San Antonio, Berraco, and Fausto ore deposits, and is said to have acquired the Sigua Iron Co.'s property, in the Sierra Maestra iron district. In addition to this it has more recently purchased and developed an extensive ore body at Mayari, on the north coast, with a port 12 miles away, at Nipi Bay, connected by railroad. This body of iron ore is also in Oriente Province, almost directly north of the Sierra Maestra deposits. Figs. 5 and 6 are illustrations of the Sierra Maestra mines, and the description need not be repeated. From the bins at the foot of the incline the ore is dumped into 10-ton hopper-bottomed cars and hauled over a broad-gauge railroad 5 miles to Daiquiri, where it is dumped, crushed, and stocked. By erecting several trestles, Fig. 7, to act as storage bins, a large quantity of ore is on hand to be loaded in steamers, thus avoiding delay; further, the regular shipments from the mines may be continued in case storms prevent steamships from being loaded. Steamships are able to carry from 3,000 to 5,000 tons of ore, and to ship 500,000 tons of iron ore, as the Spanish-

† After Harrison Souder, Vol. XXXV, Trans. A. I. M. E., page 319.

‡ Trans. A. I. M. E., Vol. XXXV, page 314, Mineral Deposits of Santiago, Cuba.

American company did in 1907, requires from 100 to 150 steamer loads. The ore is carried from the trestle bins on an endless belt, Fig. 8, moving on a cantilever extending out to deep water, where it is delivered by gravity to the hold of the steamship, as shown in Fig. 9. More than 50,000,000 tons of iron ore have been taken from the Spanish-American Iron Co.'s mines in Cuba and there is considerable still in sight. Various analyses of the ore are given; that which follows is an average for the year 1902 taken from Mr. Souder's paper: Iron, 62.250 per cent.; silica, 8.050 per cent.; phosphorus, .032 per cent.; sulphur, .080 per cent.; copper, .300 per cent.

The copper is associated with ores from the Magdalena Mine; 1.73 per cent. of chromium and 1.04 per cent. of nickel is found with the ore at Mayari, and manganese is found associated with the brown ores. Impurities such as these are not objectionable where steel is to be made from the iron produced.

In 1900 the Cuban Steel Ore Co. opened mines at Guama, 40 miles west of Santiago, and in 2 years shipped 41,241 tons of ore, after which there are no further records of shipments. The operations were evidently intended to mine and ship ore on a large scale, for extensive docks were constructed, and a broad-gauge railroad built; whatever the cause for the cessation of shipments seems to be known to but few, as no reason has been publicly given for the abandonment of the enterprise.

The best miners on the island are imported by the iron-ore companies from Spain. They are guaranteed work for several years at a specified wage. Mr. Lawrence in his paper on "Two Cuban Mines," furnishes the following information on the Mayari mines, near Nipi Bay, on the north coast:

This iron ore is peculiar inasmuch as it occurs directly on the surface to a depth of some 30 feet, and is said to be the result of a decomposition of the serpentine and the enriching of a zone of iron ore.

A complete analysis of a general sample gave the following results:

	Per Cent.
Iron, after drying to 212° F.	46.030
Silica	5.500
Alumina	10.330
Chromium	1.730
Phosphorus	.015
Hydroscopic water	31.620
Nickel	1.040

The plant is capable of handling about 5,000 tons per day at an estimated cost of $1.01 as follows:

	Cents
Mining	11
Hauling	15
Nodulizing	75
Total	$1.01

Fig. 6. Open-Cut Mining, Sierra Maestra Mine

The ore is apparently a secondary enrichment, and covers the entire plateau for some miles. It is estimated that there are one billion tons of ore in sight.

The handling of this ore is interesting. It is first steam-shoveled into railroad cars of standard gauge of 50 tons capacity. These railroad cars are brought to the top of an incline and lowered 3 miles. Here the ore is dumped by electric crane into a stock pile, and from there taken by a clamshell shovel to the furnaces, where the water is driven off and the ore is nodulized. The ore is heated by coal to a high temperature, water is driven off, and the material is loaded into vessels to be shipped to the United States.

Large deposits of iron ore exist in the vicinity of Moa Bay, back from Punta Gorda, on the north coast, but still in Santiago Province. The owners furnished the following analysis: Iron, 58.070 per cent.; phosphorus, .011 per cent.; chromium, 1.740 per cent.; sulphur, .150 per cent.; and claimed 22,000,000 tons. They also stated that by building 150 feet of dock they would obtain 40 feet of water. Moa Bay is between a reef on the ocean side and the main land.

The acquisition by the Bethlehem Steel Co. of the United States of an important iron-ore deposit located near Santiago, Cuba, is a feature in the development of the mineral resources of the Republic. The ore beds have been measured up by engineers as embracing 75,000,000 tons, a pecularity of the deposit consisting in the fact that it contains 2 per cent. nickel and 1 per cent. chromium. The tract covers an area of 875 acres and lies about 12 miles east of Santiago. It is regarded by experts as the most important discovery of iron ore made within 20 years. Other large iron deposits of recent discovery are to be

worked at Felton, Cuba. These mines are in the Mayari Mountains and are the property of the Spanish-American Iron Co. A large deposit of iron ore was also discovered in Sagua de Tanamo during the last half of the year.

FIG. 7. ORE STORAGE BINS AT DAIQUIRI

During the fiscal year 147 mines, covering an area of 21,880 hectares, were surveyed in the Republic, 97 of which were in the eastern part of the island.

PEBBLE INDUSTRY IN NEWFOUNDLAND

Consul James S. Benedict, of St. John's, states that the Newfoundland government has given a concession for handling the pebbles on its shores to a company which is shipping them to the United States.

"The government agrees to grant to the Atlantic Pebble Co. for 3 years from May 1, 1910, the exclusive right to export pebbles and beach stones from the colony, and also for 25 years from the same date the exclusive right to enter upon any crown lands situated inland within 100 yards of high-water mark along the shore of Conception Bay, between Cape St. Francis and Splint Point (near Bay de Verde), to search for pebbles and beach stones, but their sole right of export is restricted to Conception Bay. The company's present operations are at Long Pond, near Manuels, 15 miles from St. John's.

FIG. 9. ARRANGEMENT FOR LOADING ORE INTO STEAMERS

"After 3 years, exploitation of pebbles for the rest of the island is open to everybody, and only in Conception Bay has the company any exclusive right. During the 3 years all machinery which cannot be made in the colony, and all sacks and sacking imported by the company for use in its operations, will be admitted free of duty.

"Only a certain kind of quartz pebble is required, and they vary in circumference from 3 to 9 inches and are divided into three grades. They are packed in sacks weighing 168 pounds each when filled. The first cargo of 1,650 tons, valued at $13,200, was shipped to Philadelphia on July 14."

Flints and flintstone were imported into the United States in the fiscal year 1909 to the value of $230,000, almost all from France, Denmark, and Belgium. Only $60 worth came from Newfoundland. This flintstone has been mostly used for grinding cement, being placed in rotary cylinders with partly crushed cement rock. An excellent report on flint pebbles appeared in Daily Consular and Trade Reports for December 20, 1909, and in the monthly edition of February, 1910.

Quartz pebbles find use in the paint industry as well as the cement industry. The tube mills attached to cyanide mills

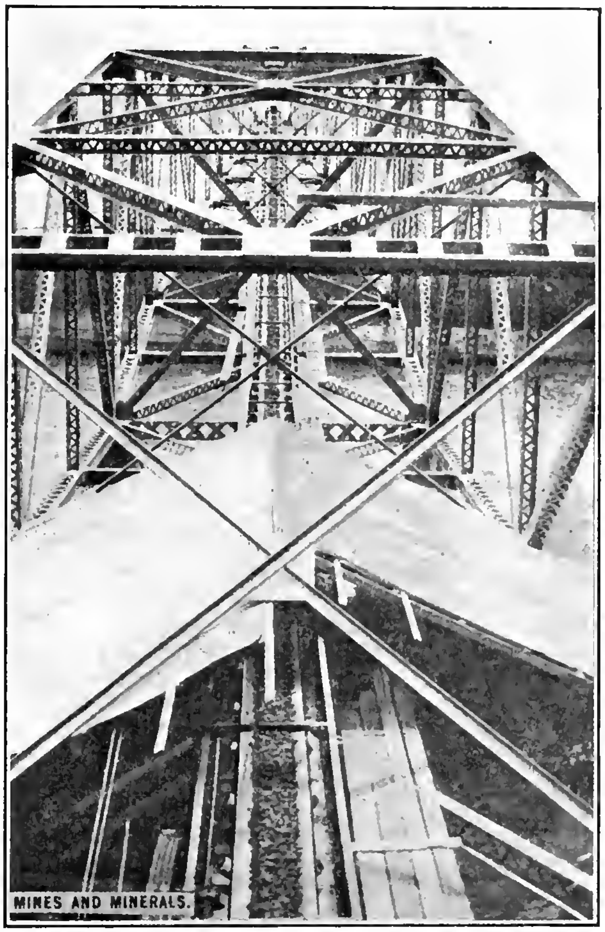

FIG. 8. CANTILEVER AND ENDLESS BELT FOR LOADING ORE

for the recovery of gold and silver, use large quantities of these pebbles, and the Danish stones being considered the best for this purpose are shipped all over the world. Each terminal morraine in the eastern United States contains suitable quartz pebbles for cement grinding, and nearly every cyanide mill can obtain suitable stones from streams in its vicinity. In many cases the quartz ore from the mine is used in large pieces to comminute the ore that has been crushed by other machinery. The ore in such cases is not rounded, although it soon becomes so in the tube mill, which is nothing more than a large tumbling barrel. Along the shores of New England from New York City to New Brunswick there are places where large quantities of excellent quartz pebbles can be found. In Northeastern Pennsylvania and other states where the ancient glacial rivers terminated, similar material embedded in sand will be found. Where particularly good cement work is desirable crushed quartz is the best material for the purpose.

ORE MINING NOTES

When Judge Dietrich in the federal court at Moscow, Idaho, ruled that mining companies operating in the Cœur d'Alene district have the right to dump tailing into streams, a decision of prime importance became a matter of record in Northern Idaho. Unless reversed by the Court of Appeals the question is settled for all time, and thus removes one of the most vexing situations which the mining companies have had to face. These cases have been pending 6 years. The suit upon which the decision was rendered was instituted by Elmer Doty, a rancher on the Cœur d'Alene River. There were 65 cases, but all of them involved the same principle, the damages claimed amounting to $1,223,000. Doty alleged that by dumping the tailing in the river the mining companies caused the river to rise and overflow the lands along the river. The case on trial was against the Bunker Hill Mining, Milling, and Smelting Co., and testimony was heard in nine of the cases. The mining companies did not introduce any evidence. Judge Dietrich said there was not enough evidence to warrant giving the cases to the jury, but instructed that a verdict be returned giving the nine plaintiffs the sum of $1 in all. The other cases against the Bunker Hill and Sullivan Co. were thrown out of court. The cases against the Federal and Larson & Greenough companies were continued until the fall term.

Mining operations are active in the St. Joe country on the north side of the Cœur d'Alenes. The Booster group, which consists of 7 or 8 claims, located north of town, had a crew of men on the property until the fires stopped them. They have a high-grade copper proposition. The Red Squirrel, located 3 miles west of Avery, has a large low-grade gold property. Nine claims have been located along the strike of the ledge, and they also worked all summer until the fires came in. Twenty-seven miles above Avery, on the river, several of the claims of the old St. Joe Quartz Mining Co. have been relocated and are being worked by Blake Miller. A strike of gold was made there last spring and as a result the mineral showing has been well staked by the Millers and J. A. Haggerty. The White Spruce group is one of the best prospects in the district. They have exposed 4 feet of milling galena and are working now about 8 or 10 men. Three parties of the geological survey are working there, principally concerned with the examination of the Northern Pacific Railway Co. land grant, to see that no mineral is included in the railroad's lien land selections.

Shortly before leaving White Horse, W. D. Greenough, of the Atlas Mining Co., White Horse, Yukon Territory, entertained Frank Oliver, Minister of the Interior for Canada, who spent a day looking over the mine and plant. He gave him a great deal of information regarding mining operations in the Klondike district, and stated that the output of gold from the creeks around Dawson would in all probability be twice as large this year as last, the product being almost exclusively obtained from dredging operations. "Coal mining in the Yukon is still in its speculative stage," said Mr. Greenough, "nothing but prospecting work having been done as yet on any of the properties."

Paul H. Fitzgerald, of Nome, Alaska, writes: "This town is in the transition state, passing from a placer to a dredging proposition. Nearly all the rich ground is worked out. The high price of fuel $18 to $20 per ton for a poor quality of soft coal and a like amount for hauling it back to the Tundra, 15 or 20 miles, prohibits the working of an immense area of low-grade ground. Wherever the ground is not frozen the dredges handle this low-grade placer profitably. Eight new dredges were brought in this spring, and expect to be in working order before the season closes, which will make 14 or 15 dredges in the Nome district. These dredges each handle from 2,000 to 3,000 cubic yards of placer dirt in 24 hours."

The most important placer find in recent years in Alaska is at Iditorod near the head of navigation on the Iditorod River, a tributary of the Yukon River. It is probable that a good camp will be established there as soon as the country is opened, say in about 1 year. The reasons are that Iditorod is in a mineralized country, 40 miles from the Innoko country and just across the Kuskyguin divide.

Of the products imported from the United States into the Philippines, 37 per cent. of the total were derived from the minerals in the United States. Of the articles exported to the United States 100 per cent. were derived from agricultural products. No country can go forward until it is able to make use of its mineral products, and the Philippines under the development of mining engineers are making a beginning.

D. W. Shanks, General Manager of the Rio Plata Mining Co., in the Arteaga district of Chihuahua, Mexico, says: "We have run about 1,200 feet of tunnels in the mine since the first of January, and the vein of silver ore continues unbroken. We find that we can treat profitably ore that has 17 ounces of silver to the ton. Altogether, there is not any other mine being operated under similar conditions in Mexico where the cost of operation is so low as at the Rio Plata. A new tube mill has recently been installed at the cost of about $5,000. There is always some scarcity of labor in the planting and garnering seasons, when part of the workers leave the mine to devote themselves to their agricultural pursuits. This crippled us to a slight extent recently, but the men have begun to come back now, and we have a full force. Despite our great distance from the railroad, and the consequent necessity of using mules exclusively, the transportation of the bullion and concentrates across the mountains continues to go smoothly. The mine is 85 miles from the nearest railroad station, Sanchez, on the Kansas City, Mexico & Oriental Railway (The Stillwell Line), but the grading for 10 more miles of railroad in our direction is now completed. Eventually, the railroad will run within 20 miles of the mine."

The New Zealand Government is making a systematic geological survey of that country. Gold dredging has been rather quiet lately with no reason assigned. A large dredge has been made in England to deepen the harbor of New Plymouth which is sand and conglomerate bottom. In front of the buckets there is a revolving digger which loosens the stuff and enables the bucket to pick it up readily. Whenever large boulders are met they are worked around and then broken up by dynamite. The Mount Morgan Mine ore deposit has undergone a decided change recently. It now produces copper with some gold associated, and is no longer worked as an open quarry. The former rich deposit of gold nearer the surface was probably a concentration due to weathering and solutions.

Away back, when herds of buffalo grazed along the foothills of the western mountains, two hardy prospectors fell in with a bull bison that seemed to have been separated from his kind and run amuck. One of the prospectors took to the branches of a tree and the other dived into a cave, but immediately came out and the buffalo took after him again. The man made another dive for the hole and again came right out. After he went right in and turned around and came right out again several times, the man in the tree shouted:

"Stay in the cave, you idiot!"

"You don't know nothing about this yere hole," bawled the other. "There's a bear in it!"

Gold placer and lode mining in Alaska in 1909 showed marked progress in production as well as in preparation for larger operations. The production of gold was about $20,463,000, an increase of $1,170,182 (about 6 per cent.) over the output of 1908 and the largest yield since 1906, the year of greatest production.

The placer production was $16,322,000; the lode production, including gold derived from copper ores, was $4,107,363. The figures representing the product of the same kinds of mining in 1908 were $15,888,000 and $3,357,335.

EVOLUTION OF HOISTING

Written for Mines and Minerals, by E. B. W.

(Continued from October)

According to Galloway* the steam engine was suggested as a means for hoisting minerals from mines by Keane Fitzgerald, in 1758. The engine and machinery he advised must have been complex, as it was originally intended to work Doctor Hale's revolving ventilators, but by the addition of horses "it could raise 600 pounds of coal 600 feet in one minute, the horses moving at a walk." In 1763, Joseph Oxley patented a steam hoister, and the first machine was considered the greatest improvement since the invention of the "fire engine" for pumping. A second improved machine by Thomas Delaval, in 1765, is said to have drawn up the coal at the rate of a bucket a minute. Oxley's machine was used at Hartley's colliery, and Mr. Jars suggested that it would be better to use the steam engine to raise water for a water-wheel hoist than to hoist with it, and this system was afterwards adopted in the North of England. Smeaton held similar ideas owing to the difficulty of producing a satisfactory rotary motion by means of gears. James Watt visited the Oxley machine at Hartley colliery and remarked that it moved irregularly and sluggishly. Matthew Washbrough, in 1779, added an improvement to the Oxley engine in the form of a flywheel.

Development of the Steam Engine for Hoisting. Balancing Weight of Ropes

The application of the crank to the steam engine is clouded by several claimants to the first invention, it was patented, however, by James Pickard, of Birmingham, England, in 1780.

In 1782, Watt arranged to produce a vacuum alternately on each side of the engine piston, thus solving the difficulty of applying the steam engine to a continuous rotary motion. There is a record of one of Watt's rotative engines being erected at Walker colliery, Newcastle, in 1784,† which continued to work as late as 1863.

The Trevithick, or high-pressure engine was introduced in 1800, and on account of its simplicity and comparative cheapness was received with favor.

The first steam engine made in the United States was a Watt engine, and it was made and placed in operation at the Schuyler copper mine, near Bellville, the town now called Arlington, New Jersey.‡ It was used for pumping water from the Schuyler Mine. The first steam engines used for hoisting were attached to a walking beam, to which was also attached the pump rod. This kind of engine carried from 2 to 8 pounds of steam above atmospheric pressure. Fig. 16 is a cut of one of the old Watt engines, which were so well constructed that some of them are said to be in use in South Staffordshire at the present time. Loaded down with pump rods and working barrels they were not rapid hoisters, and in addition were geared making them second-motion engines. The combination of pump and hoisting drum was quite popular at one time in the metal mines of the United States, particularly in the iron mines of New York and New Jersey.

The first engines used for hoisting in this country were geared to pole pumps and carried a friction wheel on the main flywheel shaft. The drum, which was on a separate shaft, was arranged with a lever attached to an eccentric so that the pillar block would slide forward and a V-shaped friction on the drum would come in contact with the friction wheel on the main shaft. The engines were of the plain horizontal slide-valve type with flywheel, and geared so that the pump would make from 8 to 10 revolutions per minute. As the engines were not reversible the bucket or slope car was lowered by gravity and the speed of descent regulated by a wooden brake block, or a brake band. Steam could be used expansively in arrangements of this kind and was at the Scott Mine, at Lakeville, New York, under the supervision of Benjamin Moffatt, Sr., who for many years has been at this property.

It is now almost the universal practice, unless as previously stated, in the case of engines coupled to pole pumps, to use two engines coupled together by means of a common crank-shaft, the object being to have them arranged so that should one be on the center the other will be off and thus start the motion. In the old one-cylinder second-motion hoisting engines there was an arrangement whereby the eccentric rod could be lifted from the valve rod and the valves thrown by a lever until the engine got under headway, after which the eccentric was hooked up. Such an arrangement would be out of the question at a large mine; and even at small ones where single-cylinder hoisting engines, such as is shown in Fig. 17, are used, the engineer takes the greatest care to avoid stopping on the center, so that when given a signal to hoist there will be no delay. In all single-engine hoists the empty car, cage, or bucket, is lowered by gravity and as a precaution against accident the drum is supplied with hand brake and the engine has reversing gear.

The single-drum engine with the single engine hooked up

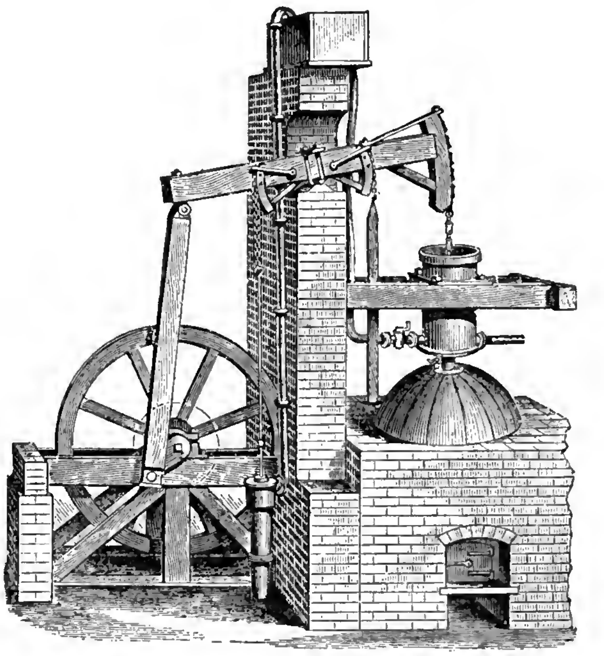

FIG. 14. NEWCOMEN ENGINE, WITH CRANK AND FLYWHEEL, 1780

to the pole pump presented some difficulties which were overcome by the engineer.

In case the engine stopped on its center, the eccentric was unhooked and the valve thrown by a lever until the engine got in motion, when the eccentric was hooked to the valve stem. In case the pump went "in fork", that is the water was pumped from the sump, the pump rod was disconnected from its gearing and the speed of the hoisting engine regulated by the throttle. The engineer, in any case used care not to stop his engine on the center, but just a trifle beyond. Of course in such cases it was impossible to balance the engine and it ran irregularly and at a speed commensurate with the speed of the pump. The skip was always lowered by gravity, and the output limited; however, these engines were the great machines in their day, and in one case a Corliss engine did the work.

Fifty years have made considerable difference in hoisting machines, and the engine shown in Fig. 16, which is a Watt engine, erected in a South Staffordshire colliery, and one of the first to which a crank was applied, made room for the slide-valve puffers as the high-pressure engines were called. In the next

* Annals of Coal Mining, page 277.
† Trans. N. E. Inst. M. E., Vol. 34, page 134.
‡ Trans. A. I. M. E., Vol. 5, page 168.

50 years even greater changes were made, as the output of the mines increased and the shafts deepened. Those mines which used the pole pump engine for hoisting, abandoned that and adopted a separate-geared engine and single drum, using the slide-valve engine to do pumping only. Such arrangements are still in use in some Missouri zinc mines.

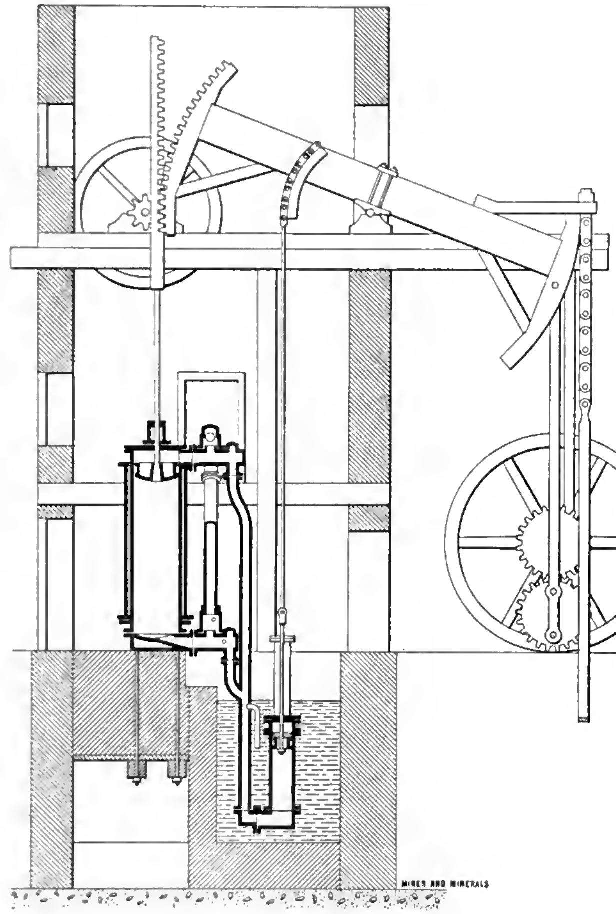

Fig. 15. Watt Double Acting Engine, 1782

The Lidgerwood second-motion hoisting engine, shown in Fig. 19, gradually displaced the slide-valve engine for hoisting, as it could be handled readily and raise a load much quicker, it also had other advantages from the hoisting standpoint that earlier engines did not possess, for instance, it could be run under or over, and hoist in balance, and could be braked by steam if necessary. At coal mines first-motion engines were always favorites, as hoisting must be done quickly to furnish a large output, and later this system was adopted at the deep ore mines Expansion engines have not come into general use at coal mines although they are in use at many ore mines, as well as compound tandem engines.

The requirements of hoisting engines are: that they must be thoroughly under the control of the engineer, that they may be stopped quickly when running at full speed; that they may be moved with certainty through a small fraction of a revolution that landing and caging may be done quickly; that they may attain full speed in two or three revolutions; in addition they must have strength to withstand the severe strains placed upon them. Until recently economy in fuel was not of much consideration at collieries, and compounding has not been practiced on hoisting engines, although in some cases expansion engines with high- and low-pressure cylinders have been coupled to the same shafts. These are not to be confounded with tandem engines, in fact they were two separate engines, one with a high-pressure and the other with a low-pressure cylinder. It was at first difficult to start these engines quickly, but this was rectified by placing an automatic throttle valve between the steam pipe and the low-pressure cylinder, thus giving both cylinders live steam at the start only.

Few mining engineers feel favorably disposed toward hoisting engines using steam expansively, although the conditions in connection with some ore mines make the economy in steam of prime importance, and not only are tandem hoisting engines installed but they are run in balance.

Balancing the load to be hoisted by means of two buckets was invented in ancient times when coggins and waterwheels were in use. However, such devices as flat ropes, cone drums, taper ropes, and balance or tail-rope are of more recent date. At first sight the question of balancing seems simple, nevertheless it has a number of features in connection with it that lend difficulties to its ready establishment, particularly where hoisting must be done from different levels.

Hoisting engines of the present time are driven by compressed air, electricity, or steam, and in their design it is necessary to know the depth of the shaft, the output per hour, and the maximum weight which can be lifted at each turn of the drum to which the engines are coupled. Usually two ropes are coiled on a drum in such a manner that one unwinds as the other winds. These ropes are attached to cages, and in their movement up and down the shaft are guided by sheaves at the top of a head-frame. The cages are so arranged that one is at the top landing of the shaft while the other is at the bottom landing,

Fig. 16. Watt Hoisting Engine

and they reverse their relative positions with each winding operation.

If the diameter of the drum, the weight of the rope, and the weight of mineral be known, a diagram may be drawn representing the resultant moments due to these weights for any position of the cages during hoisting. In Fig. 20, diagram a represents

hoisting from moderate depths when the weight of the mineral exceeds the weight of the winding rope; diagram *b* shows the conditions which prevail when the weight of the coal exactly balances the weight of the rope; and *c* when the weight of the rope overbalances the coal at the end of the hoist. Assume that the load the engine is to hoist is made up as follows:

	Pounds
Mineral	4,000
Car and cage	4,500
2,000 feet of 1½-inch rope	4,000
Total load to be lifted	12,500

It will be seen that the weight of the rope equals the weight of the mineral, and the total load is more than three times the

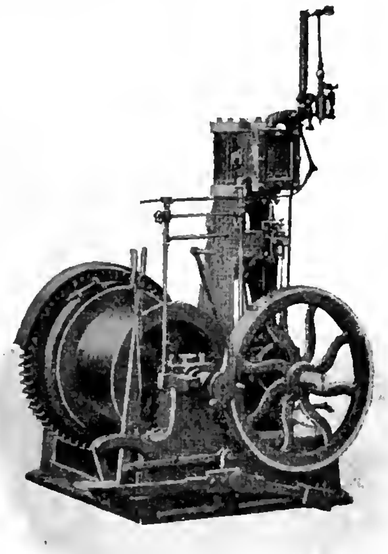

FIG. 17

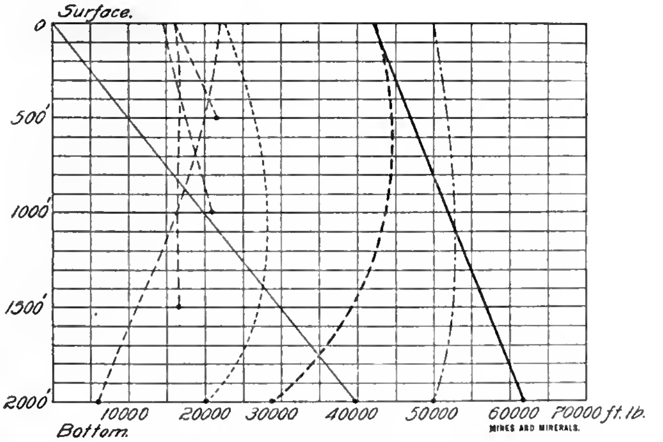
weight of the mineral, and that if the latter is to be raised without balancing, a great deal of power will be wasted. The load at the bottom is 12,500 pounds, when it reaches the surface the

DIAGRAM OF STATIC MOMENTS FOR THE FOLLOWING CONDITIONS:

Ore	4,000 pounds
Cars, cage, and rope, from head gear to cage	4,500 pounds
Round rope	1½ inch diameter
Flat rope	4½ in. × ⅜ in.
Straight drum	9 feet 10½ inches diameter
Conical drum	8 feet diameter at small end
Conical drum	11 feet 9 inches diameter at large end
Reel center	4 feet diameter



Straight drum, hoisting singly, loaded
Conical drum, hoisting singly, loaded
Flat-rope reel, hoisting singly, loaded
Flat-rope reel, hoisting singly, empty, to change levels
Straight drum, hoisting in balance, loaded, from different levels
Flat-rope reel, hoisting in balance, loaded, from different levels

FIG. 18

weight of the rope is removed and the weight is 8,500 pounds; thus the hoister must be 40.4 per cent. more powerful than would be otherwise needed in order to overcome the weight of

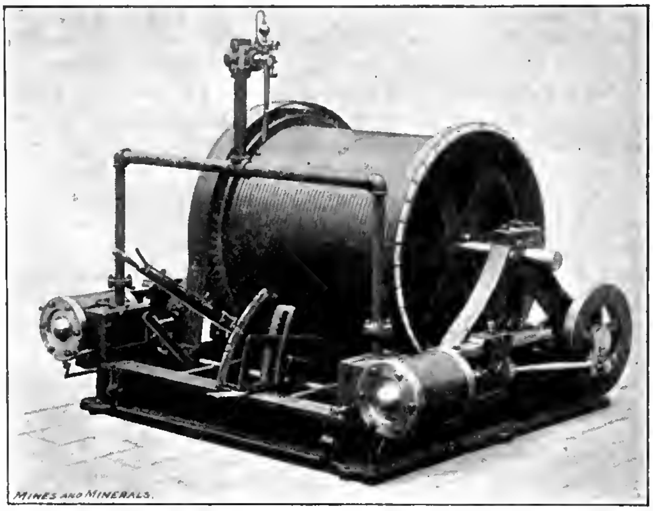


FIG. 19. LIDGERWOOD SECOND-MOTION HOIST

the hoisting rope. Different devices have been employed to overcome this condition, such as using two cages in a shaft; a tail-rope attached to the bottom of each cage, and extending to the bottom of the shaft; a taper rope so arranged that it is thicker and heavier at the top of the shaft than at the bottom; a flat rope wound on a reel and made to coil on itself; the conical drum; and the Koepe, and the Whiting systems of hoisting.

In this country the two systems of balancing most in use are the conical drum and the flat rope and reel. Both are based on the diameter of the drum or reel becoming larger and

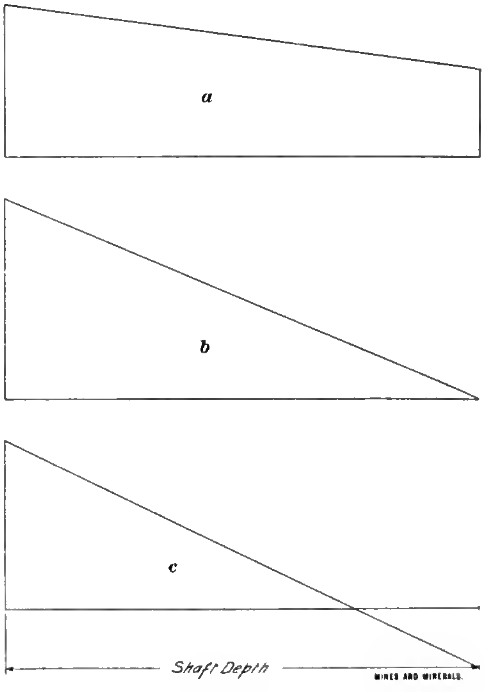

FIG. 20

larger as the rope winds up and thus offering more resistance to the engine.

When hoisting, the actual time during which the cages are moving may be divided into three periods as follows:* The time

* Arthur Whitten Brown, in Vol. 31, Trans. Manchester Geol. and Mining Society.

of acceleration t_1; the time during which the hoisting engine runs at full speed t_2; and the period during which the load is being brought to rest or the deceleration period t_3. During the acceleration period energy is stored in the moving masses and this energy must be returned in useful work or as heat during the decelerating period when the steam is shut off. As shown in Fig. 23 this stored energy *a b c d* may be represented as acting for a certain number of revolutions and having an area equal to the area *e f g h*, or that the stored energy has been used to complete the hoisting after the power has been shut off. By reference to Fig. 20 *b* it will be seen that the decelerating period will have to be longer than in the case of *a*, thus increasing the winding time and decreasing the output of mineral with a given cage loading. With *c*, deceleration is impossible and the stored energy must be disposed of in some other way, for example by a brake.

Whatever the shape of the diagram, the deceleration may be artificially increased by a friction brake, by admitting steam to the cylinder against the piston, and in one type of electric hoisting motor the energy may be returned to the generating system. Whichever method is considered, some waste is necessarily involved, and for economical reasons it is desirable that the hoisting engine should run out, that is, lose its energy, wherever possible.

As already seen in Fig. 20 *c* the engine will not, and in *b* may not, allow of deceleration so that the engine will run out in a certain fixed time. E. T. Sederholm* wrote an article for Mines and Minerals from which an abstract that has considerable bearing on equalization is taken. One method of equalization is by means of the cone drum, and to discuss this it must be understood that the duty an engine will perform depends on the size of the steam cylinders, on the steam pressure, the load to be raised, and on the radius of the hoisting drum. The larger the radius of the drum the greater is the leverage that the load exerts and the larger the cylinder will need to be to overcome that leverage. An engine works most advantageously if its load is constant and correctly proportioned to the size of the engine. It therefore follows that to obtain economy the variation due to the weight of the down-hanging rope must be equalized. With a cone drum, using the figures assumed, the relative weights to be lifted at top and bottom of the shaft are as 8,500 pounds is to 12,500 pounds, and the two corresponding diameters of the drum are in inverse proportion. If 8 feet is the desirable diameter for the load and rope selected, then the diameter of the large end would be $\frac{12,500 \times 8}{8,500} = 11$ feet 9 inches, and the average diameter would be 9 feet $10\frac{1}{2}$ inches. To wind the 2,000 feet would require 64.5 turns of the drum and that its length be 6 feet 9 inches long. Sufficient additional length should be given the drum to hold a couple of turns at the small end and a few extra grooves at the large end to provide for overwinding. The static moment to be overcome will be $\frac{12,500 \times 8}{2} = 50,000$ pounds at either top or bottom of the shaft. This static moment is not, however, constant during the whole lift, for when the rope has reached the middle groove of the drum, sometimes less than half the length of the rope has been wound up, while just one-half of the balancing effect of the radius has come into play. It follows then that the leverage of the rope on the drum will be slightly too great or the drum a trifle smaller at that point than that due to a true cone. The proper shape for the drum would be conoidal but that is out of the question as the shape then would be that of a conoid with a concave generating line. The truncated cone is therefore universally adopted as shown in Fig. 21, which is an engine at the Maxwell shaft of the Lehigh and Wilkes-Barre Coal Co , at Ashley, Pa.

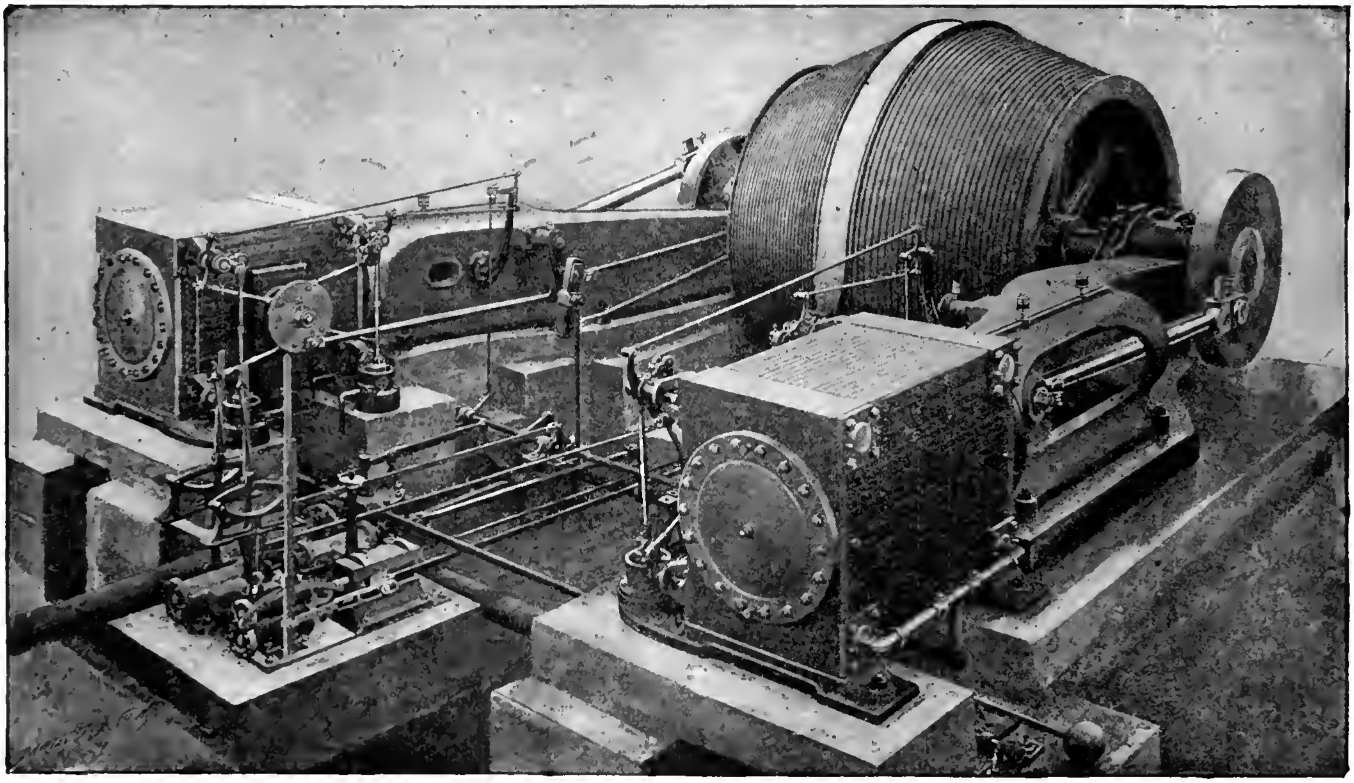

Fig. 21. First-Motion Hoist, Maxwell Shaft, Ashley, Pa.

In figuring out the different turning moments of the load on the drum it will be found that they vary. The diagram, Fig. 18, shows what they would be with the loads and dimensions given for a straight drum, conical drum, and flat-rope reel, hoisting singly, and for a straight drum and flat-rope reel hoisting in balance. From this it is seen that the maximum moment

*"Balanced and Unbalanced Hoists." Mines and Minerals, Vol. 24, page 577.

for the straight drum is at the bottom, while for the cone drum it is near the middle of the shaft. These respective moments are 61,800 foot-pounds and 52,900 foot-pounds, from which it is deduced that the cylinders of the straight-drum hoist will have to be about 13 per cent. larger than those of the conical drum, and with the cylinders of course all other parts of the engine. In the case under consideration the straight-drum engines would have cylinders 22×60 inches, and the conical drum engines cylinders 20×60 inches. The cost would vary approximately in the same ratio but so the economy, for the diagram shows little would be gained in coal consumption by the use of the conical drum. To gain in economy it will be necessary to do something more than equalize the weight of the rope.

Double hoists with conical drums show that when hoisting in balance less effort is required to start the load, but such hoists must always hoist from the same level. Under such conditions it is possible to proportion the drums to obtain a very perfect balance provided the hoist is built to always hoist in balance. Then it is not necessary to use clutch drums.

Perhaps the most common type of balanced hoist is the plain double-drum hoisting engine shown in Fig. 22, with cylindrical drums clutched to the shaft. In this hoist the cages and cars are perfectly balanced, while the rope is not balanced at all. Its proper place is therefore in mines which are not deep and where the effect of the rope is of comparatively small consequence. If the same conditions are assumed as before and drums of the same diameter are used, it will be found that 100 per cent. more power is required to start the load from the bottom than is needed when it reaches the top. This shows that while the straight drum is superior as far as balancing the cages and cars are concerned, it is inferior to the taper drum when it becomes important to balance a long rope. But the taper drum leaves very much to be desired if, as usually is the case, the hoisting is to be carried on from several levels. This has led to the adoption of the so-called tail-rope for balancing the rope itself. It consists of a rope of exactly the same diameter and weight, as the main hoisting rope, attached to the bottom of the cage and carried down to the bottom of the shaft, from which point it returns up to the other cage after passing around guide sheaves as shown in Fig. 24. With this arrangement it does not matter what position in the shaft the cages may occupy there is always exactly the full weight of rope dependent from each drum. One rope balances the other and one cage with its cars balances the other which is an ideal arrangement as far as balancing goes.

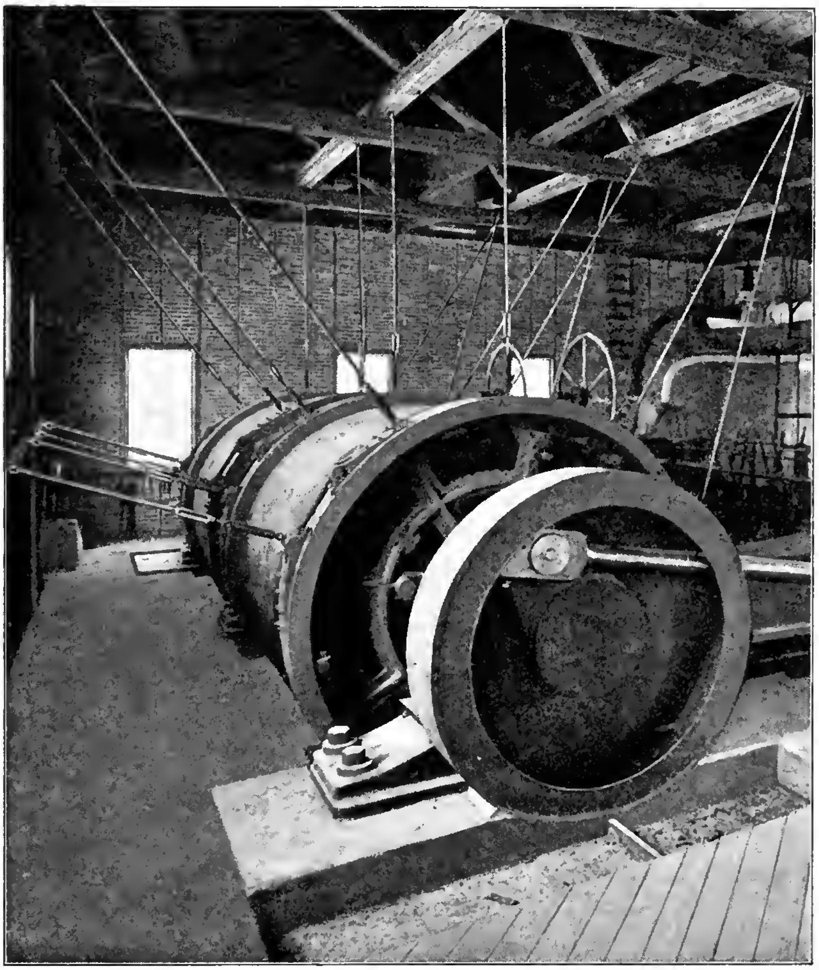

FIG. 22. SAVOY AND SIBLEY HOIST, 2,500 FEET CAPACITY, ELY, MINN.

As already stated and shown in Fig. 19 *a, b, c*, it is advisable to avoid as far as possible the use of means for artificially increasing the deceleration, and to this end attempt is made to arrange the winding moment so that it is sufficiently great at the end of the hoist to produce the required deceleration. If the weight per foot of the balance rope is equal to that of the hoisting rope, then the winding moment due to the load will not vary during a hoisting period and the diagram will become a rectangle. Such a diagram represents the greatest advantage to be gained by the use of a balance rope. If the balance rope is heavier than the winding rope the diagram will be more favorable to running out; and the stress on the winding rope will be increased, also a larger rope for the same factor of safety and perhaps a larger drum to accommodate the rope will be required. There are practical disadvantages that may outweigh the advantages of a balance rope; for instance, where it is necessary to hoist from different levels the timbering in the shaft must be arranged so as not to interfere with the tail-rope when hoisting from higher levels. This objection is not so serious, for all that is necessary is to make the timbers heavy enough to stand without partitions between the two hoisting compartments, and put the guide timbers on the long sides of the shaft.

Assuming* that the balance rope is of the same weight as the winding rope, then in Fig. 23, if the depth of the shaft be s feet, and $s_1\ s_2\ s_3$ feet be the distances described by either cage during acceleration, full speed, and deceleration, respectively, and the times $t_1+t_2+t_3$ be T seconds, the velocity in the shaft at full speed being V feet per minute, then the mean velocity over s_1 and s_3 will be $\frac{V}{2}$ feet per minute; and

$$V = \frac{120s}{t_1+2t_2+t_3} \text{ ft. per min.}$$

If the diameter of the drum is known V, may be replaced by N revolutions per minute and S by N_1 where N_1 is the number of revolutions made by the drum in completing one hoist. Similarly $n_1\ n_2\ n_3$ replace $s_1\ s_2\ s_3$, respectively, as shown in Fig. 25.

For a given speed of N revolutions per minute, the energy stored during acceleration is proportional to the sum of the moments of inertia of all the moving masses referred to, say the drum diameter. If this inertia be expressed as I = pounds

* A. W. Brown's Method.

weight × (diameter of gyration in feet)², then the winding moment M_a in foot-pounds required to produce a speed of N revolutions per minute in t_1 seconds is

$$M_a = \frac{I\,N}{1{,}220\,t_1}\text{ ft.-lb.}$$

Expressing the winding moment due to the load as M foot-pounds, then the time required for the hoisting engine to come to a state of rest is given by

$$t_3\text{ seconds} = \frac{I\,N}{1{,}220\,M}$$

Since for a given output of mineral per hour with a fixed weight raised at each hoist, the running time T seconds is fixed, the speed of winding will depend on the value t_2 and consequently the brake horsepower to be exerted in raising the load. The brake horsepower is found by the following formula:

$$\text{Brake horsepower} = \frac{M\,N}{5{,}280}\text{ during full speed; or}$$

$$\frac{(M+M_a)\,N}{5{,}280}\text{ during acceleration.}$$

Values varying from zero to .8 T may be given t_2 yet the winding engine will run out.

RETORT COKE OVENS IN MEXICO

Written for Mines and Minerals, by E. B. Wilson

About all the coal under development in Mexico is in Coahuila, tributary to the Mexican International Railroad.

Increased Percentage of Coke as Compared With Output of Beehive Ovens

The Sabinas coal field derives its name from the town near which the first coal mine in Mexico was opened in 1884.

The principal coal basins in this field, shown on the map, Fig. 3, are Sabinas, Fuente, Palau, Las Esperanzas, Saltillo, San Blas, and Lampacitos. Before a study of this basin was made by Jose G. Aguilera, Director of the Mexican Geological Survey, the coal measures were considered as belonging to the same system as the Laramie beds in the United States. Senor Aguilera found, however, that the fossils in these measures corresponded to the Montana division of the Upper Cretaceous in the United States. The Sabinas and Fuente basins are separated by what is termed the Peyotes anticlinal. The Las Esperanzas basin is separated from the Sabinas basin by a belt of hills $1\frac{3}{4}$ miles wide. The Saltillito basin is 5 miles south of Barroteran. The San Blas basin is 30 miles north of Obayos, but as this basin is not on the railroad it is not worked at present.

The Lampacitos basin is 1 mile north of Baluarte, on the Mexican International Railway. The town of Lampacitos and a general view of the coke oven plant is shown in Fig. 1. There is at this place a 6-foot bed of coking coal belonging to the Cia. Carbonifera Agujita, y Anexas, S. A. Until recently the Mexican coal, which in structure strongly resembles the semi-bituminous coking coal of the Pocahontas field, West Virginia, has been coked in beehive ovens, and in places subjected to dressing before being sent to the ovens. Owing to the low coke yields of this coal in the beehive oven, due to the fact that it is necessary to burn off a considerable amount of fixed carbon in order to generate enough heat to carry on the coking process, experiments were made in 1908 with a battery of three non-by-product retort ovens.

The first plant of retort ovens, built at Lampacitos, proved their ability to make good coke and a block of Koppers retort ovens were started, as shown in Figs. 2 and 3, the latter being a view of the foundation up to the oven yard.

At Lampacitos there are 36 Koppers retort ovens whose inside dimensions are 33 feet $1\frac{1}{2}$ inches long, 6 feet $10\frac{1}{2}$ inches high, 22 inches wide at the discharge end, and 19 inches wide at the pusher end. An analysis of the Lampacitos coal which is crushed, but not washed, previous to coking, is given as volatile matter, 17.5 per cent.; fixed carbon, 67.0 per cent.; ash, 15.5 per cent.

The theoretical yield of coke from this coal should be 82.5 per cent., or 1,650 pounds of coke for every ton of coal. In beehive-oven practice the coal produced about 60 per cent. coke, or 1,200 pounds per ton of coal. In other words, it required 1.66 tons of coal to make 1 ton of coke. It was found

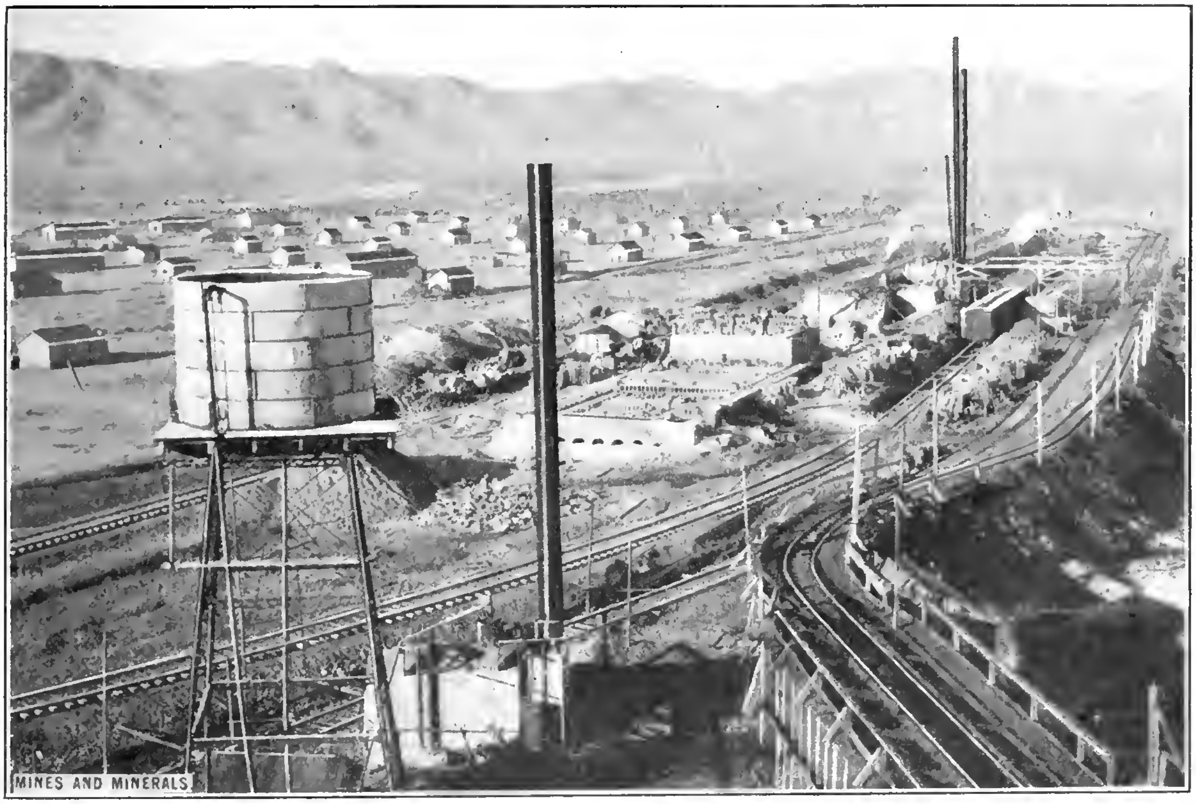

Fig. 1. Lampacitos, Mexico, Coke Plant

from the experimental retort oven plant that the coke yield amounted to 80 per cent. of the coal charged, or 1,600 pounds, thus economizing to the extent of 400 pounds of coal for each ton of coke made.

Mexican coal operators seemed to have become satisfied that if they could produce 5 tons coke where they produced four from the same quantity of coal there was conservation to be practiced, and lost little time in adopting retort ovens. The

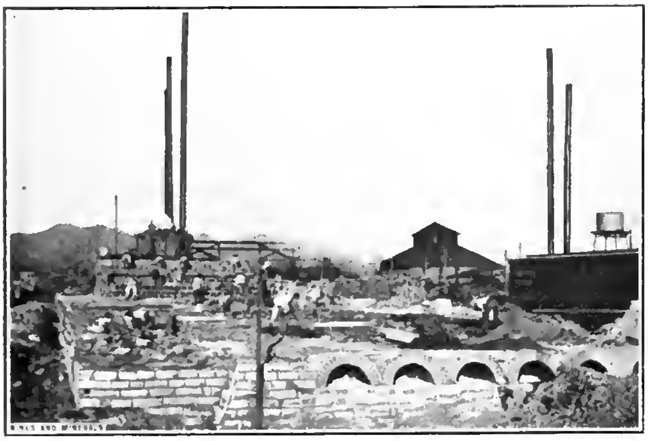

Fig. 2. Retort Coke Ovens Under Construction at Lampacitos

Mexican Coal & Coke Co., whose ovens are shown in the course of construction in Fig. 4, were next to adopt retort ovens, and have at present a battery of 50 of the same size as those at the Lampacitos plant, although differing slightly in flue construction. An analysis of the Las Esparanza coal is given as follows: Volatile matter, 21.1 per cent.; fixed carbon, 67.4 per cent.; ash, 11.5 per cent.; moisture. This is practically the same coal as that at Lampacitos, but is washed previous to coking. Theoretically, 1.27 tons of this coal should yield 1 ton of coke. However, in beehive ovens the yield is 60 per cent., thus making a difference between theory and practice of 820 pounds of coal per ton of coke. Owing to the ash in the coal remaining constant while the hydrocarbons are expelled in coking, it follows that since it requires 1 66 tons of coal to make 1 ton of coke in the beehive

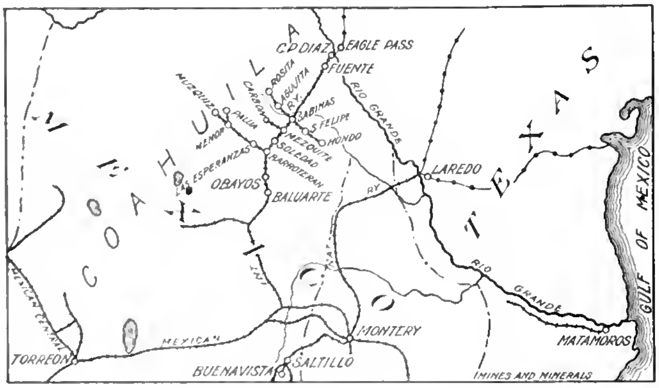

Fig. 3. Map of Sabinas Coal Field

ovens, the ash will increase from 11.5 per cent. in the coal to 19.09 per cent. in the coke. When it is understood that by the use of retort ovens the yield of coke from this coal is increased one-fifth and the ash is reduced from 20 to 15 per cent. in the coke, their value from an economic and metallurgical standpoint is evident.

The illustrations accompanying this article are of the first non-by-product retort ovens constructed on this side of the Atlantic, known as "Koppers waste heat ovens"; and are more descriptive in showing the progress and mode of construction than probably any hitherto published.

From the illustrations, the construction of beehive ovens seems simple compared with retort ovens. When, however, the crown of the beehive oven has been properly constructed there has been as much intelligence involved as anything in the line of experience required in retort oven building.

It will be noticed that in the Lampacitos ovens there are a series of flues under the retorts, and in Fig. 6 there is shown a large flue under the oven yard for carrying off the waste heat.

The flues under the ovens perform two services: (1) They raise the oven to the desired height above the loading track with less material. (2) They keep the foundation cool. The air entering at the outer end of these flues travels to a division wall in the middle of the battery where it passes through openings in the arch of the flues into checker work under the oven floor. It then works its way to the outer ends of the battery and is drawn off by a short stack. The flue under the pusher machine track collects the waste heat and leads it to the boiler plant.

The gases volatilized from the coal in these ovens are not treated for by-products, but are burned to heat the ovens. At Las Esperanzas the hot gases resulting from the combustion of the gas in the heating flues are used under three 150-horsepower boilers, and three more are being installed, making 900 horsepower of steam generated by the waste heat from 50 ovens. History states that retort ovens were first constructed for the purpose of increasing the quantity of coke from a given quantity of coal, and at the same time to accelerate the coking process. According to this, the saving of hydrocarbon and ammonium by-products distilled from the coal was an after thought which overshadowed the fact that in many cases it was not by-products but increased coke yield the operator desired.

In the beehive ovens the volatile matter in the coal is volatilized by radiated heat from the oven walls, and, by burn-

Fig. 4. Retort Ovens at Las Esperanzas

ing inside the oven, reheats the walls. The temperature of beehive ovens reaches at times 2,800° F., while that of retort ovens will vary from 2,100° F. to 2,200° F., depending on the temperature to which the air is preheated before mixing with the gas. It is probable that there is a greater loss of heat due to radiation in beehive ovens than in retort ovens, as more surface is exposed, consequently the higher temperature of the former is directly due to the combustion of the volatile matter in contact with the coal and firebrick. The

thickness of the walls of retort ovens is important because all heat for coking must pass by conductivity through the firebrick, and naturally the thinner the walls the more heat will be transmitted in a given time. The thickness of the retort walls in Koppers, vertical-flue, non-by-product coke ovens is 4½ inches, but strength is added to the ovens through the numerous flue partitions which are from 5 to 6 inches thick. When beehive ovens are watered, drawn, and left standing, it is a question of time until the bricks lose so much heat by radiation that the charge will not fire. To make good solid coke the charge must catch fire quickly. This is accomplished by keeping the oven hot and charging soon after drawing the coke. The retort ovens can be kept hot by closing the oven doors soon after the coke is pushed and by burning gas in the combustion flues, both of which add to the dispatch in coking. In Fig. 7 is shown the pusher side of the retort ovens under construction, and also the top of the vertical flues so constructed that cool air may enter for the combustion of the gas which takes place in the vertical flues. Another view of the same ovens further along in construction is shown in Fig. 5. In this illustration it is seen that the retort chambers are open at both ends and are separated by what are apparently brick walls but which in reality are partitioned inside so as to form combustion flues.

Retort chambers in general are made up to 34 feet in length; 6.5 to 7 feet in height, and from 18 to 24 inches in width; the latter width, however, is exceptional and requires about as much time to make coke as a beehive oven. Between the ovens are flues, placed either horizontally or vertically—in these particular ovens vertically—so that each flue may be supplied with a gas jet for heating the walls.*

In the Koppers non-by-product oven the gases given off from the coal pass directly into the vertical heating flues between the ovens, entering these at their upper ends and meeting cold air admitted through the dampered openings on top of the ovens. Where, in by-product ovens, the combustion takes place in these vertical flues from the bottom up, in the non-

FIG. 5. PUSHER SIDE OF OVENS AT LAMPACITOS

by-product ovens the combustion takes place from the top down, and the waste gases all enter the large flue leading to the boilers. In Fig. 8 the construction of the Koppers oven at Lampacitos is shown at that stage where two buckstaves are placed at each combustion chamber to prevent the heat expanding the walls to such an extent as to produce cracks and leaks. Each pair of buckstaves are yoked by tie-rods to the pair on the opposite side of the oven, and each buckstave is supplied with a gate hook to receive a gate bar which holds the oven door upright. It will be noted that from every alternate pair of buckstaves steel brackets are fastened whose object is to carry one of the rails on which the traveling crane moves. The oven doors are supplied with eyes at their upper ends to receive the hook suspended from the crane by a chain.

It is necessary to be able to remove and replace the heavy

FIG. 6. RETORT OVENS AT LAMPACITOS

doors quickly, and the traveling crane shown in Fig. 9 answers this requirement.

The Las Esperanzas ovens are charged with 8 tons of crushed coal, sometimes carrying as much as 12 to 15 per cent. moisture, owing to the coal being previously washed. After charging, the doors are put in place and kept tightly luted with clay, so that there will be no leakage of air into the ovens. The draft on the ovens is from 4 to 5 millimeters of water gauge.

To remove the coke from the ovens, traveling cranes, one on each side, remove the doors, as shown in Figs. 9 and 10, and the pusher shown in Fig. 9 rams the coke out of the oven, as shown in Fig. 10. The coke, which is uniform in texture, is broken by hand into lumps about 4 inches in diameter, and is then forked into cars. Mexican coke is consumed entirely by metallurgical furnaces, and although the supply does not meet the demand, the Mexican furnacemen insist upon the waste, resulting from breaking coke into lumps which will burn freely, being charged to coke production.

In Fig. 9 the various operations connected with coking on the pusher side of the ovens are shown; for instance, the crane is holding the door from the oven being discharged, while the larry is shown on top, charging an oven from which the coke has been removed.

TABLE 1

Coal	Moisture at 212° F. Per Cent.	Volatile Matter Per Cent.	Fixed Carbon Per Cent.	Ash Per Cent.	Sulphur Per Cent.	Yield in	
						Beehive Oven Per Cent.	By-product Oven Per Cent.
Connellsville	1.86	30.12	59.61	8.41	.78	64	72
Pocahontas	1.01	18.81	72.71	5.91	.79	62	85
Coahuila	1.60	15.00	67.64	12.01	.86	60	80

In Fig. 10 the door is shown suspended from the crane; the coke is on the oven yard just after it has been pushed from the oven; and the man in the rear of the hot coke is examining the interior of an oven to ascertain its condition.

Coal which is coked in beehive ovens loses some fixed carbon through combustion during the coking process and

* See Vol. XXXI, MINES AND MINERALS, page 185.

through combustion after the coke has formed. Apparently this loss follows in the inverse ratio to the percentage of volatile matter in the coal, other things such as ash being equal.

Taking as examples the Connellsville, Pocahontas, and Coahuila coking coals, and comparing the yields in coke in beehive and by-product ovens, this and other interesting conditions are observed. Table 1 gives the analyses of the three

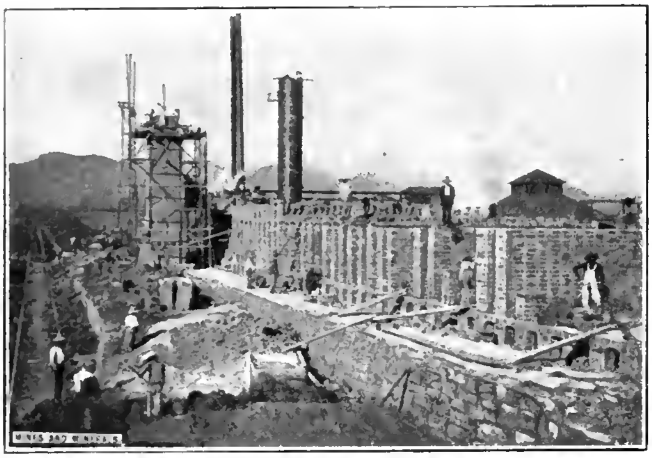

Fig. 7. Constructing Retort Ovens at Lampacitos

coals and their actual yield in coke per ton of coal in beehive and retort coke ovens.

Theoretically, Connellsville coal should furnish 68.38 per cent. coke; in beehive ovens it yield 64 per cent., thus it takes 1.562 tons of coal to make 1 ton of coke. When the same coal is coked in retort ovens it yields 72 per cent. of coke, thus conserving 340 pounds of coal for each ton of coke made, when compared with the product from beehive ovens. Pocahontas coal cokes in beehive ovens at the expense of some of its fixed carbon, and only under exceptional circumstances yields 62 per cent. coke. In retort ovens it has yielded 85 per cent. of coke, thus conserving 740 pounds of coal for every ton of coke made. At Joliet, Ill., where there are 280 Koppers regenerative by-product ovens, 80 per cent. Pocahontas coal is mixed with 20 per cent. Ronco coal, forming a mixture containing 22 per cent. volatile matter. The coke yield is 84 per cent. and the gas yield 10,000 cubic feet per ton of coal. Less than 50 per cent. of this gas is used to heat the ovens. The increased yield of coke in retort ovens with Coahuila coal has been stated previously in this article.

That coal coked in retort ovens should yield more than the theoretical quantity of coke is due probably to the decomposition of the volatile hydrocarbons, which adds materially to the fixed carbon, but the increase seems to be greater as the percentage of volatile matter decreases, as will be noted in Table 1, giving the analyses of the three coals. This is diametrically the reverse of beehive coking.

The object in coking coal is to supply fuel for blast furnaces that is high in fixed carbon and low in volatile matter, sulphur, and phosphorus. The analysis of a good furnace coke for Bessemer pig iron is about as follows: Fixed carbon, 89.55 per cent.; ash, 8.285 per cent.; volatile matter, .5 per cent.; moisture, .85 per cent.; sulphur, .8 per cent.; phosphorus, .015 per cent.

Volatile matter in coal, unless it be anthracite, prevents its use in smelting, for in addition to the large quantity of unconsumed gases created and the danger from explosions, the coal produces an agglomerate, if of the coking variety, and scaffolds if of the non-coking variety. Anthracite coal was long used in the East for the manufacture of pig iron and possibly may be mixed with coke and used at the present time, particularly where the cost of coke is high. Coke should not contain more than 1.22 per cent. in volatile matter nor more than 12 per cent. ash. The latter of course reduces the fixed carbon in the coke just 20 pounds per ton for each 1 per cent., besides it demands extra flux and heat to convert it into slag and entails extra expense for its handling and disposal. Moisture greatly lowers the heat of the furnace, and so annuls the heat of the fixed carbon to a certain equivalent extent.

Phosphorus in coal goes into the coke and will appear in a larger percentage in a ton of beehive coke than in a ton of retort-oven coke. The effect of phosphorus on iron is to make it brittle when the iron is cold, and it should not exceed .03 per cent. in coke used in blast furnaces, unless basic iron is desired. Sulphur should not exceed 1 per cent. in coke. Should a coking coal contain 2 per cent. in sulphur 1 per cent. will be oxidized to SO_2, and pass off as gas; the remainder, however, will be retained in the coke; but it requires more than 1 ton of coal to make a ton of coke, and the increase in sulphur will condemn the coke for pig-iron manufacture, although it may be employed for copper and lead smelting.

Although this article is on non-by-product retort ovens, as a whole it would be incomplete without mentioning the 60 combination retort ovens now being constructed by Mr. Piette for the Sabinas Coal Co., at Rosita, Coahuila. These ovens have horizontal flues instead of vertical and would therefore belong to the more expensive Semet-Solvay type, but so arranged that they can be changed from waste-heat ovens to by-product ovens, while the Koppers ovens, as constructed in Mexico, can be used only for waste gas. The 60 ovens of the Sabinas Coal Co. will utilize the surplus gas under six French boilers of the Babcock & Wilcox type, with superheaters, and capable of producing steam to the amount of 1,500 horsepower. At Rosita a steam turbine and central electric plant will be installed to distribute power to the various mines of the Sabinas company. The 50 ovens of the Mexican Coal and Coke Co., at Las Esperanzas,

Fig. 8. Constructing Ovens at Lampacitos

furnish steam for a 1,000-horsepower "Curtis" turbine, which furnishes electric power for the company's mines, performing all the work at the mines with the exception of hoisting.

The writer is indebted to Mr. R. D. Martin, of Agujita, for the illustrations appearing with this article; Mr. M. C. Scheble, general manager of the Compania Carbonifera Agujita y Anexas; Mr. Edwin Ludlow, general manager, Mexican Coal and Coke Co.; and Mr. W. E. Hartman, Joliet, Ill., for assistance rendered in this article.

THE STARKVILLE, COLO., EXPLOSION

Written for Mines and Minerals, by Our Special Correspondent

Method of Mining and Ventilation and Conditions Existing in the Mine Before and After the Explosion

The Starkville Mine of the Colorado Fuel and Iron Co., is situated at the town of the same name on a branch of the Atchison, Topeka & Santa Fe Railroad Co., some 4 miles south of Trinidad, Las Animas County, Colo. The population of some 1,500 is entirely dependent upon the mine for its livelihood.

The plant consists of a wooden tipple of about 1,500 tons daily maximum capacity, a 1,200-ton storage slack bin, coal-washing plant, 190 beehive ovens in blocks, and the usual repair shops, stables, etc., none of which was injured by the explosion. The tipple is some three-quarters of a mile from the mine, the coal being hauled around the hillside by a steam locomotive. The daily output, prior to the accident, was about 1,200 tons, over one-half of which was used to charge the ovens, the remainder being consumed by the Colorado Fuel and Iron Co. for various purposes.

The seam worked is known as the Starkville and is a member of the Laramie formation of the Cretaceous. Its composition, is, essentially, 35 per cent. volatile matter, 5 to 6 per cent. combined moisture and 6 to 8 per cent. of ash, with sulphur well under 1 per cent. When crushed and washed it makes a satisfactory coke.

The seam varies from 4 to 7 feet in thickness, averaging about 6 feet, and is clean except for a variable bone of from 1 to 6 inches some 2 feet above the floor. The roof, to which the coal adheres, consists of from 6 inches to 15 feet of slate to the sand rock, which, however, in numerous instances is immediately upon the coal. The draw slate is left up in both rooms and entries, and falls when wet owing to the probable admixture of a small percentage of lime. The floor is a hard slate. Seventeen feet below the Starkville is found another 6-foot seam, originally worked, but now abandoned by reason of two large and persistent slate partings. Fifty feet above is a smaller seam, not opened. The intervening strata consist of the usual shales and sandstones.

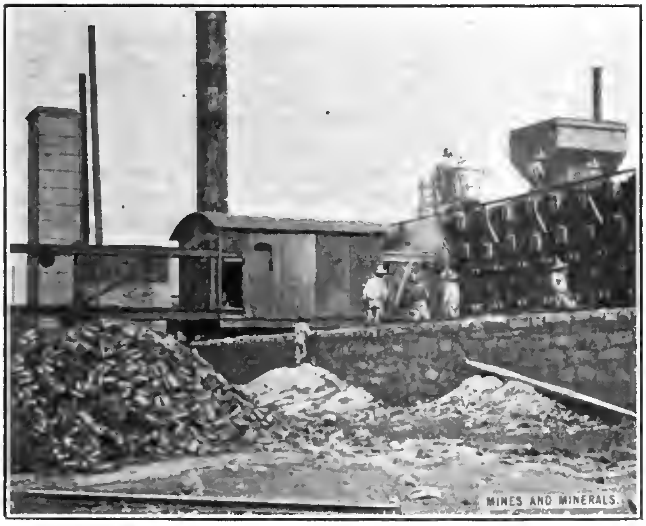

Fig. 9. Pusher Operating at Lampacitos Ovens

The covering above the coal averages a trifle more than 600 feet in thickness, running up to over 1,000 in places.

No powder is or was used in the Starkville Mine and the seam is essentially non-gaseous. The coal has a most pronounced fracture, breaking off in plates like the leaves of a book, 2 inches to 6 inches in thickness, and is shoveled out, even a pick not being generally necessary. This tendency to flake or break off is probably due to the pressure of the superincumbent rock. The mine is dry, but not unusually so, and the floors, but not the ribs or the roof of the entries were sprinkled daily by a watering car. Gas in small quantities has been found at rare intervals at the extremities of the new workings, but open lights were used and were permissible.

There are two openings about 300 feet apart at Starkville, the old and the new, although these form practically one mine.

The general plan of the workings is shown in Fig. 1. The original opening was made some 28 years ago when the mine was the property of the Atchison, Topeka & Santa Fe Railroad Co., and was for 1,100 feet driven single entry, but subsequently worked double, with a 10-foot air-shaft on the hillside, which was abandoned years ago.

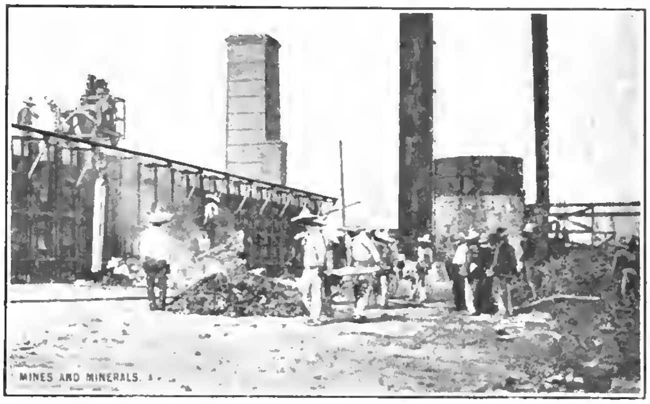

Fig. 10. Coke Charge Just Pushed From Ovens at Lampacitos

Forty-seven hundred feet in, are the third and fourth south entries, 2,400 feet long, driven over to entries M1 and M2 of the new mine. All the coal from these cross-entries to daylight is worked out and the pillars drawn. At the time of the explosion the new mine was being equipped with electric haulage and a 2-inch water line with hose connections every 75 feet for the purpose of watering the entries. Thirty-nine hundred feet further in is another pair of cross-entries, known as the seventh and eighth south, connecting the two mines as before. The coal between the fourth and seventh south entry is worked out.

There were three trolley partings or gathering places in the mine, one 8,500 feet in on the main straight road, another on the tenth south, 2,000 feet beyond, and the third on the new entry, M2, near its intersection with the seventh south, 9,400 feet from the drift mouth. The gathering was done by mules, and the hauling to daylight by Jeffrey motors, operated under 550 volts pressure, this being the oldest haulage plant in the western states. The course of the coal from the old mine was from the inner parting 8,500 feet in a direct line.

From the new mine the coal was hauled to the third south cross-entry, thence along this to the old mine and along the old heading to daylight, a total distance of 12,000 feet.

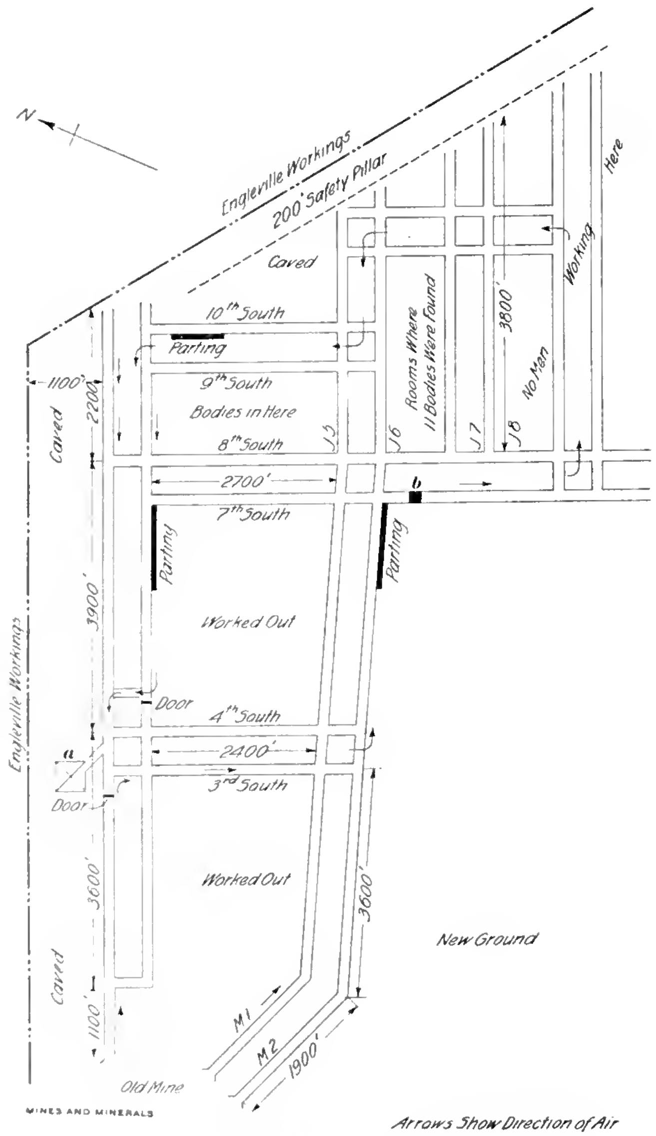
The 1,350 acres comprising the old mine was practically worked out and a new mine was being equipped. This mine is to draw its coal from the untouched area reached by an extension of the seventh and eighth cross-entries to the right, and from which extension butt entries on the original course of 78° E are driven. These new entries are known as J7 and J8, etc., and represent the only new work in the mine.

The old main heading extends 2,200 feet beyond the eighth south to the Engleville workings, the boundary between the mines extending diagonally across the field, it being 3,800 feet along the M1 and M2 or new headings to this other mine. The Engleville Mine is older than the Starkville by several years, but is still in operation, its workings extending parallel to those of Starkville on the left some 1,200 feet therefrom for a distance of over 2 miles. These workings were at one time connected, but owing to a fire some years ago, pillar drawing, etc., entrance

cannot now be had along this line between the two. As a rule, at the boundary at the end of both the old main and new main haulage roads a pillar of 200 feet has been left to protect the Engleville main heading, which here bends to follow the property line.

However, at the extreme end of the old main haulage, the two mines came together, but the openings have been bratticed off.

Ventilation.—On an average 200 men and 40 mules were employed under ground and were supplied with 60,000 cubic feet of air per minute. The ventilating system was extremely simple, only some 7 or 8 brattices and doors and no splits being used in the mine, the air making a complete circuit of over



PLAN OF MINE STARKVILLE, COLO.

6 miles from daylight to the fan. This fan was built at the foot of a shaft *a* just inside of the point where the fourth south entry turns off from the main haulage road and 4,700 feet from daylight. The air entering the mine on the old main heading, being stopped by double doors at the third and fourth south entries, was drawn down the same over to the new workings, where it met the incoming air from the new openings. The joint current proceeded along the new entry to the seventh south where it passed through a 7-foot Stine fan *b* having a measured capacity of 45,000 cubic feet a minute. Here diverting to the right, it passed up the new working places, J7 and J8, etc., turned to the left down the tenth south to the old main heading and back along it to the foot of the air-shaft *a* mentioned above. Here the air passed through a $10' \times 3\frac{1}{2}'$ fan built by the company and driven by an electric motor from the trolley current. This fan has a measured capacity of 60,000 cubic feet of air per minute at 1.5 inches water gauge and exhausted into the air-shaft 95 feet deep with a cross-section of 6 ft.$\times$8 ft.

Explosion.—At 10:07 P. M. (determined by a stopped watch found upon one of the bodies) on Saturday, October 8, 1910, the mine "blew up" and the 55 men, under the supervision of Luke Upperdine, night foreman, as well as 7 mules, were killed.

The immediate effect of the explosion was to totally destroy both fans and to partly block the mouth of the old main entry, but doing no harm either to the adjoining Engleville mine or to the new entries M1 and M2 from their intersection with the third and fourth south, toward daylight.

The condition of affairs at the focus of the explosion was found to be as follows: Six hundred feet in on the old main heading, which had caved to a height of 10 to 12 feet above the timbers, was found the electric motor with the power shut off and brakes applied. It should be noted that the motor was not jammed into or covered by the fall. Attached to the motor were 10 loaded cars, and 66 feet back were 21 more cars representing the remainder of a regular trip. The body of the motorman was found two car lengths back from his locomotive, and that of the trip rider, four car lengths forward from the rear car. In the rear section, the second car from daylight was off the track and "into the rib," and the trolley wires were down. It is reasonable to suppose that the accident happened in this manner: The motorman recognizing that his trip had split, shut off the power, applied his brakes and started back to investigate the cause of the trouble. The trip rider also started forward. Probably the jumping of the car mentioned above was the cause of the trip splitting. In any case this car knocked down several posts, and large quantities of dry dust were suddenly thrown into the air-current. The motorman had time to walk two car lengths after stopping his machine and the trip rider four car lengths before the trolley wires came sufficiently close together to "short-circuit" and thus produce the flame required to ignite the dust.

One section of the flame started toward daylight along the top of the dust-covered lagging on the entry timbers and scorched the trolley poles 250 feet from the drift mouth from 10 feet above the ground upwards. Such fallen timbers as could be observed in this short distance lay with the tops toward daylight.

Another sheet of flame started inward, but meeting the wet section just beyond the third and fourth south entries, was stopped for lack of fuel and turned to the right down the above entries over to the new workings. Following along the new entries to the seventh and eighth south, it here passed through the smaller fan and completely blew out the blades and threw the motor to a distance of 30 feet. It there turned to the right and then to the left, up J7 and J8 and their parallel entries with branches to the left along the seventh, eighth, ninth, and tenth south entries. That along the seventh and eighth south stopped for want of fuel as soon as the wet section on the old main entry described before, was reached.

The variation in intensity of the current was plainly marked. In places where dust was plentiful and the mine dry, the velocity and force of the explosion scoured the ribs clean. In other places the lack of dust or the presence of more moisture lessened the velocity and permitted the deposition of soot and coke, these conditions alternating. At the focus of the explosion, the timbers had fallen in opposite directions, but further in the heads of several sets were found pointing out while those of the following sets pointed in. Presumably this variation was due to some of the timbers being felled by the explosion and others by the recoil.

Of the bodies recovered, about 17 showed clearly the effect of burns. These were the motorman and trip rider near the old drift mouth, 11 men in the rooms driven from J7 entry near the extremity of the workings, three on the trolley parting on

the tenth south entry, and one in the workings nearby. Almost all the others were killed by afterdamp, most of them having time to seize clothing and dinner buckets and walk or run for from 100 to 1,000 feet from their working places toward daylight or toward the Engleville workings, where they probably hoped to escape through the brattices. A driver was found fully 2,000 feet from his mules, and several groups of bodies were encountered, as if the men had time to get together and talk over means of escape. In all cases, however, they were met by volumes of afterdamp and probably all were dead in 10 minutes at the most after the explosion.

As soon after the explosion as possible, word was telephoned to the local offices of the Colorado Fuel and Iron Co., at Trinidad, and by 10:45 the rescue car was on the ground.

At first, efforts were made to penetrate through the new openings but this was impossible even with oxygen helmets on account of the volume of afterdamp. It was then decided to endeavor to restore the ventilating current. To this end, a 7-foot Stine fan was placed at the mouth of the M1 entry and the M2 entry was bratticed off to prevent short-circuiting the air. This fan making 300 revolutions per minute with a 25-horse-power motor was installed by 3 A. M. Monday, and forced 50,000 cubic feet a minute into the mine. On Sunday, pending the erection of the temporary fan, entry through the old Engleville workings at the end of the Starkville main heading was effected, but the rescuers were driven back by the volume of afterdamp drawn into the workings by the fan in the other mine. In a few hours it was possible to enter as far as the third and fourth south cross-entries, which in turn were bratticed off. Work was then pushed ahead along the main entry and the necessary brattices built on seven and eight south entries to force the air up J7 and J8. When this was accomplished, only some seven brattices being necessary, the air was following its usual course throughout the mine.

The first bodies, badly decomposed, were found in the rooms off J7 and were the 11 mentioned before as being among those killed outright. These were found by the morning shift between midnight and 7 A. M. on Tuesday. After this the work of removing the dead was comparatively rapid. The last bodies, those of the motorman and helper near the old drift mouth and the last to be reached, were brought out on the following Sunday, 8 days after the explosion.

Forty-two of the 56 dead were brought out by the day rescue shift in which were B. P. Manly, mine inspector for the Colorado Fuel and Iron Co., Geo. B. Parker, in charge of the rescue station of the Carbon Coal and Coke Co., at Cokedale, who volunteered his services and remained throughout the entire week, and Thomas Tweeddale, mining engineer, who has just assumed charge of the rescue car belonging to the government service. James Wilson, superintendent of the Starkville Mine, left a sick bed to take charge of one of the rescue parties, and John T. Thomas, division superintendent, David Griffiths, superintendent at Fremont, and J. S. Thompson, also division superintendent, were on the ground and constantly in the mine. John D. Jones, State Coal Mine Inspector for Colorado, arrived Sunday afternoon and took charge on behalf of the state.

The rescue car with its four oxygen helmets and its four pulmoters were of great service. The Carbon Coal and Coke Co., Cokedale, also sent three oxygen helmets, and two others were brought by automobile from Dawson, N. Mex., 60 miles distant, sent by the Stag Cañon Fuel Co. of that place. F. C. Miller, chemist for the Colorado Fuel and Iron Co. continued throughout the rescue work to take samples of the air for analysis from the top of the air-shaft and through the brattices from the adjoining Engleville Mine. This was done to determine if a mine fire had broken out or not. Mr. Miller found as high as 1.64 per cent. of CO_2 and .5 per cent. of CO. As an item of interest, this mine is but a short distance from Sopris, Primero, and Tercio, all of which have been visited by disastrous explosions in recent years.

ELECTRIC AIR COMPRESSOR

Written for Mines and Minerals, by James A. Seager

In Great Britain the rival claims of electricity and compressed air have been for some time a matter of considerable interest and it is therefore interesting to note a recent equipment which has, in the case of the Newton pit of the Clifton & Kearsley Coal Co., yielded a satisfactory solution of the efficient application of electrical power to those appliances which are most economically worked by compressed air in collieries. In Fig. 1 is shown a large three-phase induction motor driving a Tilghman air compressor through the flexible coupling, the two machines being mounted on a combination base plate. The compressor is of the three-crank type and is driven by a motor of 350 horsepower running from a 2,000-volt, three-phase, 50-period electric circuit. This set is capable of continuously compressing 2,000 cubic feet of air per minute to an outlet pressure of 75 pounds per square inch.

The special feature of the motor is the brush shifting and short-circuiting device, the brush gear being of the box type. This gear is actuated by the small handle on the end of the slip ring cover. On pressing the handle toward the machine the slip rings are short circuited by a plate with three switch

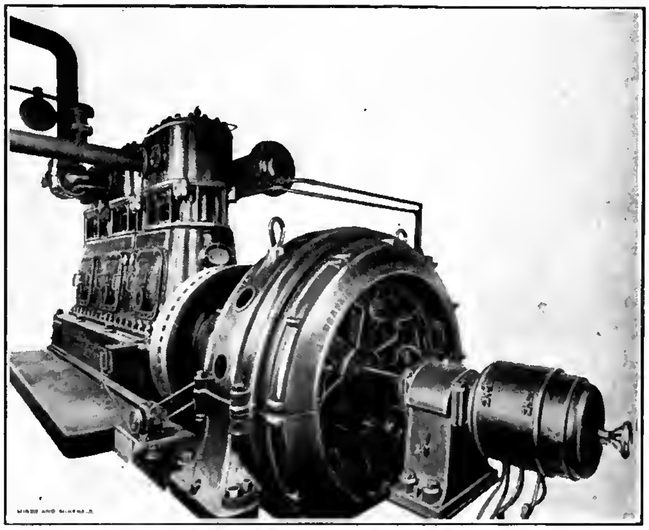


FIG. 1. ELECTRIC MOTOR DRIVING AIR COMPRESSOR

jaws making contact with knife blades connected to each slip ring. On further pressing the handle the brushes are moved on to stationary supports placed between the slip rings. This device does away with the comparatively heavy heat loss and the rotor leads to the starter, increases the efficiency of the machine, prevents wear of brushes, and keeps the slip rings cool, as they have no current to carry.

The starting panel has a three-pole oil-break switch with no volt and overload release trips fitted in two phases, and is in a sheet-iron case with hinged doors interlocked with the oil switch so that they can be opened only when this switch is off position. A liquid-type starter is used provided with a hand wheel and screw gear for slow starting, and controller fingers make contact with copper rods in the short-circuit position. The safety of the appliance, even if used by untechnical assistants, is increased by interlocking the cover of the starter so that it cannot be raised unless the blades are out of the liquid. As an example of recent British work in air-compression plant, this equipment is not without interest to American engineers.

The introduction of the Pneumelectric coal cutter and the Ingersoll-Rand electric-air rock drills into mines in the United States is a step forward which again shows the advisability of combining the two powers air and electricity wherever the use of one is unsatisfactory. Electricity alone has not proven satisfactory for rock drills.

CHEMISTRY OF COAL-DUST EXPLOSIONS

Written for Mines and Minerals

Resnlts of Studies of Dust Explosions at the Experiment Station at Liévin, France.

The chemical aspect of coal-dust explosions has been carefully studied at the Experimental Station at Liévin, France, and the discussion of the results obtained in this direction forms one of the most important parts of a report on the production of dust explosions recently issued by the Director of the Station. The experiments were conducted in the main test gallery, then 65 meters long (one meter being equivalent to .914 yard), and in order to collect the gaseous products of combustion a glass flask, exhausted of air, and connected by means of a sealed glass tube to the interior of the gallery, was caused to fill itself immediately the explosion reached that point. This was done by the flame firing a detonator attached to the tube which was shattered, thus allowing the gases to rush into the flask. To ascertain the composition of the gases entering in this way, the analyses had to be corrected for the amount of air previously existing in the flask owing to incomplete exhaustion. In the accompanying Table 1 the actual analyses are set forth in columns 3, 4, and 5, while the corrected figures are given in columns 6, 7, and 8. The figures in the first column refer to the number of the experiment, samples of the gases not being taken in every one of the tests, but only now and again.

TABLE 1

Number	Dust Charge in Grams Per Cubic Meter of Gallery	Analyses of the Gases Collected in the Flask			Corrected Composition of the Gaseous Products of Combustion			$\frac{CO}{CO_2+CO}$ (Volumetric Proportion)	Relation Between the Weight of Hydrogen Burnt and the Weight of Carbon Burnt

An examination of column 7 shows how little free oxygen remained after the passage of the flame; the combustion must therefore have been almost complete. In the test No. 43 the residual oxygen attained 8.4 per cent., but it is seen that this experiment was conducted with the lowest dust charge; namely, 112 grams per cubic meter, a gram being equivalent to .0353 ounce. Theoretically, this amount of dust is sufficient to absorb the whole of the free oxygen of the air; therefore, the analysis shows that, as 40 per cent. of the air remained unchanged, a portion only of the 112 grams of dust took part in the explosion.

In column 9 is expressed the relation between the volume of carbon monoxide and the total volume of the two oxides of carbon formed in the combustion—that is $\frac{CO}{CO_2+CO}$. Leaving the results of Nos. 150 and 151 out of account for the present, it is seen that this ratio, though very variable, is low, and that it appears rather larger for the heavier dust charges than for the lighter ones. The fact revealed here could hardly have been anticipated; it is that although an excess of dust may be present at a high temperature, the amount of carbon dioxide formed in the flame greatly predominates over the amount of carbon monoxide. It must, however, be noted that the gases were taken from immediately behind the breast of the flame, and before the red-hot carbon had a chance to react on the carbon dioxide and reduce it to the monoxide. That the latter reduction actually takes place, and that the reaction takes a short but appreciable time to complete, was demonstrated by tests Nos. 150 and 151, wherein the gaseous products were obtained from distances, respectively, 10 and 5 meters behind the breast of the flame. A glance at the analyses of the gases taken in these two tests will show that there was an excess of the monoxide over the dioxide of carbon at these distances behind the flame. It is therefore apparent that chemical activity continued behind the flame, resulting in the rapid increase in the percentage of carbon monoxide.

How very dangerous is the afterdamp of a dust explosion may be gathered from these last analyses. Not only had the oxygen almost entirely disappeared, but carbon monoxide was produced in such high proportions that if the products had been diluted with a large quantity of fresh air they would still have been dangerous to breathe even for a short time.

In the last column of Table 1 is stated the ratio by weight, w, of the hydrogen to the carbon consumed in the combustion. The figures in this column are noteworthy in that they indicate the importance of the part played in the ignition by the volatile constituents of the dust. Before the bearing of these relations can be discussed it is necessary to explain the manner in which they were calculated.

The quantity of carbon burnt is deducible straightway from the amounts of carbon dioxide and monoxide produced. The hydrogen, however, cannot be computed quite so easily, since it forms watery vapor in burning, which condenses, and hence does not make an appearance in the results of the analyses. The weight of hydrogen has therefore to be obtained indirectly by calculating the amount of oxygen which has disappeared as water. Now the analyses render account of all the oxygen, free and combined, except that forming water; while the nitrogen formerly existing mixed with oxygen, as the air of the gallery, is obtainable by difference. Thus, by using the well-known relation between the volumes of nitrogen and oxygen in normal air, we are able to compute the total original amount of the latter gas, and then, by difference, the amount which, after the combustion, exists in combination with hydrogen as water.

The following gives further particulars of the calculation:

Let 100 volumes of the gas in the flask contain a volumes of CO_2, b volumes of oxygen, c volumes of CO, and d volumes of hydrogen and hydrocarbons, the remainder being nitrogen. Among these various gases will be mixed r volumes of air, being the quantity initially present in the flask by reason of imperfect exhaustion. The latter quantity, r, is easily found from the initial pressure in the flask. Making the necessary correction for r, the total volume of oxygen entering the flask, both in the free and combined states, is:

$$O = a + b + \frac{c}{2} - .21r;$$

and in the same way the quantity of nitrogen entering is

$$N = 100 - (a + b + c + d) - .79r.$$

Of the nitrogen so calculated a small quantity, n, will have been derived from the coal dust; the remainder $(N-n)$ existed originally in the air of the gallery, and accompanying it there must have been $\frac{21}{79}(N-n)$ volumes of oxygen. If k volumes of oxygen were also derived from the coal dust, then, by difference,

$$\frac{21}{79}(N-n) + k - O$$

measures the amount of oxygen now in union with hydrogen in the form of water. Therefore, by volume,

$$\frac{\text{Watery vapor}}{CO_2+CO}=2\left(\frac{\frac{21}{79}(N-n)+k-O}{a+c}\right)$$

and by weight,

$$\frac{\text{Hydrogen consumed}}{\text{Carbon consumed}}=w=\frac{2}{12}.2\left(\frac{\frac{21}{79}(N-n)+k-O}{a+c}\right)$$

Substituting for N and O their values as obtained above, we may write:

$$w=\frac{8.75-.421(a+b)-.255c}{a+c}-\frac{d}{12(a+c)}+\frac{4k-n}{a+c}$$

This expression includes a principal term—the first one, and two corrections—the last two terms, of which the latter are of little importance. It has been found that d has a value never exceeding unity, and that the smallest value of $(a+c)$ is 12; therefore the term $\frac{d}{12(a+c)}$ is at the most equal to $\frac{1}{144}$; i. e., only 5 per cent. of the mean value of w. To evaluate the term $\frac{4k-n}{a+c}$, it is necessary to consider the weight of dust producing the quantities k and n. Let us suppose that 450 grams per cubic meter of air had been put into effective suspension. This amount will be equivalent to 45 grams per 100 liters of air, and will very nearly be equivalent to 45 grams per 100 liters of the gas in the flask. Now 45 grams of the dust used in these experiments contained 8.5 per cent. by weight of oxygen and nitrogen, that is to say, 3.8 grams of these gases; and these when liberated would occupy 3 liters. Since the residual particles after an explosion still contain a large part of the volatile constituents of the dust, only a portion of the 3 liters of gas will actually be set free. Inasmuch as those quantities of oxygen and nitrogen existing in the proportion in which those gases are found in normal air will be eliminated in the difference $(4k-n)$, the latter term can only represent a fraction of a liter. It is therefore apparent that the last term of the above expression is of even less importance than the middle one. Hence, in calculating the figures in column 10 of Table 1 these last two terms were neglected.

The general high value of w is striking and important. In the dust used for the experiments there were only 4 parts by weight of hydrogen to 75 of carbon. If the carbon had completely burned, w would have been about .05, while as a matter of fact, it always attained at least double that figure.

If the volatile matter were taken to consist entirely of hydrogen—certainly an incorrect assumption—the above results would show that the weight of the volatiles taking part in the combustion would be derived from at least twice the weight of the dust wholly burned; the proportion will, as a fact, exceed this, for besides hydrogen, the volatiles contain carbon in the form of hydrocarbons, and that element goes to swell the denominator of the ratio w.

The mean value of w appears to be increased when heavier dust charges were used, and this might be explained from the fact that the more numerous the particles of dust in a cloud, the greater the total surface from which volatiles may be distilled.

Now it has already been stated that the gases entering the flask in all the other experiments contained only an insignificant amount of unburnt volatiles; however, on estimating as marsh gas the unburnt volatiles obtained in tests Nos. 150 and 151, they were found to be present in the proportions of 3.8 per cent. and 5.2 per cent. by volume, respectively. It therefore follows that for these tests the last two terms of the formula for w derived above are no longer negligible, and must be taken into account. After the necessary corrections had been applied, it was found that the values of w for the two experiments in question were, respectively, .301 and .352. Although these figures are less than those given in column 10, they are nevertheless considerably larger than their equivalents in the other tests where the gases were taken from close behind the flame. The presence of unconsumed volatile matter, and the high value of w obtaining when the gases were taken some distance behind the front of the flame, show that the distillation of the dust continued in that region after the flame had passed. Since there is no more, or nearly no more, free oxygen available to unite with the volatiles so produced, there must remain a surplus of the latter. The increment in w shows, however, that some of the hydrogen of the volatiles liberated after the passage of the flame had united with oxygen, while the proportion of carbon monoxide has also increased; it is therefore probable that, in the region behind the flame, reactions such as the following take place:

$$H_2+CO_2=H_2O+CO.$$

Other observations were made on the phenomena of combustion. The first of these was in reference to the amount of smoke produced by a dust explosion. By raising a shutter, a connection was made after every experiment between the gallery and a fan drift, and the smoke then blown out of the open end of the gallery by the fan, when its color and other characteristics could be noted. When the dust charge was at least 450 grams per cubic meter of air, the smoke was always thick and black. With lesser charges it was a clear grey, and sometimes almost white.

Dense black smoke consists of an excess of fine dust particles, together with watery vapor which has cooled and condensed, and soot resulting from the combustion of hydrocarbons in an atmosphere almost depleted of oxygen. Grey or white smoke indicates a combustion of the dust which is complete or nearly so, only ash remaining, together with watery vapor in process of condensation. In the last case there existed a sufficiency of oxygen to burn the hydrocarbons without the formation of soot.

In a number of experiments the solid residues remaining in the gallery were systematically collected. They were obtained from the floor and from a dozen transverse shelves each 20 centimeters wide, placed every 2 meters between points in the gallery, respectively, 18 and 40 meters from the origin of the explosion, it being in this portion of the gallery that the bulk of the solid products were deposited. As a rule, little of the residues was found near the source of the explosion and often none at all in the last few meters of the gallery. This latter fact might be explained through the reentry of air occurring immediately after an explosion, which would sweep back into the interior any solid matter lying near the mouth of the gallery.

Table 2 gives the weight and composition of the solid residues collected, the weights being stated per cubic meter of the zone from which the products were taken. From what has just been said, it will be apparent that had the products been collected from the full length, and compared with the full volume of the gallery, the results would have been lower than those given below. On the other hand, they would have been higher

TABLE 2

from the gallery by the force of the explosion and not drawn in again by the back suction of air.

As would be expected, the weight of residual solid matter increases with the dust charged into the gallery; it is almost proportional to the excess of the charge over about 100 grams per cubic meter, which corresponds to the complete combustion of the carbon of the coal dust by the oxygen of the air.

The analyses show that the products were poorer in volatiles and richer in ash than the original dust from which they were derived. A reference to the last column of the table also shows that, even after the ash constituent has been eliminated from the products and the original dust, the former is still the poorer in volatiles, thus proving that the reduction in volatiles revealed by the analyses does not result merely from the increase in ash, but that there must have been a partial distillation of hydrogen and hydrocarbons from that part of the dust which was not completely burned. This result is in concordance with the conclusions which have already been drawn from the gas analyses. The solid products were appreciably more humid than the original dust, owing to the condensation of some of the large quantity of watery vapor produced in the explosion. Water was also found condensed on cold portions of the walls of the gallery.

A further examination of Table 2 shows that there was generally a more pronounced reduction in the percentage of volatile matter when the dust charge was small. In other words, although the amount of volatile matter per cubic meter is greater with the heavier charges, it does not increase proportionately with the charge, but at a lesser rate. This can be explained partly from the laws of variation of temperature during combustion, and partly from the fact that, with the heavier charges, the dust is not perfectly lifted; thus there must be a portion of the dust in contact with the floor, which, although included as "solid residue," has not been thoroughly subjected to the effects of a high temperature. Hence, in reality, Table 2 registers the analyses of a mixture of the actual solid products of combustion of the dust lifted, with dust lying immediately against the floor, the composition of which would hardly be altered.

Examination showed that the solid residues usually consisted of three parts; namely, dust whose physical aspect remained unchanged, coke either in a finely divided condition or as grains and soot. These three elements, which were difficult to separate properly, were distributed in unequal proportions along the length of the gallery. Circumstances in that part of the gallery not allowing of the agglomeration of large pieces, the coke forming in grains the size of a pea or of a pin's head, within a few meters of the origin of the explosion, was carried by the rush of air either toward the middle of the gallery or sometimes—especially for the heavier dust charges—nearer the open end. The soot, very fine and greasy to the touch, was deposited on top of the coal dust and coke. It required some time to settle, and was not seen at all when the fan was started straightway after an explosion.

In certain parts of the gallery a firm thin skin of coked matter was occasionally noticed on the surface of the unconsumed dust, but the conditions under which the skin was produced were not clearly determined.

Table 3 gives the analyses of the various solid products of combustion, separated fairly well one from another:

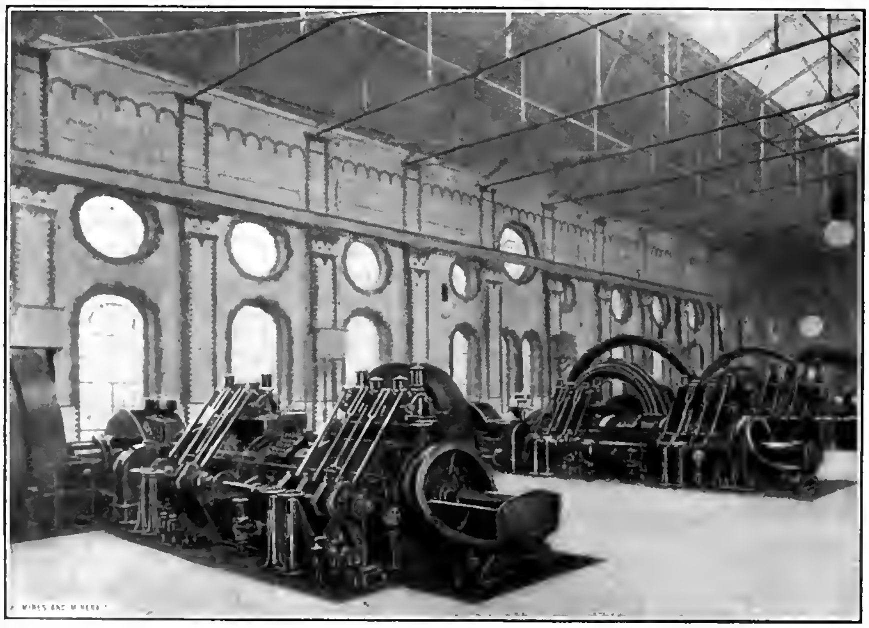

Fig. 1. German Gas Engines Using Coke-Oven Gas

COKE-OVEN GAS

The interior of the power house at Alsdorf, Germany, of the Eschweiler Bergwerksverein is shown in Fig. 1. This gas-engine power station, near Aix-La-Chapelle, is said to be the largest plant of gas engines driven by coke-oven gas in the world and consists of nine tandem double-acting units of the Nurnberg type having a total capacity of 14,600 brake horsepower.

All of these gas engines drive three-phase alternators which operate day and night in parallel, the electric current being transmitted throughout the mines for driving all the machinery, A part of the power is transformed to a pressure of 35,000 volts, the current being conducted to a considerable distance for operating various mining machinery.

Gas from bituminous coal carries from 1 to 5 per cent. of tar and other products that would gum and choke the valves of gas engines if admitted directly to the cylinders. It is customary therefore to extract the tar oils, and ammonia sulphate by previously passing the gas through suitable apparatus before it is admitted to the gas-engine cylinders. The operation decreases the heat units in the gas by lessening the hydrocarbons, nevertheless there are sufficient remaining. In some places it is customary to make producer gas from coke breeze for gas engines. This material which contains a mere trace of solid hydrocarbon and usually none at all, produces an inferior quality of gas so far as heat units are concerned, but still there are sufficient for gas-engine power.

HANDLING MINE SUPPLIES

By H. H. Fitch *

It is our understanding of the object of our institute, that it is intended, among other things, to encourage education in practical and scientific mining, and to promote study and research into mining problems of every nature.

Advantages of and Methods for Systematic Handling. Disbursement and Accounting

The great mass of subjects selected by, or assigned to, your speakers, bear on the all-important question of the actual mining of the coal, and its treatment and handling after it has left the hands of the miner.

To get just the proper procedure injected into our mining practice, it is extremely easy to lose sight of sundry matters of material importance, because they wear the commonplace aspect of ordinary business transactions, and are not garbed in the attractive phraseology of a scientific problem.

It is for this reason we decided to give you the benefit of some experience along lines quite apt to be neglected by the rank and file of coal-mining men.

The tendency of the present day is toward greater system in all lines of business procedure, and no business can long continue in successful operation without it. Where can we find a better field for system, than in the vital one bearing on supplies and machinery repairs, for use at operations equipped with costly electric plants, air plants, and steam plants, and in fact a machine of some description for nearly every operation formerly performed by man or mule, when we consider that any one of these machines is liable to require at a moment's notice repairs ranging from a set screw up to some part weighing a ton or two, which, while not particularly high in intrinsic value, is capable of tieing up your whole operation if not at hand when needed, and so kept as to be available without delay?

We believe that the well-equipped and properly managed supply department is essential to the coal plant in order to minister to the demands of the sick and disabled machinery that is being pushed to the limit of its endurance to keep the output up, and if not properly fed on repair rations, drawn from the bounty of the supply house, will soon lie down to die by the wayside of commercial hustle, utterly unable longer to perform the duties laid upon it.

At first glance, the uninitiated are apt to pass over the supply account as one of minor importance, to be handled by any old dub of a clerk who possesses sufficient ability to write legibly and add a row of figures.

To those possessing that idea, let us quote from our supply department, which looks after the needs of five medium-sized plants.

Our annual inventory shows that we carry a stock containing approximately 20,000 items of material. The value of this stock averages about $25,000, and from it we make an annual disbursement of $100,000 worth of supplies, of all kinds. This means that the stock is moving all the time, and if you will stop to think of the details involved in properly storing, disbursing, and accounting for a stock of this size, and the care needed to keep it up to such a standard of efficiency as to enable it to be of actual service to your operation, you will realize that it is a man's job, and deserving of serious consideration.

The account is not an abnormal one, but merely such a one as must be carried by any operation embracing two or more plants, if the management makes any pretense of keeping its equipment up to successful working efficiency. As a rule, most developments are away from the centers of supply, and in cases it takes days and even weeks to procure repairs or supplies of the simplest nature. This puts us at the mercy of Mr. Breakdown, whenever he visits us, or of some local merchant who is enterprising enough to keep what we want and let us pay him 50 per cent. on his investment, when we buy his material. The only successful method of getting away from these alternatives is to maintain a supply depot of your own, managed by a man big enough for the job, and with enough experience in mining work to give him an intelligent conception of what is needed, and sufficient interest in the work in hand to take pride in keeping his department up to the mark set by the needs of his operations.

For the sake of comparison, glance for a moment at the fellow who does not consider it necessary to use any system in caring for his repair supplies. In his scramble to get his production up, he has brushed this question aside as one not worthy of attention.

On the day we make his acquaintance, Mr. No-System, the man in charge of our plant, is a little bit ruffled, for just when everything was going along finely, one of his haulage locomotive armatures comes to grief.

At first glance this does not appear very serious, for we have a set of coils somewhere (?) about the place, and we have the man who can wind the armature.

We will set him to work at once and with any kind of luck we will be ready to haul coal again tomorrow. We simply must have that motor, says our friend, for if we do not, it will mean a loss of a hundred cars in our production, and since we are already short of coal we cannot charge our ovens.

In the meantime the search for the needed coils goes hurriedly on, but of no avail. They cannot be located high nor low. It finally dawns on our electrician that he must have used that set of coils on the last armature, and somebody, we can't tell who, has forgotten to send us a new set.

We are then treated to an example of desperate hustle on the part of our friends who do not believe in system, in their effort to locate a set of armature coils to fit that motor. The long-distance telephone is brought into use in a vain endeavor to borrow a set from some one within a radius of 100 miles or so, but no one is found who has a set that can be spared. As a course of last resort the manufacturer is called upon, and since they are 2 or 3 days away from our plant by the fastest express service, the only thing left for us to do is to wait.

The result of this is plenty of trouble and annoyance back at the plant. The locomotive is snugly lying in the shop, keeping perfectly cool, and taking a welcome rest. The men down on the heading are howling for cars that they cannot get. The coke foreman is yelling for coal to keep from blowing out his ovens. The sales department is loudly calling for the coke that cannot be made. In fact, if we were inclined to be poetical, we could make you a nice little parody on the old nursery rhyme, which tells about the horse shoe nail that first caused the loss of a shoe, then a horse, a man, a battle, and finally a kingdom; but in this case we would end up by telling about the contract that was lost all on account of an armature coil.

If persisted in, how many occurrences of this kind would it take to put you down and out.

But, says our friend, No-system, this is not going to happen again. We are going to correct this condition at once. A few dollars worth of copper wire is not going to shut me down another time. We will order enough stuff to run this plant in safety in the future. Forthwith, the orders begin to go in from that mine, and they do not stop until everything has been bought that can be anticipated as liable to be needed for months and weeks to come.

Not satisfied with getting plenty of stuff for himself, he proceeds to be neighborly, and citing his own case as an example of the danger of not being prepared, he has the fellows at the company's other mines joining the scramble to get ready for trouble. This causes them to duplicate most of the material bought for the other plant. With an operation embracing three of four plants, everything being charged direct to cost of

* Read before the Coal Mining Institute of America, June, 1910.

production, what is going to happen to the cost when the bills are paid.

Of course this heavy demand for material is noticed at the general office, but is passed on the assurance of the mine heads that the stuff is needed.

The operator is usually a pretty keen sort of fellow, and when he embarked in the coal-mining business he did so with his eyes open, and after careful estimates of the cost of operation. He knows what he expects to realize from his investment, after all reasonable allowance has been made for waste, bad management, etc.

When the bills for this lot of material reach him, he is shocked to see his prospective profits dissipated, and when the yearly statement shows a deficit against the operating department, he asks pointed but rather unpleasant questions.

While pondering over the matter let us return to our plants and see where his profits really go. Our mine people are still unconvinced of the fact that loose material absolutely refuses to stay around a coal plant, so when the newly purchased lot arrives, it is hauled up to the mine and turned over to the care of Mr. Any Old Chap. He scatters it around nicely, so it will be handy when needed. This proves to be an excellent method of getting rid of it quickly, for we see all of the boys dropping around and helping themselves to whatever they need, and whenever they need it. The result is that it is only a short time until we are in our same old state of unpreparedness, and Mr. Break Down catches us in short order and repeats his former treatment without the least compunction.

In the meantime our friend the operator has been assured that the trouble would not be allowed to occur again, and he puts the first experience away in his memory for future reference. When the second fall dawn comes to his notice, he is about convinced that his methods need fixing about as badly as his machinery.

A general conference takes place, and results in much talk, and schemes for curing our ills are many. All of the talk and all of the schemes, however, finally narrow down to the one which they think is the best. It is this:

Instead of letting our material lie around loose, we will establish local supply depots at each mine. We will charge all invoices received to a general material account, instead of direct to the operation. The mine clerk never has much (?) to do except to keep the time, issue checks, make his pay roll, rent the houses and sundry other little duties, so we will in addition make him supply clerk, just to give him something to do to kill time.

All material will be issued only on written order from the mine head, and charged out to the cost of coal as it is used. This will insure a uniform monthly cost of production, and we will not lose sight of any material.

Looks like a plausible scheme, does it not? Let us follow it out in practice and see how it works.

We must remember that our man who is to carry the order book, is none other than Mr. No-System, who got us into trouble before. He looks on anything of this nature as mere red tape. True he looks at the matter according to his best light, but very likely he has no conception of anything pertaining to accounting. He knows he uses the stuff at the company's mine for the purpose of getting out the company's production. Why any one should care to know just where it was used or for what particular item in the production is not at all clear to him. However, for the first week he manages to fill out orders for what he needs from the supply room.

The second week it is different; he leaves that pesky order book home and when he finds his machinist waiting for him to get an order for some stuff needed in a hurry, he cannot wait to send for that book, so he telephones the clerk to let the stuff go out and promises to fill out an order in the evening

That breaks the ice, and from that time on it is as easy to get material out of that supply room as it was when it was lying around loose. The clerk cannot be censured, for he is simply carrying out instructions from his superior officer, and any other course would be classed as insubordination.

The orders, which are all the clerk gets from which to make up his list of material used, are neglected more and more as time goes on. After a time the machinist, the electrician, and the pump man have, when the clerk was busy, been allowed to go in and help themselves, and we find all kinds of material disappearing from the supply room without record being made of it, and as far as any one in authority knows, it is still on hand.

This method of doing business results in a nice monthly cost while it is going on, but wait. Down in the auditor's office, all of the invoices have been religiously charged up to material account, as agreed in the beginning. After a time the inventory day rolls around. On that day we must square accounts for the year and start new. The auditor comes along with his assistants, and they proceed to give our supply rooms a careful check. They list and price everything they find, and cannot be persuaded to list a single article which we are unable to show them. They go back to headquarters and make a comparison with what we have and what their books say we ought to have. The chances are that every supply room will show a shortage of from $1,000 to $2,000 worth of material.

What are we going to do with this shortage? It must be taken care of, or else our yearly statement will look like a joke. There is only one fellow who is ever able to take care of a thing of this nature. He is our old friend Mr. Coal Cost, and it has a bad effect on him. We see this particular cost bulging far beyond what we had falsely been led to believe would be his size, from the estimate, based on the monthly cost, and our reform in handling supplies has placed us in a worse position than ever with our management.

Having thus briefly glanced at what actually happens to the man who does not believe in system, and to the fellow who tried to remedy his troubles and "got in wrong," let us search for a plan that will cure the troubles our experience has taught us are to be overcome.

Some of the points in our first trial are all right and we will use them where they will fit.

We must first do away with our numerous scattered local houses. To do this we select a location for a central supply house, at some point easiest of access from our principal present development, or our most important future one.

We must plan our building in such a manner as to permit easy handling, and systematic storing of the goods to be taken care of, for we are going to do a pretty extensive business, of a much varied character, in our new home.

The house itself must be fireproof and of sufficient size to take care of our growth for a number of years to come. It should be located on the railroad main line, as near as possible to the depot, to avoid hauling when shipping to other mines.

We must have a raised platform of ample room, where the local freight may load and unload supplies, and where heavy articles, such as locomotive ends, trucks, armatures, etc., may be handled in and out of the cars without the use of a crane.

If room permits, a short siding should be provided at the house where carloads may be placed for unloading.

Our unloading platforms must be covered with a shed roof to protect any perishable matter being handled in wet weather.

The working floor of our house must be on a level with the raised platform, so that material may be trucked to and from the trains without the use of an elevator or an incline.

The inside of our building must have the walls solidly built, with bins or compartments for storing goods, and must have a balcony extending completely around the room, about midway from the floor to the top, so that the material stored in the upper bins may be used without using ladders.

The bins must all be provided with label holders, in which can be placed cards, naming the article in each bin. This is necessary, for we are going to have some queer looking stuff to

take care of, and we must have it in such shape as to be found by the uninitiated when occasion demands.

The center of the room will be used for the storing of extra motors, pulleys, armatures, and such other material of a bulky nature as cannot be placed in the bins.

In one end of the room we need a rack for the storing of the different sizes of pipe and iron which we need to carry.

With our building in readiness, we need to select a man for the position of supply agent, whose duty it shall be to give his exclusive attention to the care of the supply business, for our operation.

We must have a man of sufficient business ability and experience to manage the details of a business of these proportions. He must be a man able to keep his book records in such a manner as to enable him to tell at all times just how his account is running.

And above all he must have sufficient acquaintance with mining machinery in general to give him a working knowledge of the different component parts of the various machines in use.

After we get the proper man, he is sent out to the local houses, and at each of them a careful inventory is made of what is on hand, and it is shipped to the central house.

When it is all assembled at that point it is carefully sorted and classified and placed in the bins. In this operation it is important to begin the observance of system in its strictest sense. A section of the bins must be allotted to the storing of pipe fittings, another to trolley-line material, still another to electric-light supplies, and others to the parts of each separate machine in use, etc.

The total of the inventory from the local houses is used as a basis from which to start the new stock account and retire the former material account from the auditor's records. Whatever shortage appears in the old account is charged to the operation and cleaned up.

The items of the inventory are then entered in a permanent stock record. This form carries three general divisions, the first showing a complete record of all goods received, with its final cost at the supply house divided into a unit price at which the material will be sold to the mines, the second showing a record of disbursement, and the third a periodical balance of the account. On account of the continual expansion of the stock on hand by the addition of new items to be carried, this record, as well as all others used in our supply work, is bound in loose-leaf form.

The matter of a proper system of indexing this record is a serious study, for the reason that it embraces so large a number of varied items, many of which bear several names, or could be described under so many different letters of the alphabet.

We take as the basis of our index the regular alphabet divisions, and then subdivide our letters as needed to get our material properly classified.

For instance, take the items of bolts. We place their record under the letter B, then classify them as carriage, machine, track, and miscellaneous, giving each class a separate place in the record. Then each class is again divided according to their size, ½-inch bolts of various lengths, in one group, ¾ inch in another, and so on down the list.

In a similar manner motors of the various types would be grouped under the letter M, subdivided according to the class of motor, all motors of the same type in which the parts are interchangeable being placed in one group, and all repair parts for that type motor are listed under this division, regardless of their alphabetical name.

Locomotives would be found under the letter L, with their parts subdivided in accordance with the manufacturer's catalog heading, such as resistance parts, brush-holder parts, controller parts, etc.

This method enables you to turn without unnecessary leafing, to the item wanted, no matter under what name it is called for.

The rule as it now stands is that all requisitions must bear the approval of the general superintendent, or other officer in charge, before they are good for credit at the supply department. With this method the man in authority, who must account to the management for the cost of production, has a chance to be in touch with every item to be used in making the production. If any item on the order appears unnecessary, or unreasonable, he is in a position to veto it or request additional information as to its necessity before passing it, and the supply agent being no longer under the control of the local heads, is in a better position to refuse to issue material except on the proper order.

In order that your plants may not be tied up for want of repair parts in the case of a break down, the supply agent is made the judge as to the immediate need of any material requested, and authorized to issue it in cases of extremity on a telephone or verbal request after satisfying himself that the proper requisition has been made and sent to headquarters. A record is kept of these emergency requests, and same are reported at the end of each month, and the mine foreman who appears to be abusing the privilege is called upon for an explanation, and unless a satisfactory one is given he is liable to have an unpleasant interview with the man who makes the orders down at headquarters.

In order that the prepaid freight from the supply house to the mines may be kept as low as possible, each mine endeavors to cover each week's requirements on one order. This, however, is optional with the mine heads, as they may make a requisition at any time when they find it necessary. On receipt of the order at the supply house, it is immediately filled from stock, if the items are carried, and if not the goods are ordered shipped direct to the mine from the manufacturer on requisition by the supply agent.

After filing the requisition, the items are billed against the mine receiving them, the same as if purchased from a regular mercantile concern.

The form of invoice is an adoption of the usual form of invoice, amended to suit our needs by the use of special ruling.

Each invoice is entered in the middle division of the stock record, as it is made, showing deductions from stock on hand.

A charge of 5 per cent. of the value of all goods passing through the supply house is made, and this is distributed throughout the items on the invoice, making a proportional distribution of the cost of maintaining the supply department, based on the amount of stuff used at each mine. Only sufficient commissions are charged in any one month to cover the actual running expenses of the department, and when that item has been cared for, the charging of future commissions is discontinued for the month.

At the end of each month the supply agent makes an itemized report showing all material disbursed to each mine. The totals of this report are distributed to the several headings of the monthly coal cost, and this distribution shows at a glance the actual amount of material used in each phase of the month's production, and is further run out to a cost per ton basis by the auditor.

By the use of the above system of reports and distributions, under the control of one man, a consistent basis of comparison is possible between the different operations, along certain lines of cost. Under the old plan, each mine clerk had a different idea as to where certain material should be charged, and a consistent comparison of material cost was not possible.

This covers in a brief manner all that is of interest pertaining to the disbursing of supplies passing through the house. A separate account is kept of all bulky material, such as steel rails, pit props, ties, sand, brick, etc., which is delivered direct to the mines in car-load lots. On receipt of a car load of material it is tallied by the mine people, and a receipt for it is forwarded to the supply agent. By him it is attached to the original invoice and becomes a part of its approval record.

At the end of each month, before closing his accounts for

the month, the supply agent makes a personal visit to each mine yard, and in company with the foreman makes a careful check of all yard stock remaining on hand unused. This is deducted from the amount showing against the mine on the supply record, and the difference between the two shows the amount to be billed against the cost for the current month, this being done in the same manner as if it had actually passed through the supply house.

The details of our system follow: In the first place, as the stock is depleted from time to time through the drains of the service, the supply agent replenishes it by means of requisitions made on the purchasing agent of the company.

Experience teaches the supply agent what lines of material are in greatest demand, and he regulates his orders accordingly. His aim should be to keep the amount of money tied up as small as consistent with ability to care for his dependent operations.

The order on the purchasing agent first goes to the general superintendent for approval, thus again giving the man responsible to the management an opportunity to keep in touch with the details of money expended for material.

No one but the supply agent having authority to make requisition on the purchasing agent, it is not a difficult matter for the general officer to keep run of the material being purchased, while under the old scheme, with requisitions coming from every point on his operation for the same lines of stuff, it was practically impossible to keep any consistent line on it.

In due course, the goods having been purchased, the invoice for them is received, in duplicate, by the purchasing department, where it is checked as to price and extensions, and passed to the auditor.

The auditor lists the invoices and sends the original for approval to the mine, if the material has been shipped direct, or to the supply department if the goods are for stock. The original copy of the auditor's list goes to the supply agent, showing to what point each invoice has been sent. The mine foreman approves the invoice when it is to cover goods received direct from the shipper, and passes it along to the supply agent for record, and to be included in the total of the material used for the month, all invoices passing through his hands before going to the general office for final approval and payment.

All invoices received at the supply department are entered in a permanent invoice record.

On their entry in this record they are given a record number, by which means they are easily identified in future handling.

After being checked against the material which they cover, they are carried to the permanent stock record, and the price of the goods, plus the transportation charges, and any other item entering into their cost, in the supply house bins, is carried to a total, and reduced to a unit price, at which price they are sold to the mine.

After passing through the supply department records, the invoices are approved by the supply agent, and sent to the general office.

At the time they leave the supply office they are listed and a copy of this list sent to the auditor.

These lists show a total at the end of the month of what items have been purchased on account of stock, and the auditor balances the total amount he is charging to stock for the month against the total of the lists received from the supply agent, and as these lists show what the supply agent says he is charging to stock, it will readily be seen that the two accounts are bound to agree on the debit side of the ledger.

When the supply agent bills out his material after filling his requisitions, he makes an entry of the total of each of his invoices for each mine in a record provided for that purpose.

This record is ruled to fit the form of invoice, and its total is the amount that is to be credited to the stock account and charged against each mine. At the end of the month the auditor lists all of the approved supply department invoices he has received, showing the amount he is to credit to the stock account for the month. This is entered under auditor's credit on the supply record and shows to a penny how the two departments agree on the credits the stock account is to receive.

As a further means of agreeing on the standing of the stock account, the supply agent makes a monthly summary of all amounts to and from the account, and shows the balance to be carried to the next month's account. Any discrepancy in the amounts one way or the other is taken up immediately and such adjustment made as is necessary to line up the account and thence we see that it only requires careful watching on the part of the supply man to keep his goods on hand up to the amount called for by his records, to be at all times in check with the auditor.

The way we have adopted in our house of keeping the stock up to the records, is to watch the matter and when we find a line of material getting low we make a check of what is left and compare it with our records and balance it up.

By this means we are able to catch up any little shortage that may occur and retire it before it is able to join a lot of other little shortages and make a big one.

We find that our account will invariably run ahead, for the reason that in figuring unit prices they seldom divide out to the exact penny, and we take the next higher full cent for our unit. In an account the size of ours, this item amounts to considerable in the course of a year.

We have thus shown in a general way what a simple matter it is to avoid shortage in our supply account when we are willing to organize for it, and go after it in a businesslike manner.

The benefits of the organized supply department do not stop, however, at the mere improvement in handling, disbursing, and accounting.

They are of a much wider scope. For instance, when we organized our department we found our boys pretty badly spolied by the habits they had acquired under Mr. No-System. Supplies had been allowed to lie around indiscriminately, and they were easy to get. Being easy to get they were not appreciated. It was easier to put in a new valve than to bother sending away for a new stem for the old one, and so with all other classes of repairs. Economy in their use did not enter into the practice in vogue.

As a lesson to the boys, we made it a practice to watch for such little worn material, which had been discarded, and it was gathered up from time to time and sent to the supply house. There we went over it carefully, and renewed all worn parts, and placed it in practically new condition, at a very small percentage of its original cost. It was then sent back to service at the price of a new article, and the resultant profit allowed to accumulate to the credit of the stock account.

The first 18 months gave us a profit from this source amounting to \$1,658.32. At the end of that period it was credited to coal cost for the year, and that gentleman thus got back some of the losses he had suffered under the old plan.

Another important opportunity for saving offered the supply agent, is the plan adopting standards for every line as far as conditions will allow.

After having decided on a standard article, it becomes possible at the central house to lump the total requirements along that line, and on the basis thus arrived at to secure contracts direct with a manufacturer of the goods wanted, at prices much more favorable than those paid to jobbers or middle men.

To show the saving possible along this line, allow us to quote briefly a few items from our own account.

First we will glance at the item of brake shoes. When we were buying our shoes, a set at a time, from each of the concerns who built the machines, it cost us on an average, counting transportation, etc., \$1.30 per shoe, or \$5.20 per set of four, for our locomotive shoes. Our car shoes and larry shoes were correspondingly expensive.

A standard locomotive shoe, and a standard for cars and

larries was adpoted, our yearly requirements estimated, and bids asked for a contract to cover them.

In due time one was placed with a prominent brake-shoe foundry at a price which brought our locomotive shoes down to 60 cents each and all others on the same proportion, resulting in a saving on our first year's requirements of $256.

Take again the item of brass and other composition bushings for bearings, etc., used in such abundance about a coal plant, where the conditions are so adverse to long life in linings.

Nearly every machine on the place has from two to a dozen which need frequent renewals. The machines themselves are made in widely scattered localities, and if your buy your linings from the concerns who manufacture the machines you not only have to shop all over the country for what you need, and pay correspondingly heavy freight bills, but you also pay the machine builder a midleman's commission on what he sells you, for very few of them maintain their own factory for making this kind of material, but buy by contract from some foundry or machinist.

A contract placed direct with a brass foundry, covering our total requirements, netted us a saving of 30 per cent. on previous prices. This meant to us a saving of from $400 to $500 yearly.

We have a couple of machines using considerable detachable link chain for driving its conveyers. The chain put out by the builders of the machine was of the ordinary soft metal used in such chains, easily broken, and quickly worn out under the adverse condition in which it was working. After a careful study of these conditions, they were laid before a manufacturer of the type of chain needed and suggestions requested as to the adoption of a type of chain for this work which would lead to greater economy. They sent us a sample chain for which they charged us 28 cents per foot. At this price, a complete chain for the drive costs us $11.20. The new chain lasted over 1 year with 64 cents worth of repairs, making a total cost for the drive for the year $11.84.

The old chain cost us 30 cents per foot, and we used up 20 feet per week. This means that we spent $312 a year for 1,040 feet of the old conveyer chain to keep our drive going. Add to this the time lost by the machine runners in renewing the chain as it broke, which caused the day-workers to run into overtime, and you will get an idea of what our reform in this line meant to us.

We want to convince you without tiring you, and we will refrain from any mention of something like 20 or 30 other lines on which we were able to show similar savings after installing the use of system in our supply account.

By no means the least of the arguments in its favor is the relief from the necessity of carrying so many duplicate parts of the same kind at each mine, which, while not so important in some items, it amounted to considerable in others.

To illustrate, let us compare a few of the leading items we found that we were carrying unnecessarily when we abandoned our local house.

Description	Found on Hand	Necessary to Carry	Price	Excess Investment
Locomotive end frames.......	6	2	$ 51.82	$ 207.28
Locomotive field coils.........	5 set	1	196.20	784.80
Locomotive armature coils....	3 set	1	25.00	100.00
Locomotive main drive gears..	9 ten ton	2	35.52	248.64
Locomotive main drive gears..	5 five ton	1	23.55	94.20
Locomotive controller cylinder	6	1	29.84	89.52
Locomotive armature housings	4	1	25.66	128 30
Locomotive finger boards.....	11	1	4.59	45.90
Mining machine cables........	5	1	45.27	181.08
Mining machine cutter chains..	2	12	13.50	136.50
Total overinvestment.........				$2,016.22
Interest on overinvestment for 1 year at 6 per cent.........				$ 120.97

If we can find an overinvestment of this size in ten items of our stock account, do you not believe we could show you a pretty nice saving if we took your time long enough to go over the entire list?

Some one may object that the cost of maintaining an establishment such as described would be prohibitive to any but large operations.

Allow us a moment to take care of that objection. In our own department, which has now been in existence for $2\frac{1}{2}$ years, we have taken care of the needs of five plants. All of the bookkeeping work, the report work, the handling of the stock in and out of the house, and keeping it in a neat and orderly arrangement while in the house, and in fact every detail that pertains to a business of the size described has been handled by one man, and in addition to doing the work described, he has found time to do much special work, entirely foreign to the supply work, as occasion demanded. At least two additional plants could be taken care of without adding more help. For the years 1908, 1909, and 4 months of 1910, we found it necessary to charge commissions amounting to $4,074.58, this charge covering the entire expense of our supply organization during that time.

During the same period it cost us in prepaid transportation to haul the goods from the supply house to the mines $599.

These two items are the only additional ones entering into the cost of central house as compared to the local ones.

Let us see if we cannot offset them by using only the few examples we have cited in our article, without touching at all on the great body of the account.

When we checked up and closed out our local houses we found an average shortage of $800 for each of the four houses in use at that time. That made a total shortage of $3,200, which covered goods paid for in cash and unaccounted for.

As far as practical business methods are concerned this item constitutes a loss, and if you cut off a shortage you save a loss, therefore we claim credit against the cost of our central department for the amount of the shortage in the previous year, which we cut off entirely.

In addition to stopping the shortage, the account showed a gain of $1,658.32, made possible by having a man to look after material and see that it was not thrown away while yet fit for service. In other words, we saved from the scrap heap the amount mentioned.

Lining the items up in a statement form for the 28 months above mentioned, we find it looks something like this:

Shortage abolished ...	$3,200.00	Cost of supply Dept..	$4,074.58
Gain by salvage......	1,658.32	Cost of prepaid transportation..........	599.00
Saving on brake shoes .	600.00		
Saving on brake brass .	934.00		
Saving on conv. chain..	728.00		
	$7,120.32		$4,673.58

This shows a balance in favor of the central house of $2,446.74, on the few items mentioned. To this could be added the interest saved on duplicate investment under the old style, the amount lost through shut downs caused by lack of material needed when we do not have it where it can be located promptly, and many other items, if we cared to take the time to go into further detail.

The results obtained in our own case are available to any operation of like extent and character, or to any combination of independent operators who care to combine and run a joint supply department and reap the benefits to be derived therefrom.

We believe our system to have been boiled down to the smallest possible amount of so-called red tape consistent with proper record of the transactions involved, still making our records plain to any one who has an interest in examining them.

Briefly summed up then our method has the following advantages, viz.: from the operator's standpoint, it involves less capital invested in supplies than under any other system, and insures a saving in their purchase, and that they will be properly cared for and accounted for after being purchased.

From the standpoint of the general operating official, it keeps him at all times in touch with the expenditures of the company's money for material, and gives him consistent control of what is placed in use at the mines. For his additional information along that line we report to him every 10 days the total amount of material charged against the production at each mine, and from being in touch with the daily production he can readily figure how liberal he can be in approving requisitions and still keep his cost within bounds.

From the auditor's point of view it does away with the annoyances which accompany the loss of invoices, delayed reports, improper charge out, and a dozen other details that apply to his work when he is trying to keep straight on a big account when it is handled by several men in as many different ways before it reaches him.

The mine foreman likes it because he has found it a pretty nice thing to let some other fellow do the worrying about getting his repairs to him when he breaks down. All he has to do now is to go to the telephone and make known his needs for the occasion, and it is up to the supply agent to do the rest.

What further argument do you need to convince you that it is possible to save money and trouble by adopting a rigid system of handling your supplies, if you do not already have it, and after its adoption following it up with a strict enforcement of the lines laid down.

NO PROGRESS IN ALASKAN COAL MINING

The condition in the coal fields in 1909 presented a contrast to that in the gold-placer districts. Not only was there no industrial advance but in some regions there was decided retrogression. The long delay in the issuance of patents to coal lands and the popular clamor against all Alaskan coal claimants has discouraged claimants and investors and it should be hoped that it may soon be possible to devise some reasonable or satisfactory means of exploiting Alaska's wealth of coal, which is so much needed for development of Alaska mines.

THE TAYLOR CONCRETE BREAKER

Written for Mines and Minerals, by E. B. W.

Coal-mine operators have watched with interest the construction and progress of the new Taylor coal breaker of the Delaware, Lackawanna & Western Railroad. This is the first all reinforced-concrete breaker constructed in the anthracite fields, although the Pine Hill breaker, at Minersville, Pa., was built in 1906, of reinforced concrete from the foundations to the main breaker floor, including the coal pockets, slate pockets, and shaker and jig supports.

The First All Reinforced Concrete Breaker in the Anthracite Region

Under favorable conditions the average wooden anthracite breaker has a life of about 20 years, but mostly conditions are unfavórable to such longevity, and this, coupled with the rapidly advancing price of timber suitable for such structures, has caused engineers to consider the more durable iron and reinforced concrete as building materials. Wherever anthracite is prepared wet the timbers are alternately dry and wet, conditions which are unfavorable for keeping timber sound indefinitely as in other buildings, therefore sooner or later rot sets in and the structure is weakened. Where structural steel has been adopted in wet breakers it has been found to corrode badly, especially where mine water is used in cleansing and preparing the coal. Before the Pine Hill breaker was constructed the engineers made a series of tests to ascertain what effect mine water had on concrete. Their experiments, which proved very little, have been confirmed by the structure, which has been completed over 4 years and shows no signs of disintegration or other weakness.

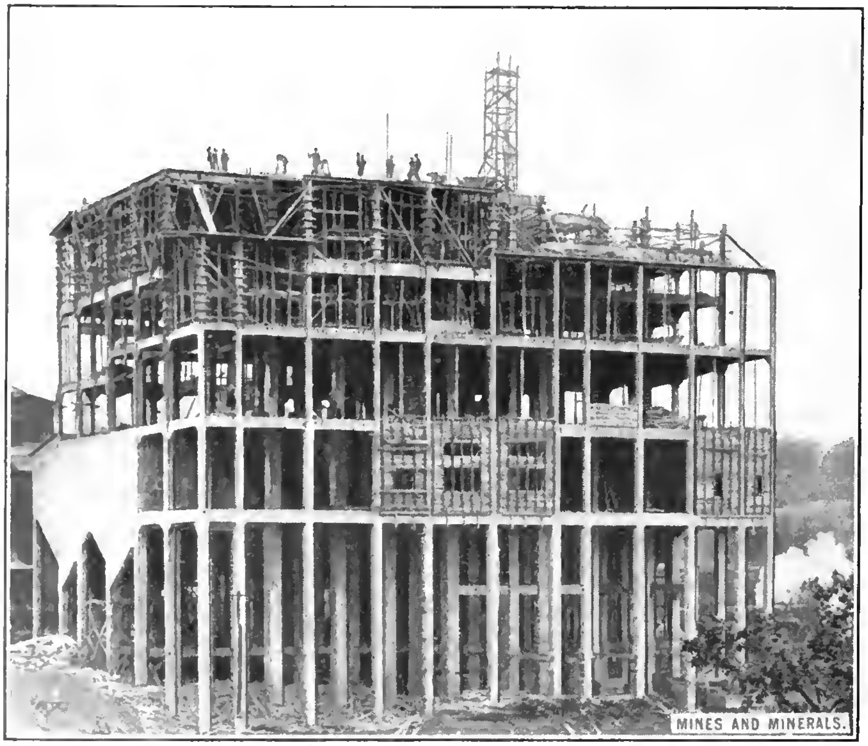

FIG. 1. TAYLOR CONCRETE BREAKER IN COURSE OF CONSTRUCTION

The Taylor breaker, as a model for future reinforced concrete breakers, has developed the difficulties of construction to be overcome in future structures of this kind to such an extent that duplicate breakers could be built in much less time and at reduced cost.

The rear of the breaker in the course of construction is shown in Fig. 1. While the bents from the rear to the front of the breaker are evenly spaced, those from side to side are spaced to accommodate the machinery and support the weight of the machinery and coal. The first two rows of posts in the rear of the breaker are about 2 feet square and up to the second or pocket floor have a length of 65 feet. Directly under and between the pockets where the most weight will come the 2-foot-square posts are supplemented with 36-inch-square posts. As the posts are carried upwards this size is decreased until at the top floors they are but 12 inches square.

In Fig. 2 the breaker is shown practically finished with the top forms still in place, and as it looks today from the outside, could be taken for an office building. It will be noted that the architect has furnished windows for daylight; also each post is supplied with tubes for wiring for electric lights, thus making this breaker an exceptional one for light and comfort of the employes. In the construction of the posts and beams, corrugated rods $1\frac{1}{2}$ inches in diameter were placed at each corner, then bound with hoop bands and wire so as to form a rectangular cage. They were reinforced by smaller corrugated iron rods from $\frac{3}{8}$-inch diameter up to $1\frac{1}{2}$-inch, as the occasion demanded. Inside this cage pipes for the electric wiring were placed and then wooden forms were constructed around these skeleton post frames. Concrete was poured in a little at a time from the top

of the forms and tamped with iron rods about the pipes and rods. In this way the posts were built up to the height of a floor, where the iron corrugated rods for the beams were tied with those of the posts. The beams were made the same as the posts. Forms were built around the skeleton beams and then concrete tamped about the rods and pipes. A description of the construction of these posts and beams from the foundation to the top of the breaker, a height of 149 feet, would in no case adequately explain the delays, petty annoyances from changes necessary in forms and the difficulties of handling material. However, the builders have learned by the experience in what manner they will be in future avoided.

It will be noted that the coal pockets are large and provided with two chutes so that two cars can be loaded from the same pocket at the same time. Each chute is provided with a gate and lip screen. Under the lip screens there will be a scraper line which will carry the fine material to an elevator bucket and back to that part of the breaker where it may be utilized. There are 14 chutes for each track, or 28 for both tracks. To the rear of Fig. 2 is seen the old Taylor breaker, constructed of wood. This structure, which is built over the shaft about 200 feet from the new breaker, must be wrecked before the new breaker is put in commission; then above the shaft will be erected a steel head-frame, connected with the top of the new breaker by a steel incline about 218 feet long carrying a scraper line. Self-dumping cages will be hoisted 50 feet above the shaft collar, then discharged into a boot feeding the scraper line. The coal is to be discharged from the scraper line at the top of the breaker, riddled over bars, and from the bars sent by gravity to the various crushing and sizing machines, finally reaching the coal pockets. About two-thirds of the breaker will prepare coal dry, the other third will be for washed coal.

Another new feature in connection with this breaker is the installation of individual electric motors for driving the individual machines used in the preparation of coal, and it was owing to this feature that so much care was used to place pipes for wires in the posts.

The D., L. & W. Co. have in recent years electrified their breakers and mines, using power generated at conveniently situated electric plants. The power for the Taylor breaker will be supplied by the Hampton electric plant situated about 2½ miles distant, in Keyser Valley.

It may be of interest to know that while the Taylor breaker is concrete, 500,000 feet of lumber will be needed inside for machinery bed-plates and other fittings. However, very little if any of this lumber is large sized and there are no sticks such as breaker framing demands.

We are indebted to S. M. Ives, foreman for D., L. & W. Co. for the information contained in this article.

ENGLISH SLAG PAVING BLOCKS

Scoria bricks, or slag paving blocks, have been manufactured in the Middlesbrough district, England, for many years and considerable quantities have been shipped to the United States since 1894. The bricks are manufactured from molten slag from the blast furnaces. The slag is drawn from the furnace into slag cars lined with firebrick and hauled to the brick plant. There the slag is poured into iron molds made with a hinged bottom and mounted on the circumference of a circular iron framework. This revolves and allows the molds to be filled separately. As the bricks solidify they are removed and placed in a beehive soaking oven, where the residual heat anneals the whole of the brick.

PERSONALS

John Gross, of the firm of Draper & Gross, mining and metallurgical engineers, 746 Equitable Building, Denver, Colo., has gone to Sonora, Mexico, on professional business.

On November 9, Ellis Soper, of Detroit, delivered a lecture on "Rotary Kilns," before the A. S. M. E. in New York City.

Frederick A. Delano, President of the Wabash Railroad Co., addressed the students of the University of Illinois on October 25. His subject was "The Railway as a Profession."

A. Bement, of Chicago, addressed the students of the University of Illinois, October 22, his topic being "The Practical Uses of Coal Analysis."

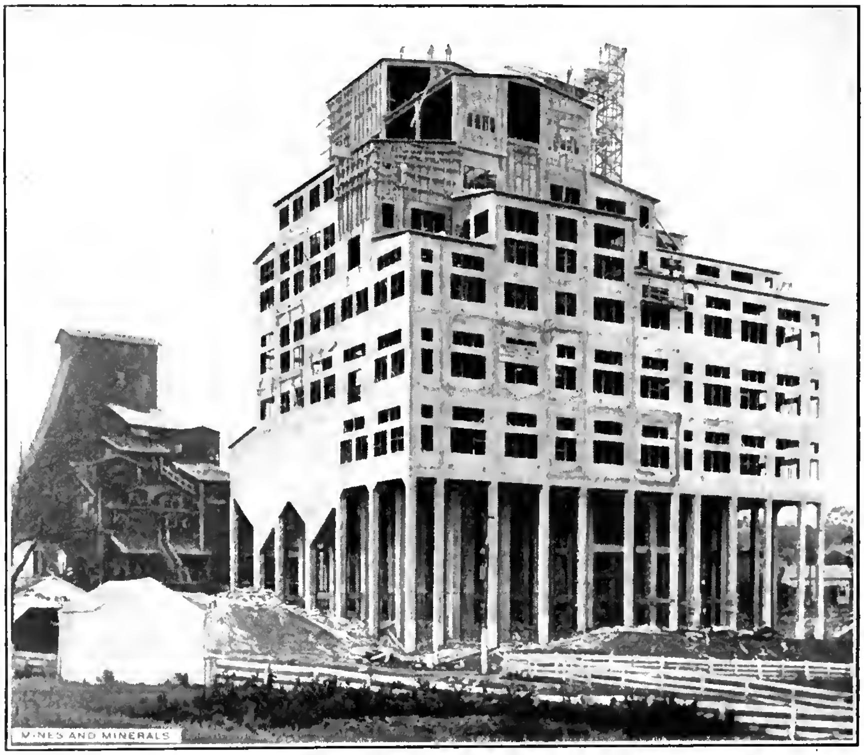

Fig. 2. The Old and the New Breaker at Taylor, Pa.

George F. Duck, E. M., Western Editor of Mines and Minerals, has returned to his office in Denver, after an extensive tour through the West and Southwest in the interest of the western readers of Mines and Minerals.

Kenneth Seaver has been appointed chief engineer of the Harbison-Walker Refractories Co., of Pittsburg, Pa.

Prof. C. T. Knipp, of the Physics Department of the University of Illinois, is in Europe on a year's leave of absence. He will spend the greater part of the year in Cambridge studying under Prof. J. J. Thompson.

Prof. H. H. Stoek, of the mining department of the University of Illinois, has been visiting various cities in the East in connection with his work.

William C. Cuntz, for 18 years with the Pennsylvania Steel Co., has accepted the management of The Goldschmidt Thermit Co., with offices in New York City.

At the November monthly meeting of the A. S. M. E., at their club rooms in New York, Charles W. Baker, editor of *Engineering News*, gave an illustrated lecture on the Panama Canal.

MINE FIRES

*By Thomas K. Adams**

While the death rate resulting from mine fires in this country, in the years past, has not been high compared with those resulting from other causes, yet it is sufficiently high to warrant us in devoting some time to the proper consideration of such a subject.

Lessons from Disastrous Fires in the Past—Precautions—Dealing with Mine Fires

We are cognizant of the fact of the direful effects both in the loss of life of the workingmen and the destruction of valuable property, large expense, and general annoyance to the mine owner.

The causes and effects of mine fires, and their preventatives, are all reasonably well known to every intelligent, thoughtful, and practical mining man. Such disasters ought to be classed as being preventable.

In looking over the accounts of some of the mine fires which have happened in this country, which have startled the general public more than others, I was forcibly struck with three of them (Avondale, Hill Farm, and Cherry), especially in the general aspect at least of the similarity of their cause and effect, and of the cycle of years between each. The Avondale Mine was a single-shaft opening. The structural material used in the shaft lining, partitions, derrick, and breaker, was composed of wood. The fire originated at the bottom of the shaft, caused by the carelessness of the furnace man in lighting the furnace fire, thereby setting fire to the wooden partition, etc. This fire occurred in the month of September, 1869, and in it 109 lives were lost. As you remember, no adequate means were at hand with which to extinguish the fire.

Hill Farm Mine fire was the direct result of a very thoughtless act on the part of the mine superintendent in directing the work of cutting into a drill hole adjacent to the main slope, which was 520 feet deep, with explosive gas and water in it, and doing this work on the day shift when men were at work beyond the location of the bore hole toward the bottom of the slope; the said hole being penetrated by the miner's pick, released its contents, consisting of water and explosive gas, and the boy Hays, standing nearby, seeing the immediate danger, he, with manly presence of mind, thought of the men at the bottom of the slope, and while he was on his thoughtful mission in passing the location of the fateful bore hole, with his open light, to warn the miners below, he ignited the gas, the flame therefrom set fire to the brattice cloth on the opposite side of the slope; the flame from the brattice cloth in turn set fire to the wooden overcast, the men beyond the fire were trapped and their means of escape cut off. This mine fire happened in April, 1890, 21 years after the Avondale disaster. Thirty-one persons were lost, and now, with 19 years intervening, the public was almost paralyzed by the effects of the Cherry Mine fire.

The Cherry Mine disaster, the effects and details of which you are all more or less familiar with, originated at the No. 2 seam landing of the escapement shaft and was caused by the ignition of hay from the flame of a crude, improvised, unprotected illuminating contrivance. The flame from the hay was communicated to the overabundance of wood supporting material at the landing, and adding thereto the inadequate means available to successfully deal with a fire of such magnitude, with the ill-judged actions of the inexperienced men at the bottom, the trap was complete and the men caught therein, so we have now to record the greatest and most disastrous mine fire in the history of the coal-mining industry of this country, so far as the loss of life is concerned. Two hundred and sixty-eight lives were lost in the Cherry Mine disaster.

After the Avondale disaster it became very plain even to our law makers that two openings, separated and apart, were necessary to every seam of coal to afford a reasonable measure of protection to the workmen in the mine in the event of mine fires at shafts or slopes.

The Hill Farm Mine disaster made again evident to our legislators the additional necessity of providing better means of exit to and from mines for the miners, and the elimination, under certain conditions, of the use of combustible material in the erection of overcasts and permanent stoppings, and providing additional passages for traveling ways, etc.

Now that the Cherry Mine disaster has passed into record, with its baneful effects, keenly felt by all sane men, will the lesson to be learned therefrom be remembered and heeded by us?

The coal-mining operations are visited by other mine fires, from other causes than those mentioned, and which are destructive in their effects, such as fires at mule stables, at oil shanties, electric and gasoline pump houses, from blasts firing explosive gas and fine coal at the face of the workings of the mines, fires at trap doors, fires on intake and return air-courses, probably from carelessly constructed and unprotected electric cables or wires, etc., and gob fires caused by reason of leaving fine coal and other combustible matter in them.

It has always appeared to me that the causes of mine fires were so apparent to the thoughtful and intelligent mining man that their occurrence and their ill effects were unnecessary and an unnecessary burden to be borne by the coal-mining industry of this country. The prevention of mine fires lies in the removal of the causes, which are well known, and the knowledge of means and methods to be employed for their elimination, being within the range and scope of the ability of the ordinary mine official, the wonder is that they do happen. To secure freedom from mine fires I believe lies almost entirely within the intelligently directed administrative powers of the mine management, and in my opinion if the mine officials are careful, alert, and capable, immunity from them can be secured.

When the people engaged in the coal-mining industry realize that the mining of coal is surrounded by many hazards, when they settle down to a more sober reflection and learn to reason out the fact that certain causes will produce certain effects, that life is more than meat, more safe and sane methods in operating the coal mines will prevail in this country.

Preventive Measures.—There should be employed at every mine a competent, thoughtful, careful, and ever-vigilant mine foreman to have exclusive control of the employes and the workings of the mine; and a part of his duties should be to see that all employes are instructed and trained in the use of all fire-protective appliances, to keep the mines free and clean, as far as practicable, of all refuse combustible matter, and that other protective regulations, through the maintenance of rigid discipline among all employes in the mine, are observed, and that the details of the operating system relating thereto be strictly attended to.

Every coal mine should consist of two separate openings and one of them should be used exclusively for an escapement, and these two openings should be separated by at least 500 feet, if practicable. The escapement shaft, if over 100 feet in depth, should be equipped with safe and efficient hoisting apparatus. The structure at the hoisting shaft should be built of steel, and the engine and power houses should be built of concrete, brick or masonry; the shaft linings to be of concrete, and the shaft bottoms, if needing supports for the roof, should be of steel I beams, concrete, or brickwork; doors between main shaft and the escapement shaft should be so located as to be easily accessible to the workmen from all parts of the mine by convenient traveling ways, other than those which lead directly to the bottom of the hoisting shaft; mule stables, if not entirely prohibited in the mines, should be built of incombustible material and illuminated with protected incandescent electric lights; all oil, electric and gasoline pump houses should be kept free from combustible material, and be built of concrete, brickwork, or

* Paper read at Summer Meeting of the Mining Institute of America, 1910.

masonry. When the main workings of a mine have advanced 5,000 feet in length and the remaining extent of the property and the other conditions warrant it, an auxiliary escapement opening should be provided and equipped with efficient and necessary machinery; a water system under sufficient pressure, and men of the different languages instructed and trained in its use, should be installed at all important mines, and the said system should be carried into the interior of them, and the whole equipment tested frequently to prove its efficiency, and all parts and connections kept in first-class condition and ready for use at all times; all electric cables or wires, etc., should be well supported and insulated, and not allowed to come in contact with combustible material. In the blasting of coal, permissible explosives should be used; mines should be patrolled by experienced and reliable miners after shots have been fired; all combustible material should as far as practicable be removed from gobs or abandoned parts of the mines and then kept as well ventilated as possible; a telephone system should be provided at important mines so that communication can be had between persons outside, and at all important stations inside of them; refuge chambers, efficiently constructed and equipped and conveniently located should be provided in all large and dangerous mines.

Mines should be provided with a powerful reversible fan, and it should be placed on a separate shaft, cased in steel, and fitted with relief doors opposite the direct line of tunnel or shaft, and so situated as to be out of the direct line of the possible dynamic forces which may result from explosions.

Dealing With Mine Fires.—In dealing with mine fires time is an important factor. A mine fire must be quickly and accurately located and dealt with promptly. The first thing to do after a fire has been discovered is to warn the men in the interior of the mine and have them removed as expeditiously as possible. Never forget this safety measure, no matter how trifling the fire may appear at its inception, especially if the fire originates at a dangerous location in or about the mine. Prepare to fight the fire with the means at hand, and at once. The air-currents must be kept under perfect control by the parties dealing with the fire. The main point to keep in view in the control of the air-currents is to so conduct them as not to carry the smoke to the workmen or to carry the explosive gas to the fire, if there be any accumulation of it at hand. The smoke must be carried directly to the return air-course. Whether or not the fan has to be reversed, or the air-current reversed or short-circuited, will depend on the location of the fire and the surrounding conditions. This matter will be determined by the persons having control of the work. The men dealing with the fire must fight it from the direction of the intake air-current, keeping the current always under control by means of temporary brattice work. The workmen must use safety lamps while doing the work. The fire must be fought persistently by means of hose and water and extinguishers and the fight must never be given up while hope lasts, or until it is certain that the fire has passed the stage of control.

The utmost care should be exercised by those engaged in such work to protect themselves from any dangerous gases which may be produced while dealing with the fire. If the well-directed efforts put forth to extinguish the fire have failed, it should be sealed off promptly so as to exclude the air, at the same time observing the necessary precautions when building the dams to provide them with the escapes so that accurate readings can be had from time to time of the condition of the enclosed atmosphere and of the temperature and nature of the gases in the fire zone. After a reasonable time has been allowed, if the exclusion of the air has not accomplished its purpose, the burning area must be filled with water and allowed to remain flooded until there is no doubt of the fire having been extinguished.

In making preliminary inspections to determine the exact location of a mine fire, we would advise the persons while doing so to use the rescue apparatus or oxygen helmet, and when going to make tests to ascertain the conditions surrounding the fire that they should use such apparatus by all means.

To successfully deal with mine fires the human factor engaged counts for more than anything else. The ideal man to cope successfully with mine fires must have decision of character, good judgment, and general intelligence; be physically strong and not afraid to use his strength, courage, and great tenacity and persistency; and above all, when conditions are well considered, decisions made, and plans and methods agreed upon, do not allow anything emanating from irresponsible parties to intervene in the carrying out to a finality the plans agreed upon.

COST OF SINKING A MEXICAN MINE SHAFT

The following costs of sinking a mine shaft through andesite, at the Esperanza Mine at El Oro, Mexico, are given by Mr. W. E. Hindry.* The shaft was a three-compartment vertical shaft, having two 5'×5' hoisting compartments and a 5'×7' pump and ladderway. The timbering was 10 in.×10 in. with 2-inch lagging; sills 5 feet center to center, and 6 posts per set. The total depth of the shaft was 679 feet, of which 101 feet were sunk by windlass and hand work, and 578 feet by steam hoist and machine drills. The work was done in 1899 and the prices of materials and wages were as follows:

Materials	Prices
Timber per M ft. B. M.	$13.58
Wood per cord	3.15
Coal per ton	7.27
Powder, 60 per cent., per pound	.14$\frac{3}{4}$
Fuse per foot	.0055
Caps, each	.0058
Candles, each	.0194
Labor	
Superintendent, per 24 hours	$4.850
Shaft men, foreign, per 8-hour shift	3.220
Shaft men, native, per 8-hour shift	.528
Top men, per 8-hour shift	.422
Fireman, per 8-hour shift	.485
Hoistmen, per 8-hour shift	.970
Blacksmiths, per 8-hour shift	1.455

The cost of excavation was as follows:

Labor	Per Linear Foot
Superintendence	$2.529
Shaftmen, foreign	3.510
Shaftmen, native	7.043
Top men	.578
Blacksmiths	.718
Firemen	.317
Hoistmen	.894
Miscellaneous	.936
Total	$16.525
Materials	
Timber	$ 3.961
Wood, fuel	3.781
Coal	.179
Powder	2.853
Fuse	.014
Caps	.294
Candles	.223
Oils, grease, etc.	.025
Miscellaneous	.051
Total	$11.381
Grand total	$27.906

The above costs are converted from Mexican money assuming the peso to have a value of 48$\frac{1}{2}$ cents.

**Mining and Scientific Press*, April 9, 1910.

MINE ACCIDENT PREVENTION

*By J. J. Rutledge**

Mine-rescue work is done most efficiently by men who have been carefully trained in such work, who are in good physical condition, who are equipped with the proper apparatus, who are close to the mine at the time the explosion happens, and are familiar with the mine workings. To be of any value the rescue apparatus must be kept at the mine and be always ready for instant use. Some of the employes, both outside and inside, should have received proper training in its use and should be in such physical condition that they can make immediate use of it in rescuing any men who may be left alive in the mine after the explosion. A volunteer corps composed of young, cool-headed, brave, active, and vigorous men can be of great value, if they are brought immediately to the scene of the explosion. If this corps is large enough, some members can be assigned to the auxiliary work that must be done before the men in the mine, living or dead, can be removed—such as putting up brattice, hanging brattice cloth, running telephone lines, extinguishing fires, repairing damaged machinery, and rendering first aid to those injured, while the remainder are busy with the actual rescue work.

Preparation for Rescue Work. Importance of Uniform and Efficient Laws

Those mining men who have somewhat critically observed the operation of the rescue apparatus now used by various rescue stations should remember that this is not the only apparatus of the knapsack type that has been used in rescue work, but there are about five or six other patterns, some using liquid air instead of oxygen. It is perfectly practicable to use these other patterns instead of the type at the rescue station, but it should be remembered that some of the patterns have a more limited range of action.

Prevention of Accidents.—In recent years the medical profession has made great advances in combating disease, but perhaps its greatest achievements have been in what is called "preventative medicine," that is, in endeavoring to prevent disease by doing away with unsanitary and unhealthful conditions, thus removing the necessity of expending more energy in trying to overcome disease after it has made its appearance. This is why some of our Alabama mining camps are so carefully looked after by the physicians in the employ of the various mining companies. In like manner, coal mining should have its methods of "preventative medicine" for its mine accidents, besides and in addition to its method of mine-rescue work after an accident has happened. It is of the preventative phase of the subject that the writer proposes to speak.

Laws.—It will be difficult to enforce safety provisions in coal mines, and to decrease the loss of life, so long as the inspectors, superintendents, mine foremen, and managers are not working under a good mining law. The laws governing mining should be, as far as local conditions permit, uniform over the various coal-producing states. Coal miners are constantly passing from one state to another, and any bad practices that originate in one state, are soon widely disseminated; hence there is great need of uniform laws to meet general conditions. It is especially important that the penalties for violation of the laws should be uniform in all the bituminous coal fields.

SUGGESTED PROVISIONS OF UNIFORM LAWS

Mine Plans and Methods of Working.—The law should stipulate that previous to the commencement of mining operations the operating company must submit to the State Mining Board, or Chief Mine Inspector, a detailed plan showing the surface plant it proposes to erect, the manner in which it plans to reach the coal bed, together with the number and location of the different shafts, slopes, or drifts; the proposed method of working the coal; and the proposed plan of ventilating the mine. It should be distinctly understood that these plans, if approved, are as a whole to be rigorously followed and only departed from, if at all, in minor details. The state authorities should then carefully scrutinize the plans submitted, approve those which in their judgment are in accordance with the best mining practice, and reject those which are not. The law should grant the public officials responsible for the safety of the miners the authority, under the police powers of the state, to approve only such plans as are, in the opinion of the best mining men, most conducive to safe and economical work. The mining company would, by such a procedure receive the best of advice as to the proper choice of methods to be used, and would be assured that every possible means providing for the safety of the employes had been adopted. Many of the conditions under which coal mining is carried on are not conducive to safe or economical work, and these conditions are not always appreciated by a mining company in haste to begin operations. The approval of the plans by an impartial official or officials having authority to approve or reject will be a guarantee that the best possible plans have been adopted.

The writer believes that it is nearly always possible to limit an explosion to the immediate vicinity of its origin, if a suitable method of opening out the mine has been adopted at the outset. Dividing a mine, if it is to be worked by pillar and room, into districts or panels, each of which shall be self-contained, ventilated by a separate split of air, and separated from the remaining panels by a solid, unbroken rib of coal, is, in the writer's opinion, a most effective method of preventing the spread of an explosion.

Ventilation.—One of the most important features of any plan for safe coal mining is the arrangement, adjustment, and control of the appliances for ventilation. The fan should be so installed that it cannot be injured by the force of any explosion in the mine. To this end it should not be placed directly over the mouth of the shaft, slope, or drift, but should be placed at least 50 feet away from the mine opening and communicate with this by a tunnel which makes a sharp angle with the shaft, slope, or drift; there should be balanced explosion doors on the fan, and two independent means of operating it.

Air-courses should be large and free of all obstructions; a large volume of air moving through ample courses at a velocity sufficient to speedily remove all dangerous gases, is, in the writer's estimation, much safer than the same volume of air passing at a great velocity through narrow courses. There is much more liability to dangerous concussion in the latter than in the former. The opening and closing of doors will not as seriously affect the slow-moving current as it will the fast-moving one. The air supply should be split as much as possible, consistent with the proper removal of the dangerous gases, and each district or panel should have its own split. There should be no doors on main entries or slopes. At the mouth of main cross-entries, through which coal passes in considerable quantity, there should be double doors with a space between them sufficiently large to contain the longest trip hauled from the cross-entries. All doors should be automatically self-closing, and at all important doors there should be attendants.

In the writer's opinion, overcasts and stoppings should be made strong enough to withstand only the force of the ordinary ventilating pressure, in order to insure their collapse under the sudden violent pressure exerted by an explosion. In addition, the writer believes there should be explosion doors built into every overcast or undercast. The writer is convinced that by such precautions the danger of widespread explosions would be materially lessened.

In case doors are permitted on main haulageways their operation should be regulated by statute. In some coal fields it is an offense, punishable by fine, to allow an important door upon which the safe ventilation of the mine depends, to remain open.

* Read before the Alabama Coal Operators' Association.

Miners.—Every miner should be shown the risks in using explosives, and the safe methods of handling them. He should, if at all possible, be given ocular demonstration of the fact that coal dust is explosive. This can be done by means of laboratory apparatus. He should be compelled to properly timber his working place, and should be held strictly accountable for the condition of it. To insure the safety of the miner in his working place and in his going to and from the mouth of the mine to the same, suitable rules should be enforced by the mine foreman or manager, violation of these rules to be punished by fine and imprisonment. Those in charge of coal mines and those responsible for the safety of the mine employes should have their actions backed by the power of the law.

The miner should be made to understand and to fully realize that if he places and drills his holes in a workmanlike manner he will not only produce the maximum amount of merchantable lump coal, with consequent financial benefits to himself, but will also be working under safe conditions; but if on the other hand, he does not exercise judgment in the placing and drilling of his holes, the chances are about nine to one that he will not only endanger his own life, but the lives of all others in the mine.

The writer, however, does not place all the blame for mine accidents on the miner by any means. A great deal of the trouble is due to poor discipline in the mine and to lax supervision by mine foremen and managers. Too often the miner continues following dangerous practices, taking chances day after day, because he is permitted to do so. Were he punished when detected in dangerous practices, and were his punishment required by law, he would soon cease to endanger the lives of himself and others. An inspection of the mines in those states which have and enforce strict regulations on the use of impure oil, size of powder cans, and shooting off the solid, will soon convince any one that the average miner has a proper respect for the law when strictly and impartially enforced. As far as the miner is concerned the remedy for the greater mine accidents, though much can be done by education, lies in the establishment of strict mine discipline.

Deputies.—In every large mine there should be for every 50 miners a practical competent miner to act as a deputy foreman. This man should be an assistant to the mine manager or foreman and would report directly to him. He would examine all working places at least once every working shift, see that the places are properly timbered, and that all holes were properly drilled and fired. The miners should preferably be concentrated in a limited area in order that his supervision may be as efficient as possible.

Shot Firers.—In mines generating explosive gas, or in which fine coal dust is found, all shots should be fired either by special shot firers, or from the outside by electrical appliances, after all other employes have left the workings.

Safety Lamps.—In any mine where as great a quantity as 2 per cent. of explosive gas has been found in the return air, safety lamps should be employed. Although such a mine may be perfectly free from gas for a considerable length of time, there is liable to be at any time a further outburst and any disarrangement of ventilating appliances will then render the mine dangerous.

Mine Employes Other Than Miners.—For positions that play an important part in the safe operation of the mine, such as cagers, trip riders, motormen, trackmen, timbermen, fire bosses, or mine examiners, shot firers, and all employes other than miners, only men whose courage in face of danger has been demonstrated, or who appear to be brave and cool headed, should be employed, as on any one of them at some time may depend the safety of the entire working force of the mine. Any single individual in a mine may by his own carelessness or criminal action at some time endanger the lives of all those underground. It is imperative, then, that for the responsible positions men of known courage and resourcefulness fully aware of all the dangers that surround coal mining should be chosen.

Foremen or Mine Managers.—The writer believes firmly that the person who is the greatest factor in the prevention of mine accidents is the mine foreman or manager, and has reached this conclusion after 7 years' experience gained as mine examiner, assistant mine foreman, mine foreman, mine manager, and superintendent. Although his length of service is not as long as that of some others here present, still he lived hard while in the service, and his conclusions should be given due weight. For 10 years the writer has acted as mine engineer and geologist, and in that time has visited many of the important coal mines in this country, and has been brought into close personal contact with mine foremen and superintendents of various kinds. The following, in the writer's judgment, are the qualifications of a safe and successful mine foreman or manager.

First, and foremost, he should have had practical experience in mining coal at the face; this should be insisted upon.

Second, he should be a man of good judgment, with ideas of his own, and strength of character sufficient to advance and defend his actions.

Third, and this is of great importance, he should have previously demonstrated in some subordinate capacity his ability to handle labor.

Fourth, he should be temperate in habits and truthful in character, and should possess executive ability and initiative.

Having the above qualifications, the mine foreman or manager should pass a strict examination, both oral and written, to determine his qualifications, and before he is admitted to the examination his character and ability should be certified to by at least three men of integrity and standing in the business of coal mining. The examination should be strict and impartial, so as to prevent the cheapening of the certificates of competency issued to those foremen or managers passing it; at the same time, practical knowledge or experience in mines should be given preference over the mere ability to give correct answers to technical questions relating to coal mining.

The candidate passing the oral and written examination should be given a certificate of competency as mine manager, and this certificate should be subject to annulment by the proper authorities upon the presentation of evidence of carelessness in mine management or non-compliance with the state mining laws on the part of the holder. But the state regulations should go further than this. If a man has shown himself capable of passing a strict examination as to his qualifications as mine foreman or manager, he should be given, in addition to his certificate, some insignia of authority by the state, such as a badge, and should have certain police powers in the mine over which he has charge. In this way the mining laws will be more carefully enforced and life and property conserved. If the powers thus given to the mine foreman or manager were abused or used for purposes of oppressing the miner, there would be prompt annulment of the certificate, after the facts had been established upon investigation by the State Mining Board.

In the advent of disputes relating to matters of mine discipline between the mine foreman or manager and the miners, the police power given him could not be abused, for his actions would be subject to review by the Mining Board. On the other hand, should the foreman or manager be handicapped or hindered in his work by the failure to receive proper supplies or equipment from his superiors, he would be encouraged to demand the same and would be insured against possible loss of employment by reason of his making such a demand, realizing that the law would back him up in making such demands.

It seems to me absurd to put a mine foreman or manager in charge of a large mine employing several hundred men, all of whose lives he must be responsible for, without giving him the proper means of enforcing such rules and regulations as he may make for the safe operation of his mine. Some may say that the mine foreman or manager can enforce his orders by discharging those employes who refuse to obey them; but though

this course is theoretically open to him at all times, it may be a difficult one to take. When men are scarce or strongly organized a discharge is not always a practicable solution of the problem.

A consideration of the difference in the attitude of the miner toward the foreman who represents the company and the mine inspector, who is backed by the authority of the state, will convince those who doubt the wisdom of the above suggested plan; clothe the mine foreman and manager with the authority and dignity which his position entitles him to possess, and the writer is sure that mine accidents will be very greatly decreased.

Superintendents.—The mine superintendent should be a man of practical experience, preferably with some technical training, and should possess great executive ability; he should have reached his position as superintendent by promotion from mine foreman or manager, as he will then have that knowledge of details which is essential to economical and safe operating. In matters of mine discipline he should be supreme, but he should always support the foreman when the latter is in the right and should see that the foreman works in harmony with him.

In the matter of supplies, the superintendent should disallow requisitions from the foreman, if after close investigation he ascertains that such supplies are not required, but he should never cancel any requisition for supplies that are absolutely required. Perhaps the greatest abuse of this sort is the cancellation of supplies which are required to make ventilation more effective. This strikes the foreman at a vital spot, for he is answerable to two other parties in this affair, besides the superintendent; viz., the inspector and the miners. Both place the blame on the foreman if the needed supplies are not forthcoming.

In such matters as pertain to mine management, when disputes arise between the general office and the mine officials, the superintendent and mine foreman, if in the right, should not hesitate to declare themselves, for subsequent developments will discredit their work if they fail to stand for what is right and proper.

Inspectors.—The mine inspector should be a man of mature years and of good judgment, who has a practical knowledge of coal mining and considerable strength of character. His position, in my judgment, should be under state civil service rules, and not subject to change by reason of changes in state government. He should possess police powers granted him by the state and should be empowered to conduct sworn investigations of mine accidents.

Conclusion.—The writer is fully aware of the fact that the adoption of the above suggestions will add materially to the cost of coal production at the beginning of operations, but he is quite sure that the final returns on investments in coal mines will be greater because of fewer accidents and more efficient mining.

TRADE NOTICES

Cia. Minera Santa Ana y Anexas, of Pachuca, State of Hidalgo, Mexico, has entirely equipped its property with electric apparatus, the power for operating being purchased from the Cia. Electrica é Irrigadora. The power is furnished to the mining company at 6,000 volts, 50 cycles, and in order to reduce this voltage to 400 volts, that required by the motors, a large bank of oil-insulated transformers with protection apparatus has been installed. A part of the equipment comprises a double-drum electric hoist fitted with brakes and clutches operated by compressed air supplied from a separate electric-driven air compressor. The capacity of this hoist is 9,000 pounds total load at a hoisting speed of 700 feet per minute. The hoist is fitted with a 225-horsepower, 400-volt motor of three-bearing type with usual controlling device as furnished by the Westinghouse Electric and Mfg. Co., the entire outfit being purchased through G. and O. Braniff & Co., of Mexico City, who represent the manufacturers.

The Joseph Dixon Crucible Co., of Jersey City, N. J., has just gotten out a very attractive little booklet of envelope size on their paint for steel cars. Any one interested in steel-car painting should send for a copy of this booklet which will be forwarded, free of charge.

The Bristol Company calls attention to its new model of recording pressure gauges equipped with 6-inch chart as illustrated and catalogued for the first time on page 8 of Bulletin 141. Radically new lines of instruments are also illustrated in Bulletins 145, 146, and 147. A description of the Bristol–Durand radii averaging instrument is given in Bulletin 147.

The government mine rescue cars are being equipped with Hubbell electric mine lamps. Special cabinets have been designed for them, attached to which is a charging board which makes it possible to charge these lanterns from any voltage from 700 to 110. The cabinet consists of a locker wherein extra supplies are kept, such as reflectors, compound, and a ½-gallon bottle of solution, also two shelves each to hold four lanterns, which can be charged without moving them from their places. The weight of the type of lantern used is a trifle over 3 pounds. An advantage claimed for these lamps is that, owing to the nature of the battery with which they are equipped, they can be charged and put away for a long period of idleness without losing their efficiency or diminishing their storing capacity. An additional feature of the lighting equipment for this work is the portable electric searchlight which has proved very valuable for brattice work or for searching for bodies after an explosion. This light is equipped with two powerful batteries and a 20-candlepower light on a parabolic reflector which throws a long piercing ray as well as a generally diffused light. The construction is so arranged that one battery can be charged while the other is in service, and the light can be in service for 24 hours in a day. These lights were supplied by the Servus Rescue Equipment Co., Keenan Building, Pittsburg, Pa.

The consolidation of the Terry Core Drill Co. with the McKiernan Drill Co., under the name of the McKiernan-Terry Drill Co., is announced. The new company will manufacture the various products of both companies, including rock drills, hammer drills, core drills, core cutters, sheet-pile drivers, compressors, etc., and the business office will be at 115 Broadway, New York City.

Goyne Bros., of Ashland, Pa., recently shipped to the Buck Mountain colliery of the Lehigh Valley Coal Co., at Mahanoy City, Pa., two especially large triple-expansion duplex mining pumps, the shipment requiring four large-size cars; and this shipment constituted the first one of the large pumps produced at the greatly enlarged plant in that section popularly termed the "East End." The enlargement of these works has been held back by an extremely busy season, requiring the capacity product of both plants. While orders at present on the books will keep both plants rushed throughout the early months of 1911, the addition to the machine shops and erection of a commodious office building and other structures that will comprise one of the most substantial exclusive mine pump manufacturing plants in the country will go forward with the dispatch characteristic of Goyne Bros.

Frank Toomey, Inc., 127-131 N. Third St., Philadelphia, Pa., is placing upon the market the fomous Reilly steam pumps.

This line comprises mine pumps, fire pumps, water works pumps, circulating pumps, pumps for wrecking, irrigating, artesian wells, oil lines, quarries, etc.; also air pumps and air compressors for various purposes.

ANSWERS TO EXAMINATION QUESTIONS

Written for Mines and Minerals, by J. T. Beard

Mine Bosses' Examination Held at Terre Haute, Ind., August 17, 18, 1910

QUES. 1.—Omitted.*

QUES. 2.—(*a*) What are the requirements of the Indiana statute relative to the visiting of working places by mine bosses? (*b*) What are the benefits that should be derived from conformity with this statute? Points 6.

ANS.—(*a*) See Section 33 of the Indiana mining laws. (*b*) The working places will be kept in better condition and greater safety will be assured in every part of the mine. Fewer lives will be lost and fewer persons injured by falls of roof and coal. Work will be done with more care and system and the daily output of coal increased. The mine boss will be better acquainted with his men and the needs of the work.

QUES. 4.—(*a*) What are the factors necessary to insure efficient mine ventilation? (*b*) What are the conditions that should determine the quantity of air to be circulated through a mine? (*c*) What are the conditions that frequently arise that necessitate an increase in the quantity of air circulated through a mine? Points 9.

ANS.—(*a*) A sufficient volume of air must be circulated throughout the mine to make it healthful and safe. The air-current must be made to sweep the working face, and must be so distributed that the volume and velocity of the air passing in each section of the mine shall be sufficient for the needs in that section. All abandoned workings must be sealed off or ventilated to prevent a dangerous accumulation of gas; and all void places and headings must be kept free from gas by the use of temporary brattices if necessary. (*b*) The quantity of air to be circulated in a mine should be determined, aside from the requirements of the law, by the number of men and animals employed, the gaseous condition and size of the workings, the size of entries and rooms, method of working, depth of the seam below the surface, and area of abandoned workings requiring to be ventilated. (*c*) Any sudden outburst of gas, or increase in the flow of gas into the workings, due to a fresh blower, a fall of roof, or striking a fault where gas is given off freely. The opening up of a new area or section of a mine; or the occurrence of a mine squeeze, which may cause a loss of air due to leakage of doors or stoppings. All of these may require an increase of the circulation.

QUES. 5.—An airway 14.5 feet wide and 6.5 feet high is passing 47,125 cubic feet of air per minute; what is the anemometer reading? Points 4.

ANS.—The sectional area of this airway is $14.5 \times 6.5 = 94.25$ square feet; and the average velocity of the air-current is $47,125 \div 94.25 = 500$ feet per minute. Assuming the anemometer is exposed to the air-current for exactly 1 minute in such a manner as to obtain an average reading, this reading should be 500, making no allowance for the inertia in starting and friction. As proof, $Q = a\,v = 94.25 \times 500 = 47,125$ cubic feet per minute, which is the volume of air passing.

QUES. 6.—(*a*) Which should be the larger, the intake or the return airway, in a mine? Give reasons for your opinion. (*b*) What are the benefits to be derived from splitting the air-current? (*c*) When would you deem it not advisable to split an air-current in a mine? Points 7.

ANS.—(*a*) The return airway should have a larger sectional area than the intake for the reason that the volume of the return air-current is commonly increased by the addition of gases generated in the mine; also, by the natural heat of the mine, and by the decrease of the ventilating pressure as the current moves from the intake opening toward the return. All of these causes act to expand the air passing through the mine, which would increase the velocity of the return current and produce a greater mine resistance, but for the enlargement of the sectional area of the return airway. (*b*) By splitting the current one or more times a larger volume of air is circulated in the mine with less power; purer air is obtained at the working face; the velocity of the current is reduced; and the distribution of the air is made to conform to the needs in the several splits; in other words, the entire circulation is under better control. An explosion of gas or dust is often limited to the split in which it occurred. (*c*) An air-current should not be split when the velocity of the air would thereby be reduced below what is required for efficient ventilation; or when it would be necessary to build an air bridge, and the development of that section of the mine is not sufficient to warrant the expense.

QUES. 7.—Two mines, No. 1 and No. 2, have an equal number of square yards excavated, and employ an equal number of men and mules; all conditions are similar except the height of the coal in the seam. The coal in mine No. 1 is 3 feet thick, while that in mine No. 2 is 8 feet thick. Would the same minimum quantity of air required to properly ventilate No. 1 furnish efficient ventilation for No 2? Explain fully the reasons for your opinion. Points 4.

ANS.—No. 2 mine opened in the thick 8-foot seam would require a larger quantity of air in circulation to produce equally efficient ventilation with that in No. 1 mine in a 3-foot seam; for the reason that its openings, airways, and chambers all have a larger sectional area than those in the thin 3-foot seam and with the same quantity of air in circulation the velocity of the air-current in No. 2 would be much less than that in No. 1, which the question states is only sufficient to properly ventilate that seam. Efficient mine ventilation requires a certain velocity of the air-current, sufficient to sweep away the gases generated, but not sufficient to render the workings uncomfortable.

QUES. 8.—A certain mine is ventilated by means of a blowing fan located at the intake opening. The fan furnishes a volume of air that, under ordinary conditions would be more than ample for the needs of the mine. The air-courses, however, pass through extensive old workings, which contain large quantities of blackdamp that mixes with the air-current. Conditions are such that it is practically impossible to seal off the old workings entirely and prevent the flowing of the air. Can you advise some method by which this mine can be properly ventilated, and avoid carrying the blackdamp to the working faces? Points 5.

ANS.—Alter the fan so as to make it exhaust the air from the mine, thereby reversing the air-current and causing the intake air to traverse the working faces before it reaches the old workings and becomes fouled with the blackdamp. This would necessitate changing the doors throughout the mine so that they will close with the air. The blackdamp would then mix with the return current and be carried by it out of the mine.

QUES. 9.—(*a*) How many stages of underground haulage are there? (*b*) How should each stage be arranged? Points 5.

ANS.—(*a*) In all the larger mines there are two stages in the underground haulage; namely, the first or gathering stage in which the coal is hauled from the working face to the main inside parting where trips are made up to be hauled to the shaft or slope bottom, or out of the mine; this last or main haul constitutes the second stage of the underground haulage. (*b*) The main haul should be of such length that the trips can be hauled only as fast as the coal can be brought from the face to the parting. As the working face is advanced and the distance to the parting or the gathering haul becomes too great to put the coal on the parting as fast as the trips can haul it away, the main haul must be extended by making a new parting or gathering station nearer the face and thus reducing the gathering haul.

QUES. 10.—In selecting a location for a double parting to be used as a gathering point for mules, there are two available

* Questions 1, 3, and 14 were omitted, as to answer them the mine law must be quoted. Every miner should possess a copy of the mine laws of his state and become familiar with them.

sites, one being where the seam dips with a 1-per-cent. grade against the loaded cars. About 300 feet outside of this point the road passes over a slight rise and then has an inclination of 1 per cent. toward the shaft. (*a*) If motor haulage is to be used on the main road, from the parting to the shaft, at which point would you locate the parting? (*b*) Which of these two locations would you choose if mule haulage is to be used for this stage? Explain in detail the reasons for your choice. Points 6.

Ans.—(*a*) If motor haulage is to be used on the main road it would be well to select the inside location first mentioned; for the reason that the motor when pulling the empties into the mine can take the switch at the outby end of the parting and be in readiness to pull out the loaded trip as soon as the empties, running now by gravity, clear the switch. The motor will do the same at the shaft bottom, taking the switch, and allowing the loads to gravitate toward the shaft while it is coupled to the empty trip ready to start back into the mine. (*b*) In the use of mule haulage, it would be difficult for the mules to start the loaded trip against a grade however slight. The outside location should therefore be chosen in this case so as to give an easy start where the grade favors the loaded cars.

Ques. 11.—(*a*) Name the chief factors essential to successful mine haulage. (*b*) What arrangements would you make for the safety of drivers or other persons along haulage roads? Points 7.

Ans.—(*a*) The chief points are a good road bed, sufficiently heavy iron for the traffic, good solid track, ties well ballasted, straight track as far as practicable, well rounded easy curves, light grades, as far as practicable favoring the loaded cars, automatic switches at turnouts, and a good signal system. Keep rolling stock in good condition; use large, self-oiling wheels (not less than 16 inches in diameter), and well-built, tight cars that will not scatter the coal along the roadways. (*b*) Avoid doors on haulage roads wherever possible and never locate a door at the foot of a sharp grade where the driver cannot always have control of the car. Leave a clear space on one side of the track for persons to pass cars without danger; ample room should be provided where it is necessary for drivers to sprag their cars and on each side of doors. Where trappers are employed there should be refuge holes cut in the sides of the entry where the trapper will be protected in case of accident. Refuge holes should also be provided not exceeding 25 yards apart on all haulage roads used as traveling ways, and on slopes, and at slope bottoms.

Ques. 12.—Referring to Ques. 10, suppose the double parting or gathering station is 1 mile from the shaft, and there is a single-track road to the shaft bottom. The mine cars are 7.5 feet in length, out to out, and have a capacity of 2.5 tons of coal. Two 10-ton motors are used to haul the coal from the parting to the shaft bottom, each hauling 25 cars in a trip, which is made in 25 minutes. There are 10 gathering mules, each hauling a single car and requiring an average of 5 minutes to make the trip from the face to the parting. (*a*) What size of iron should be used on the motor road? (*b*) What arrangements should be made for the motors to pass each other between the shaft bottom and the parting? (*c*) What should be the length of the shaft bottom? (*d*) What should be the lengths of the turnouts and the inside parting? (*e*) How many mine cars will be required to keep drivers and motors going and avoid loss of time from having to wait on one another (not counting cars being loaded at the working face)? Points 12.

Fig. 1

Fig. 2

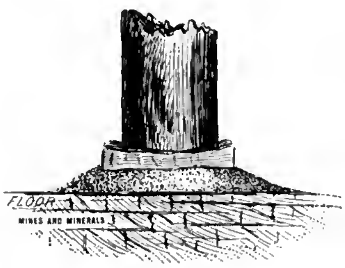

Fig 3

Ans.—(*a*) Use 40-pound rails with fish-plates and well bonded on the motor road. (*b*) A turnout should be made at the meeting point, half way between the parting and the shaft bottom. The switches at each end of the turnout should be automatic, spring-pole switches, so that the switches will always be set for traffic in one direction, but will be operated automatically by cars moving in the opposite direction. One track of the turnout will thus always be used by the loaded and the other by the empty trip in passing to and from the shaft. (*c*) The shaft bottom should be long enough to accommodate two loaded and two empty trips, in case this becomes necessary from some delay either in the hoisting or the haulage of the coal. In this case, the length of the trips hauled is 25 cars, and the shaft bottom should afford standing room for at least 50 cars, or have a clear length of $50 \times 7.5 = 375$ feet. (*d*) The turnout need only be long enough to hold one trip of 25 cars, or say 190 feet of clear track room. To enable the inside drivers and miners to continue work as long as possible, in case of trouble in hoisting, the inside parting should be able to hold two trips, or its length should be the same as that of the shaft bottom; namely, 375 feet of clear track room. (*e*) To avoid as far as possible any delay in hoisting, or stopping work at the face, there should be cars sufficient to form five loaded trips, or $5 \times 25 = 125$ cars, which would stand finally two trips on the bottom, one on the turnout, and two on the parting inside. This would not include the cars in process of loading at the face, which would depend on the number of working places in operation, and a few extra cars undergoing repairs, and in use for delivery of timber, rails, hay, and other daily supplies.

Ques. 13.—Again referring to Ques. 10, an average of 85 kegs of powder are delivered each day to the miners, in their working places, by the company. What arrangements should be made for the safe delivery of this powder? Points 5.

Ans.—This powder should be delivered at the top of the shaft, at a certain specified time each day, and placed in mine cars, lowered down the shaft, and hauled at once to the inside parting, from which point it should be distributed carefully to the men for whom it was intended. The handling and transportation of the powder should be done with great care and no lamp should be brought near the powder; no person but the driver should be allowed to ride on the trip carrying the explosive As each keg is delivered to the miner it should be placed at once in his box and not left at the side of the track.

Ques. 15.—If a prop 5 inches in diameter is required in a 5-foot seam, what should be the diameter of a prop, under the same conditions, in a 7-foot seam? Points 4.

Ans.—For post timber in mines a good rule is to make the diameter of the small end of a post, in inches, equal to its length in feet. Under the same conditions, the diameter of a mine post should be proportioned to its length; or in this case, the diameter of post in the 7-foot seam should be 7 inches.

Ques. 16.—Name the different conditions met with in coal mines in relation to the timbering of rooms, and state how props should be set under each of these conditions. Points 6.

Ans.—There may be a hard roof and floor, or vice versa a soft roof and hard floor, or both roof and floor may be soft. Also, the seam may be level or inclined. A hard-roof-and-floor condition is most destructive of post timber because of the unyielding character of the strata. Under these conditions posts should be provided with thick cap pieces of soft wood, and should not be driven tighter than is required to hold them

in place till they take the weight (Fig. 1); or they are frequently tapered at the foot so as to yield gradually to the weight without destroying the post (Fig. 2); or the post is sometimes set on a slight mound of dirt, for the same purpose (Fig. 3). When the floor is soft a foot-board may be required, the size being adapted to the condition of the floor; or in some cases, it may be sufficient to stand the prop with the large end down. With a weak roof a good cap piece must be used and the post is usually stood with the large end up. If the roof is very frail, or contains slips, planks are often used above the posts to secure greater safety, and the posts must be set closer together and nearer the face. The same precautions must be adopted when both roof and floor are soft. In a practically level seam posts are stood vertically, but when the seam is considerably inclined the post should be (underset) inclined a few inches up the pitch from the perpendicular to the seam.

A NEW SMOKE HELMET FOR MINE-FIRE FIGHTING

A new form of oxygen helmet, known as the Eveready Smoke and Ammonia Helmet, is receiving attention from the mining industry in connection with rescue work. It consists of a hood reinforced by a steel frame which fits snugly over the head and rests on the shoulders, and is made tight around the neck by a steel spring. The wearer breathes into a small mouthpiece and the exhaled air is passed through and over an oxygen-producing compound which utilizes the moisture from the breath and absorbs the carbon dioxide, and liberates oxygen in proportion. The simplicity of the device commends it for many purposes.

Several of these helmets have been used successfully in fighting mine fires, for which they are particularly efficient because the leather does not readily radiate heat. To recharge the apparatus it is only necessary to insert a new cartridge of chemical, and each cartridge, if cleansed after 1 hour's service, will render continued service. The Alabama Fuel and Iron Co., as well as the Pratt Consolidated Coal Co., both of Birmingham, Ala., have recently been equipped with this device, which is made by the Servus Equipment Co., Keenan Building, Pittsburg, Pa.

COAL NOTES

The Harding tipple of the Davis Colliery Co., at Harding, Randolph County, W. Va., which was totally destroyed by fire on September 17, has been rebuilt. The charging of ovens was restarted October 1, and the loading of railroad cars October 8, since which time the tipple has been in full use. Run-of-mine, lump, nut, and slack coal are loaded as before the fire.

On February 17, of the present year, the Legislature of Illinois enacted a law establishing three mine rescue stations and making an appropriation for their complete equipment for the work of rescue following a mine disaster. These stations it has been decided will be at Benton, in the Southern Illinois coal field, at Springfield in the Central coal field, and at La Salle in the northern coal field. Two men will be appointed for each station, one as general manager and the other as superintendent. Eight men have recently passed preliminary examinations for these positions, and have been in training for this work at the government rescue station at the University of Illinios. These men have had unexpected additional practice in a mine fire which occurred during their stay at the University of Illinois.

MINE ACCIDENT INVESTIGATIONS

*By George S. Rice**

While it is evident that there is a great diversity of opinion among American mining men as to the proper functions of the new Federal Bureau of Mines, on one point, at least, there appears to be general agreement, namely: That the investigation of accidents in coal mines, started under the jurisdiction of the Geological Survey, should be continued, and a similar investigation should be made of accidents in metal mines

Method of Tabulation of Accidents in Metal and Other Mines Suggested by the Bureau of Mines

A prominent English mining engineer, while speaking of accidents in metal mines, remarked that coal miners were fortunate in having disasters occur in their mines. This, at first, seems like a brutal statement, but when the matter is considered carefully, the meaning becomes clear, since in spite of the large number of men who have been killed and injured in the great colliery disasters that too frequently have appalled the world, the number of deaths and injuries from this cause have formed only a small part of total number killed and injured in coal mining by other causes, particularly those due to falls of coal and rock.

In 1907, the year of the series of greatest American colliery disasters, Mr. E. W. Parker reports 947 men were killed and 347 injured in gas and dust explosions. During the same year in all the coal mines of this country, there were 1,122 killed and 2,141 injured from falls of roof or coal; and from all causes the totals for that year were 3,125 killed and 5,316 injured. Therefore, of the total number killed and injured in that year of greatest mine explosions, less than one-third were killed and one-fifteenth were injured by explosions.

In more normal years like 1908, during which 2,450 were killed and 6,772 injured, only one-sixth of the killed were lost in disasters and one-twentieth of the total were injured by explosions of gas and dust.

Nevertheless, as previously indicated, the horror produced by the explosions has caused attention to be directed to accidents in coal mines, and the precautions taken on this account have led to a general improvement in colliery conditions, and in all civilized mining countries except the United States the accident rate has been steadily decreasing.

In the United States the annual accident rate of coal mining nearly doubled in the 10 years from 1897 to 1907, when we attained the high annual death rate of 4.86 deaths per 1,000 employes. Fortunately, the year 1908 showed a reduction to 3.60 deaths per 1,000, and in 1909 the death rate was still further decreased; we can only hope it will continue to decrease. The present rate is most appalling when one considers it in comparison with that of France or Belgium, where the annual mortality rates are but 1 per 1,000.

In view of the high accident rate in the collieries of this country, it might be questioned if the attention attracted by the disasters has led to much improvement of conditions. Undoubtedly there has been improvement, but it has not, until 1908, kept pace with increased dangers due to rapid development, and greater natural dangers arising from greater depth of workings with consequent increase in flow of explosive gas and the increased use of black powder in lieu of pick work.

Metal-Mining Accidents.—When attention is directed to metalliferous mining accidents, we are surprised to find that many of the states in which mining is done make no record of the deaths and injuries in metal mining, and the Federal Government has hitherto made no attempt to gather such statistics. This strange lack of information cannot be because the metal-mine operators as a rule are less interested in the welfare of their employes; there are many instances to show the contrary.

It is noticeable that the states that do not gather mine accident statistics are chiefly those in which there is no coal mining. Coal miners and operators, in going from the old-established coal-mining centers of the East and from Europe have carried with them their customs and systems of law and regulations, which include the recording of mine accidents.

Metalliferous miners in this country have largely formed their own precedents, and, probably due to the wide diversity of mining systems, in turn due to great differences in natural conditions, there has not been the same community of interests among metalliferous miners until more recently. Your committee on uniform mining laws and prevention of mine accidents in its report to this Congress, has clearly brought to attention the lack of metal-mining statistics, except in certain states, and those states have the best mining laws.

Mr. Frederick L. Hoffman, the well-known statistician, has done valuable service to the metal-mining industry in attempting to obtain, in spite of lack of official statistics, the fatality rates in different sections of the country. As his report, published in the *Engineering and Mining Journal* of March 5, 1910, has been republished by the committee on uniform laws, I will not attempt to comment on it, except to call attention to the fact that he finds the average rate is practically the same as in coal mining, despite the general acceptance that the natural conditions are less hazardous. His figures also show that there is a greater variation in different metal-mining districts than in different coal-mining districts, and that the accident rates in both are appallingly high as compared with those of European countries.

Attacking another phase of the conditions under which miners work, Mr. Hoffman in an article in the *Engineering and Mining Journal*, July 2, 1910, has commented upon the excess of sickness and ill health of miners as a class, compared with those who work in the open air.

Haldane and Thomas Paper on Miners' Diseases.—Messrs. J. S. Haldane and R. A. Thomas, in an article which appeared in the Transactions of the Institute of Mining and Metallurgy, Volume 13, reached the following conclusions after a study of the health statistics of miners and others living in England, Wales, and Cornwall:

"1. Apart from lung diseases and a slight excess of fatal accidents (many of which are not underground), metalliferous mining in England is a very healthful occupation.

"2. After the age of 25, there is an extraordinary contrast as regards the death rate from lung diseases between colliers and ironstone miners on the one hand and metalliferous miners on the other. Since 1892, the death rate from lung diseases has so increased that now the deaths due to lung diseases in the metalliferous mines are 8 to 10 times as great as that of colliers or ironstone miners of the same age."

The authors further state "the variety of lung diseases which is chiefly responsible is returned as phthisis on the death certificate. Among older men deaths from bronchitis are in excess. * * * the following causes have been attributed in the past as wholly or in part the cause of miners' phthisis:

"1. Absence of sunlight. This cause dismissed as having nothing to do with the disease.

"2. Exposure to high temperature and sudden variations in temperature. This cannot be an important cause as coal miners are similarly exposed.

"3. Gaseous impurities. Surprisingly little attention is given to the question of ventilating metal mines as compared with coal mines. Consequently, lung diseases in metal mines have been largely attributed to poor ventilation."

Messrs. Haldane and Thomas did not agree with the foregoing suggested causes as they found that the mines that they examined in Cornwall were freer from gaseous impurities than the air of coal or ironstone mines. They discussed three possible causes:

1. The stone dust produced.
2. The smoke produced by explosives.
3. Infectious bacteria.

* Paper presented before the American Mining Congress, Los Angeles September, 1910.

They decided that infection by tubercular bacillus will not explain the facts relating to miners' phthisis. They considered that the smoke from explosives and candles was "probably inappreciable." The final conclusion of Messrs. Haldane and Thomas was that the inhalation of the stone dust was the cause of the lung disease which is common among the Cornish and other miners. They state that out of 142 men who had worked rock drills in the Cornwall district, 94 per cent. died of lung diseases and the average age at death was 37 years, and of 178 men who did not work with rock drills, 65 per cent. died of lung diseases, but the average at death was 50 years.

They, therefore, considered that the introduction of rock drills in Cornwall is responsible for the recent great increase in the mortality of Cornish miners between the ages of 25 and 50 years. They thought that there was no reason for believing that the dust produced its effects upon the lungs in any other way than mechanically by its hardness, sharpness, and insolubility, as there seemed to be little difference in effect whether the dust was from quartz, granite, flint, gannister, or hard sandstone.

In a discussion which followed the Haldane and Thomas paper, Doctor Oliver stated "that miners' phthisis belonged to a group of diseases in which the spongy texture of the lungs became converted into a hard solid tissue."

Mr. R. J. Watkins, who had charge of a sampling mill, stated that when certain kinds of dust were sampled, men were knocked out often for many days, and that a certain sulphide ore of certain composition gave the most trouble.

South Africa.—Much attention has been paid in South Africa to the miners' phthisis, and in 1902 prizes were offered for "the three best practical suggestions and devices for obviating, minimizing, or combating the causes leading to miners' phthisis." The advertisement offering these prizes stated that while no definite information was before the Commission, it was generally assumed that the cause of the disease lay in the inhalation by the men of fine dust produced by rock drills.

Two hundred and twenty-nine competitors responded. Most of the suggestions were regarded as impracticable methods for wetting, through jets, the dust as made by the drill, and atomizers or sprinklers for laying the dust when made, received most attention, and some of the devices were regarded by the Commission as promising.

Gases From Blasts.—In addition to the menace of stone dust and despite the statements in the foregoing quotations, it is evident that in some mines and in some places, where there is no positive, or little, ventilation, the breathing of gases from the combustion of explosives produces an unfortunate effect upon the men, which at times has been accumulative in its effects. We know from the work which has been done by Haldane and others the poisonous effects of minute quantities of carbon monoxide which is absorbed by the blood in lieu of oxygen, and if a man is continuously exposed he rapidly succumbs. This is the case when there is over .3 of 1 per cent. in the atmosphere. Moreover, recovery of one partly poisoned is slow. It seems probable that when a man is regularly exposed to small quantities in the air, he may become in time more or less incapacitated.

With nearly all high or quick explosives on the market, carbon monoxide forms a large portion of the gases of combustion. From time to time we hear of men being overcome in the mines by such gases and in some instances even being killed—notably the case that occurred in the Gunnison tunnel, in Colorado, on January 16, 1910, when a shift of men while waiting for the smoke from a round of 50 holes to clear, were overcome and nine of them died, evidently due, according to the facts as reported, to monoxide poisoning.

Investigation of Mine Accidents by Bureau of Mines.—Under the terms of enactment of the Bureau of Mines, the investigation of coal-mine accidents, started under the jurisdiction of the United States Geological Survey, will be continued by the Bureau of Mines. This investigation consists of testing of explosives for use in gaseous or dusty mines (those that pass being listed as "permissible explosives"), the investigation of safety lamps and of rescue apparatus of all kinds; the establishment of rescue stations for the education and training of miners in the use of rescue apparatus; the investigation of mine disasters by mining engineers, with a view to finding preventives; the study of the humidity of mine air in its effect upon the drying or moistening of coal dust; the collection and analysis of mine gases and study of their sources and changes of efflux from the strata; the study by electrical engineers of the different phases of mine installations with a view to lessening the dangers therefrom, and the collection by the mining engineers of samples of coal throughout the country, which, while partly for governmental fuel supplies, is also of service in connection with mine accident work, through the relation of the coal to the production of dust and gas.

The foregoing work has in the past been carried on by a well-equipped laboratory at Pittsburg, aided by a small field force of mining engineers. Much time has been occupied in purely educational work among the miners and foremen. It is proposed to continue all this work and possibly to enlarge slightly from time to time as funds may be provided by Congress, to better cover the widespread coal fields of the country.

Under the law establishing the Bureau of Mines, the scope of the work has been enlarged, and the investigation of mine accidents has been extended to cover both quarries and metalliferous mines. It is expected that mining engineers who have been already connected with the mine-accident investigations on coal mines will extend their observations so far as possible to all kinds of mining and quarrying.

The appropriation for this year will allow but few additions to the force, but if the results justify, it is not improbable that Congress will provide for extension of the work in the future.

It is manifest that there is ample room to do good work in the investigation of the metalliferous mine accidents, particularly in studying in the field the effects of stone dust and of gases arising from the discharge of explosives and, at the Pittsburg station, in the study of the explosives used in metal mining with a view to obtaining such explosives that the products of combustion will be less harmful to the health of the miners.

In another direction, in quarries and in metalliferous mines, the gathering of statistics of accidents by a Federal Bureau, working in conjunction with state bureaus, a work hitherto ably done by Mr. E. W. Parker for coal-mine accidents, will be of great value, inasmuch as it will lead to precautions being taken to prevent many accidents, the causes of which are often overlooked. Unification of the methods of gathering such mine-accident statistics will also be of value, inasmuch as it will enable the intelligent comparison of similar kinds of accidents in different districts and countries and thus lead to betterment of conditions.

Beside this valuable feature there is another. It is the tendency of the times to look forward to a time when each industry will bear the load of caring for its killed and injured. Already a number of progressive mining companies have started insurance organizations, the cost of which is borne partly by the employes and partly by the companies. In any case, there can be little question that if an industry is in a thoroughly healthy condition, it should be able to bear the cost of caring for those injured in its business, and for the pensioning of needy widows and orphans, to a greater or less extent. As a matter of common humanity, this proposition can hardly be disputed. If prevailing conditions prevent, it means that the price obtained for the product should be raised to meet these conditions. No doubt this movement must be gradual to not disarrange business affairs.

Accompanying this paper, there are forms giving suggested classifications of accidents in metal mines and coal mines. These classifications are not in any sense final, but are put

forward for discussion. They follow to some extent the English system, though a little more elaborate. It is only by close subdivision that analysis of the causes of accidents can be made satisfactorily.

In another matter the Bureau of Mines may be able to give valuable aid, namely: In promoting the unification of mining laws and regulations, such as those proposed by the several committees reporting to this Congress.

There are doubtless many problems in connection with mine accidents which are not mentioned in this paper, and of which members of the Bureau of Mines staff will be glad to learn from the mining engineers of the country. While the question is complex, it is worthy of our best efforts since it deals with the lessening of loss of life and limb.

SUGGESTED FORM FOR TABULATION OF METALLIC MINE ACCIDENTS

I. Underground Accidents

(*a*) *Falls of Roof, Wall, or Timber:*
- 1. Fall of roof or hanging wall in headings.
- 2. Fall of ore or wall in stope or winze.
- 3. Slippage or breakage of timbers.
- 4. Run of ore in chutes.

(*b*) *Miscellaneous Underground:*
- 1. Explosives:
  - (*a*) Handling loose explosives.
  - (*b*) Thawing.
  - (*c*) Premature fires.
  - (*d*) Digging out misfires.
  - (*e*) Flying pieces from blast.
- 2. Suffocation:
  - (*a*) By natural gases.
  - (*b*) By gases from fires.
  - (*c*) By gases from blasts.
- 3. Irruptions of water.
- 4. Haulage.
  - (*a*) Breakage of rope.
  - (*b*) Run over or crushed by cars.
- 5. Electric shocks.
  - (*a*) Trolley.
    - 1. Below 300 volts. 2. Above 300 volts.
  - (*b*) Power cable.
    - 1. Below 300 volts.
    - 2. Above 300 volts.
  - (*c*) Switches.
  - (*d*) Electric machines or pumps.
- 6. Man falling down: (*a*) winze. (*b*) chute. (*c*) stope. (*d*) manway.
- 7. Drilling accidents (from machine or drills).
- 8. Miscellaneous.

II. Shaft Accidents

- 1. Overwinding.
- 2. Connections or ropes breaking.
- 3. While ascending or descending shaft by machinery.
- 4. Falling into shaft.
  - (*a*) From surface.
  - (*b*) From part way down.
- 5. By things falling down shaft:
  - (*a*) From surface.
  - (*b*) From part way down.
- 6. Miscellaneous shaft accidents.

III. Surface

- 1. Head-house accidents.
- 2. Outside tramway.
- 3. Power-house accidents.
  - (*a*) Boiler and engine. (*b*) Electric shocks.
- 4. Miscellaneous surface accidents.

Note.—It is proposed gathering the statistics for the number of accidents and number of men killed and injured by accidents, tabulating each of the three classes separately.

SUGGESTED FORM FOR TABULATION OF NON-METALLIC MINE ACCIDENTS

I. Underground Accidents

(*a*) *Explosions:*
- 1. Coal Dust.
- 2. Firedamp.
- 3. Coal dust or firedamp (cause undertermined).

(*b*) *Falls of Ground:*
- 1. Fall of roof at face.
- 2. Fall of roof in drawing pillars.
- 3. Fall of coal at face.
- 4. Fall of roof in roadways.

(*c*) *Miscellaneous Underground:*
- 1. Explosives:
  - (*a*) Handling loose explosives.
  - (*b*) Thawing.
  - (*c*) Premature firing.
  - (*d*) Digging out misfires.
  - (*e*) Flying pieces of rock or coal from shots.
- 2. Suffocation.
  - (*a*) By natural gases.
  - (*b*) By gases from fires.
  - (*c*) By gases from blasts.
- 3. Irruptions from water.
- 4. Haulage.
  - (*a*) Rope breaking.
  - (*b*) Run over or crushed by cars or locomotive.
- 5. Electric shocks from:
  - (*a*) Trolley wire.
    - 1. Below 300 volts. 2. Above 300 volts.
  - (*b*) Fixed power cable:
    - 1. Below 300 volts.
    - 2. Above 300 volts.
  - (*c*) Switches.
  - (*d*) Machines or trailing cables.
- 6. Man falling down:
  - (*a*) Winze.
  - (*b*) Chute.
  - (*c*) Stope.
  - (*d*) Manway.
- 7. Drilling or mining machine accidents.
- 8. Miscellaneous.

II. Shaft Accidents

- 1. Overwinding.
- 2. Rope or connections breaking.
- 3. While ascending or descending on cage.
- 4. Falling into shaft.
- 5. By things falling into shaft.
- 6. Miscellaneous shaft accidents.

III. Surface Accidents

- 1. Tipple or tower accidents.
- 2. Outside inclined-plane or tramway.
- 3. Power-house accidents:
  - (*a*) Engine or boiler accidents.
- 4. Electric shocks.
- 5. Railroad accidents (incident to loading and switching).
- 6. Washery and coke-oven accidents.

Note.—It is proposed gathering the statistics for the number of accidents and number of men killed and injured by accidents, tabulating each of the three classes separately.

According to Professor Phillips of the University of Texas, 10,767,866 tons of coal and 5,488,218 tons of lignite have been mined in Texas since 1884. There are 8,000,000,000 tons of lignite and 23,000,000,000 tons of coal remaining in an area of 68,500 square miles,

TURBOBLOWERS AND COMPRESSORS *

One of the newest uses to which steam turbines have been successfully put is the driving of turboblowers and turbocompressors.

Construction and Operation of Air Compressors on the Turbine Principle for High Pressures

The turboblower and turbocompressor, is a suitable machine for exhausting or compressing large volumes of air or gas. It is suitable for ventilating mines, for supplying the blast to cupolas and coke ovens, and for respectively supplying compressed air or gas to, or for exhausting air or gas from, the various apparatuses and processes used in chemical works and similar undertakings.

Although only a short time ago it was usually considered to be impossible to make a commercially efficient and serviceable blower for any but the lowest pressures, it is claimed that even at pressures as high as 150 pounds per square inch the new type of turbocompressor is at the very least equal in thermal and mechanical efficiency to the best kind of reciprocating air compressor, whilst from a commercial point of view, the turboblowers or compressors are often preferable on account of advantages attainable through their introduction. The following are some of these advantages:

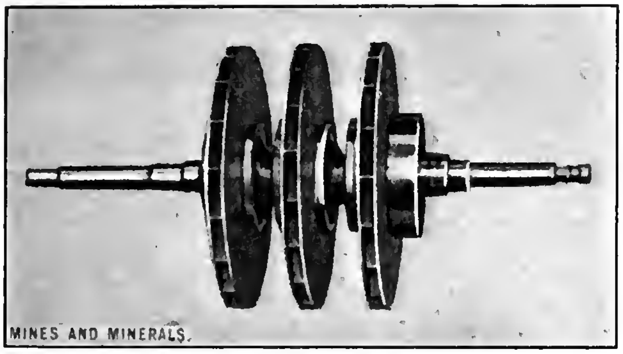

Fig. 1. Impellers for Turboblower

1. The turboblowers and compressors deliver a steady (non-pulsating) current of air or gas.
2. They run practically without noise at all loads.
3. They are simple in construction, have all parts easily accessible, and are reliable in action.
4. They not only require very little attendance and lubrication when at work, but relatively speaking, a minimum of space for their accommodation.
5. They require a minimum of power to drive; they are also easily governed through a wide range of variation of speed, without materially affecting their economy.
6. They are perfectly balanced both dynamically and in respect of axial thrust.

As already stated, turboblowers are adopted for a variety of purposes. It is possible they are preferable to reciprocating engines in all cases where the volume of the air or gas to be handled is sufficiently great, quite irrespective of whether they are required to produce a rise of pressure or a partial vacuum. The turbo compressor, in a like manner, is suitable for all pressures up to 120 pounds per square inch, if the volume of gas to be handled is sufficiently large. Both the blowers and compressors are suited for direct coupling to steam turbines, but they may equally well be driven by electromotors of suitable size and speed.

The impeller shown in Fig. 1 is similar in design and detail, whether intended for a blower or for a compressor. To avoid the high stresses to which it is subjected the impeller is built up of those materials which are most suitable for the various parts of the wheel. Thus, the bosses are steel castings, whilst the cheeks are of special steel plates. The latter, as shown in Fig. 2, are conical in cross-section, and attached to the boss in such a manner as to allow free expansion of both cheeks under

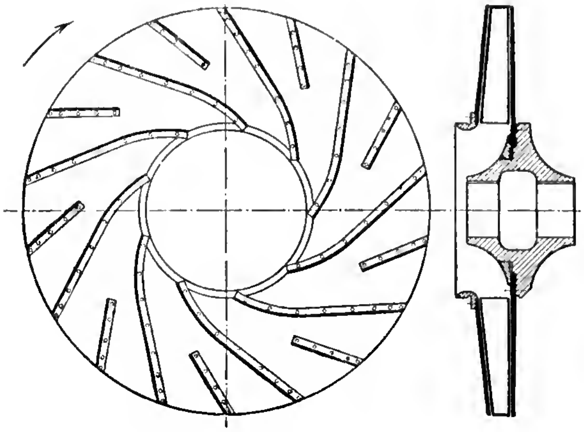

Fig. 2. Sectional View of Impeller

the influence of centrifugal force. As a result of this construction, the impeller runs true and steady at all speeds, and permits of the running clearances being reduced to a minimum, with the result that internal circulating losses are small.

The housings of these turboblowers and compressors are respectively designed to suit the requirements of the two types of machine. In both cases the housing is fixed at one (the driving) end only, and is free to move with variations of temperature at the other.

In the turboblower shown in Fig. 3 the inlet cover is provided with substantial feet solidly connected to the bedplate. The pressure end and intermediate parts of the casing overhang the bedplate, but are well connected to the inlet cover by

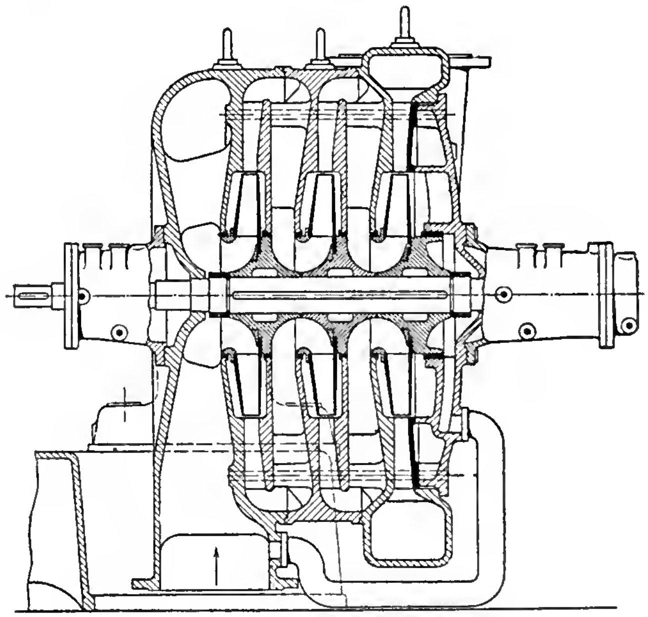

Fig. 3. Section of Turboblower

vertical, cylindrical, spigot, and faucet joints. The general design is such that all parts of the blower are easily reached for examination or adjustment.

In the case of the turbocompressors, the same general principles of design are followed. As, however, a compressor is usually of considerably greater length than a blower, the two

* *Iron and Coal Trade Review.*

bearings of the former, situated one at each end of the machine, are designed to support the casing as well as the rotor at both ends. Here, too, on account of the greater length of the unit, although the vertical divisions of the casing are maintained, a further horizontal division is introduced, as shown in Fig. 4, so that, after removing the upper half of the housing, each impeller and its corresponding part of the casing are freely accessible for inspection.

The ease with which air may be cooled whilst being compressed in a turbocompressor is to no small extent answerable

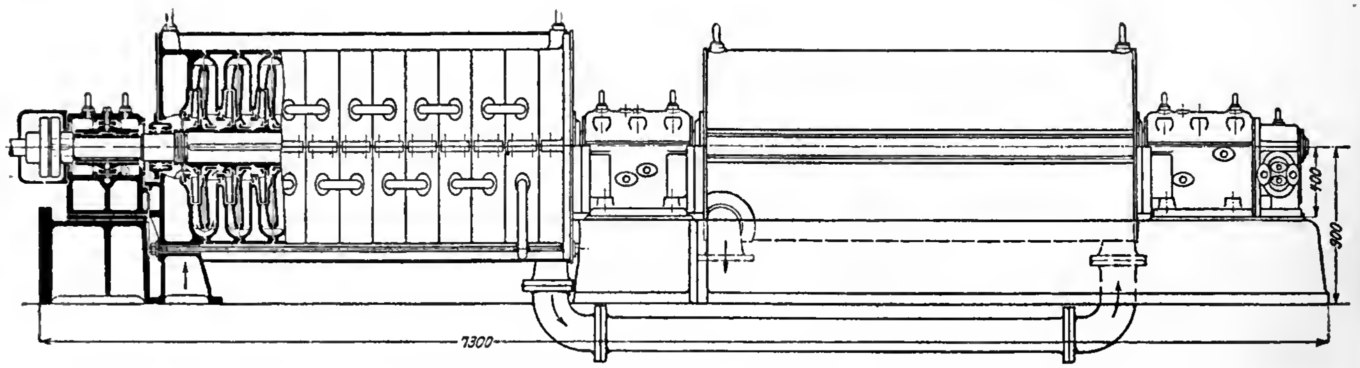

Fig. 4. Sectional Elevation of Two-Cylinder Turbocompressor

for the good efficiency of the unit. When reciprocating engines are employed, the effect of water-jackets decreases as the cylinder volume increases; for which reason, if low final temperatures are to be obtained, multistage compressors must be resorted to and intermediate coolers employed. In the case of turbo machinery, the form of the housing and the condition in which the air or gas passes through the machine are both favorable to the efficient use of water-jackets. The rise of temperature can therefore be reduced to a minimum.

The easy and economical method of regulating the delivery and pressure of these blowers compares favorably with the methods—such as by-pass mains and variable clearance volumes, etc.—necessary with some types of blowing machinery. Delivery volume, pressure, and rotary speed vary, as is the case with centrifugal pumps, in fixed proportion to one another; consequently, delivery volume and pressure may be changed by simply varying the rotary speed. At constant speed, volume and pressure may be varied by adjusting the regulating valve usually situated in the suction main. By this means the delivery volume may be varied between its maximum value and zero, the power consumed falling with the reduction of volume, while the efficiency, as shown in the curve, Fig. 5, is but slightly affected, even by comparatively large changes of volume.

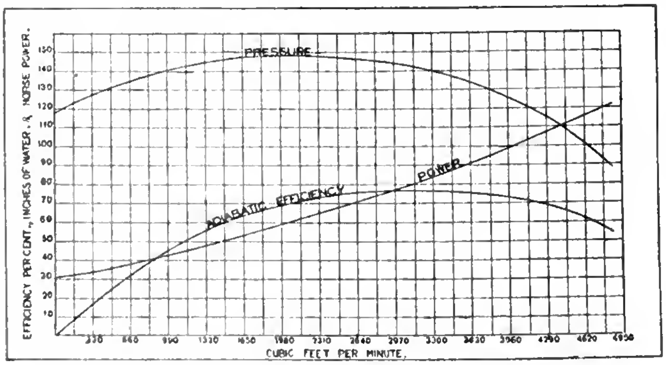

Fig. 5. Pressure, Efficiency, and Power Curves of Turboblower

If turbocompressors are directly coupled to steam turbines, a pressure-regulating device can be made to govern the speed of the turbine in such a way as to maintain a constant air or gas pressure in spite of variations of delivered volume. The high efficiency already obtained (78 per cent.) as referred to adiabatic compression, places these turboblowers very favorably in comparison with the best reciprocating blowing engines. Within the past three years electricity has been applied to air compressors attached to coal cutters and its adoption would be in line as power for multistage blowers.

SOCIETY MEETINGS

About 120 members of the American Institute of Mining Engineers left New York on the steamer Prinz August Wilhelm, on October 21. The itinerary of the canal zone meeting includes Havana, Cuba; Kingston, Jamaica; Colon, Panama; Port Limon, Costa Rica; Colon, Kingston, and Fortune Island; arriving in New York, Tuesday, November 15. An account of the trip will appear in the January issue of Mines and Minerals.

The West Virginia Coal Mining Institute will hold its next meeting at Wheeling, W. Va., December 6, 7, and 8. An interesting and instructive program has been arranged, which with the entertainment features will make this meeting one to be remembered.

The 1911 annual meeting of the Canadian Mining Institute will be held on Wednesday, March 1. Members contemplating contributing papers to the proceedings will greatly oblige the secretary by informing him as soon as possible. It is desirable that the manuscript of all papers should be in the hands of the secretary not later than the 15th of January next, to admit of the issuance of advance proofs for discussion purposes. If manuscript is received later than the above date, its publication in advance of the meeting cannot be guaranteed.

Coal Mining Institute of America will hold the next meeting in the Engineering Building of the Carnegie Technical Schools, Pittsburg, December 15 and 16. Membership in this institute is open to all mining men, and all members receive the proceedings each year in a bound volume of about 400 pages. Membership $2. Bound volume to non-members $2. Charles L. Fay, secretary, Wilkes-Barre, Pa.

Coal Mining Institute of West Virginia will hold the next meeting in Wheeling, W. Va. Membership in this institute is not confined to West Virginia. The proceedings are published annually and can be purchased from Edward B. Day, secretary, 108 Smithfield Street, Pittsburg, Pa. The annual membership fee is $2.

Consul Frederic W. Goding writes from Montevideo, Uruguay, that arrangements are being perfected to develop the manganese deposits in and around Zapucay, Department of Rivera, which consist of two large mountains of that mineral, one of which, according to British geologists, is among the richest known, containing 150,000,000 tons of first-grade manganese. As the current price is $15 per ton, the mineral contained in the measured area represents $2,250,000,000.

FALCONE OVEN TILE-LAYING MACHINE

Written for Mines and Minerals

In the October issue of MINES AND MINERALS there was a brief article by Bert Lloyd on "The New Tile-Laying Machine," which was introduced at the Cokedale plant of the Carbon Coal and Coke Co., in Colorado. The tool, which was invented by Michele Falcone, of Cokedale, is strictly an expense reducer in laying tile where beehive or Welsh coke ovens are in operation.

Operating Data From the Cokedale Plant, Las Animas County, Colorado

The cost data given below relative to this machine are authentic in every respect and will be of special interest to all who are connected with or interested in the operation of coke oven plants. Frederick P. Bayles, E. M., superintendent of the Cokedale plant has kindly furnished the data relative to this machine which has been in use since July, 1909, during which time 140 hot ovens have received new bottoms without the loss of a single charge of coke from the oven cooling. Information concerning these ovens is that they are of the standard 13 feet diameter, 7½ feet high, beehive type with one hundred and thirty-five 4″×12″×12″ tile per oven, therefore the tool has replaced 18,900 tile since its introduction, and withdrawn nearly as many more. At the Cokedale plant the ovens are pulled by a machine, similar to those shown in Fig. 1, and are charged with 11,466 pounds of washed slack containing 9.4 per cent. moisture, but whose dry weight is 10,388 pounds (5.294 tons) and whose coke yield is 7,593 pounds (3.797 tons) or 73.09 per cent.

FIG. 1

The Cokedale ovens are of special interest because of the ring and wharf walls being of concrete, while the oven walls, Fig. 2, and the piers, Fig. 3, are of reinforced concrete. It is believed that the remarkable yield of coke, 75 per cent. of the charge, is due in a measure to the oven construction, which prevents the entrance of excess air, and also to the close regulation and control of the oven draft.

The ovens are pulled from 1 A. M. until about 10 A. M., and as the day shift, who repair oven bottoms, do not come on until 7 A. M., there is a delay which is an operating convenience and not a necessity. After pulling the coke, and before cleaning out the old bottom tile previous to repairing, there is an average delay of 3.60 hours. From the time the coke is pulled until the oven is charged after repairing, the average is about 12.23 hours, divided as follows:

	Hours
Before cleaning out the old bottom	3.60
Cleaning out the old bottom	2.01
Placing and leveling sand	.77
Laying new tile by machine	1.15
Delay after repairs	4.70
Total	12.23

The delays before and after repairs are due to normal working conditions and could be eliminated were the saving in so doing of sufficient moment. The time necessary for the charge to catch on fire, after an average delay of 12.23 hours, using an average charge of 11,466 pounds of washed slack containing 9.4 per cent. of moisture is 1.60 hours.

TABLE 1

Leveling Sand		
1 machine man at 30 cents for .77 hour	$.2310	
1 helper at 17½ cents for .77 hour	.1347	
	$.3657	$.3657
Laying Floor		
1 machine man at 30 cents for 1.15 hours	$.3450	
1 helper at 17½ cents for 1.15 hours	.2012	
	$.5462	$.5462
Total cost of machine laid floors		$.9119

In the year 1909, 37,862 ovens were pulled at Cokedale, producing a total of 190,093 tons of coke, or an average of 5.02 tons coke per oven pulled. The loss in coke yield due to placing a new bottom with this tile machine was 1.223 tons or 24.5 per cent. of the normal yield, which is practically $\frac{1}{30}$ of the loss which occurs when laying tile by hand.

The total loss in the production of coke from the delays caused by the repairing or relaying of 140 new floors amounted to 171.2 tons, which in the production of 466,254 tons is .0003 per cent. The cost of removing the old floors, hauling and placing sand in the oven, would be practically the same with machine or hand practice. See Table 1

To appreciate the difference in saving in time and money it is to be borne in mind that with hand-laid floors the oven must be cooled down sufficiently to permit a man to enter; this calls for a shut-down of from 10 to 12 days before repairs can be made and the oven again put in coke.

On account of the heat in the oven it will take a brick mason and helper one-half day and often longer to relay a floor by hand,

FIG. 2

exclusive of the time necessary to remove the old floor and place sand.

1 mason at 30 cents, 5 hours	$1.500
1 helper at 17½ cents, 5 hours	.875
Total	$2.375

Before comparison between machine and hand work is made the cost of reheating the ovens after repairing by hand is to be considered, and this Mr. Bayles gives as follows:

½ cord wood, $4 per cord	$2.00
Hauling, splitting, and placing in oven	1.50
3 tons coal, $1 per ton	3.00
Stirring, building, and tending doors, pulling and disposal of sweat coke	3.00
Total	$9.50

This makes the total cost of hand work $11.88 as against 91 cents by machine.

With machine-drawn ovens the bottoms should be replaced once every year and with hand-drawn ovens once every 2 years, if the ovens are to be kept as they should be.

The loss in production of coke while the oven is out and from faulty and inferior coke from the first and second charge will bring the operating cost to very close to $15 per oven per annum for machine-pulled ovens, and about $7.50 per oven per annum for hand-pulled ovens, against a cost of $1 per oven per annum for machine-repaired machine-pulled ovens, and 50 cents per annum for machine-repaired hand-pulled ovens.

Fig. 3

DETERMINING VERTICAL DEPTHS IN DRILL HOLES

In the construction of the new aqueduct of the city of New York, which crosses the Hudson River just north of West Point, it became necessary to determine accurately the vertical depths of the narrow diamond-drill bore holes which are being sunk under the Hudson River at various angles and which have already reached depths of 1,500 feet.

This problem has been solved by Prof. G. N. Lewis and Prof. H. T. Kalmus, of the Massachusetts Institute of Technology, who have devised a self-recording pressure gauge which has a diameter of less than ¾-inch and can therefore be placed directly in the terminal section of the drill rod. Since the bore holes are constantly filled with water, the maximum hydrostatic pressure recorded is a direct measure of the vertical depth. It seems probable that this instrument may be of service in other engineering and mining work where it is desirable to determine the vertical depth of bore holes used in prospecting.

The pressure gauge proper consists of a very thin strip of tempered steel bent into the form of a hollow rectangular tube approximately ⅝-inch wide, $\frac{1}{32}$-inch thick, and 18 inches long. The edges and the lower end of the tube are welded together with the oxyacetylene flame. Into the upper end is welded a small steel tube which in turn is sealed to a straight glass tube, the upper end of which enters an air-tight chamber. The gauge and connecting glass tube are filled with mercury and when subjected to an external pressure the thin steel walls of the gauge undergo considerable temporary deformation, thus diminishing the total volume of the gauge and forcing the mercury from the upper end of the glass tube into the surrounding chamber. When the pressure is released the gauge resumes its original volume and the mercury level in the glass tube falls through a distance which measures directly the pressure to which the apparatus has been subjected. The mercury may now be returned to the glass tube from the surrounding chamber by a simple device.

The instrument gives remarkably reproducible results and is able to record vertical depths up to 1,500 feet with an error of no more than 2 or 3 feet. On account of the extremely small volume of the thin steel gauge, the effect of temperature changes, even amounting to 30 or 40 degrees, is entirely negligible.

THE INNOKO DISTRICT, ALASKA

The discovery of gold placers on Otter Creek, a northern tributary of Haiditarod River, in the Innoko Valley, caused a movement of population in 1909 which promises to be important. Thousands of prospectors and miners flocked to this district from all parts of Alaska, as well as from points outside the territory. Although the district may not support the large population it has acquired, it seems to offer a promising field for exploitation. The output of the year in the Innoko is variously estimated at $300,000 to $400,000 in gold. A government survey of the district is now under way.

ELECTRICALLY DRIVEN PUMPS

The electrically driven three-stage centrifugal pumps, shown in Fig. 1, are of particular interest to coal miners where electricity is in use for driving machinery.

One of the most up-to-date plants of this kind is at the Eureka mines of the Berwind-White Coal Co., at Windber, Pa.,* where there is a central pumping station which drains a large area. The Windber plant pumps 4,000 gallons of water per minute against 330-foot head.

Another centrifugal stage pump is installed in the Keyser Valley central pumping station near Scranton, Pa. Each unit of the pumps shown in Fig. 1 comprises a Westinghouse induction motor designed for 500 horsepower at 750 revolutions per minute, with three phase-current at 400 volts direct-connected to the pump. There are three of these units although but two are shown in the illustration, and after being installed at the pumping station for which they were designed they were tested.

Each unit was run continuously for 15 hours, during which time readings of the electrical input were taken every 5 minutes; readings of the Venturi water meter every 10 minutes; pressure gauge every 5 minutes, and revolutions of pump every 15 minutes. The results of one test will answer for all.

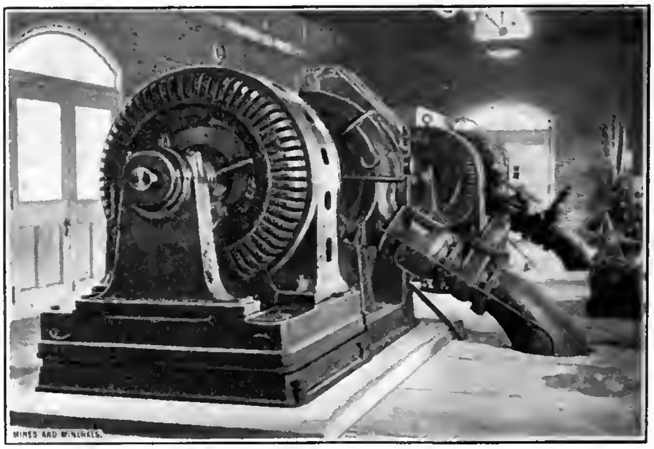

Fig. 1. Electrically Driven Pumps, Keyser Valley Plant

Maximum revolutions per minute	746
Minimum revolutions per minute	738
Average revolutions per minute	743
Maximum gauge pressure, pounds	143.5
Minimum gauge pressure, pounds	119.5
Average gauge pressure, pounds	136.9
Average head, feet	315.8
Gallons pumped per hour	238,000
Gallons pumped in 24 hours at this rate	5,712,000
Kilowatt input per hour	343.4
Gallons per kilowatt hour	1,454
Hydraulic horsepower	318
Electric horsepower	456.6
Efficiency per cent	69.6
Duty, foot-pounds per 1,000 kilowatts	30,800,000
Degrees temperature rise in 15 hours	41

* Mines and Minerals, Vol. XXX, page 457.

PROSPECTING FOR SILVER

Silver, once called a precious metal, is now an ordinary commercial substance, whose intrinsic value is so low, about 20 cents per ounce, that it it not sought so eagerly as formerly.

Tests By Which It May Be Identified Methods of Occurrence and How Deposited

It would be folly on the part of the prospector to pass it by simply because it is so common a substance, for there are possibilities that it may be in large quantities or associated with other metals which will enhance its value. While silver is found occasionally in metallic form, it is more frequently found associated with other metal minerals, for instance, copper, lead, and gold. When native it resembles the silver in coin, although possibly a little brighter or darker in color. It can readily be distinguished in this form, but if there is doubt it can be melted with a blowpipe on charcoal, or if that useful little instrument is not available it will dissolve in nitric acid. If a little salt be added to a silver nitrate solution white silver chloride will be precipitated. If a few drops of hydrochloric acid be added to a silver nitrate solution silver chloride will be precipitated, which is soluble in ammonia, while lead chloride is not. Silver chloride is insoluble in hot water, while lead chloride is soluble, but will precipitate on the solution becoming cold.

With these few simple tests the novice can distinguish lead from silver, although frequently the two are associated in nature; in fact it is a rather rare occurrence to find lead sulphide free from silver.

The greater part of the silver produced in the United States is obtained when smelting lead and copper ores.

The greater part of the silver produced in Mexico comes from lead-silver ores. These ores also carry some gold, which oftentimes is sufficient to pay for their treatment, although not in such quantity that they could be classed as gold ores.

The greater part of the silver produced in Ontario, Canada, is almost native, although associated with cobalt and nickel minerals.

The first large silver deposit found in this country was the celebrated Comstock lode, in Nevada. The black sulphide of silver was at first thrown away by those who were washing for gold, and even broken up to obtain the free gold in the lumps. As soon, however, as an assay disclosed its nature mining commenced in earnest. The gangue in this deposit was mostly quartz and the vein has been worked to a depth of 3,100 feet, making it evident that the solutions forming the vein came from great depths. Argentite, or silver sulphide, contains 87.1 per cent. of silver and 12.9 per cent. of sulphur. It occurs in cubes and octahedrons, massive; as scales, coatings, and tree-like markings. It has a blackish lead-gray color. Its streak on porcelain has a lead-gray color and a shining metallic luster. It is partly soluble in nitric acid, and when in solution will silverplate a copper strip. The mineral is as readily cut as lead; will flatten under the hammer, and is easily melted.

Other silver deposits were found in Nevada, although they were not remarkable, and it was not until 1878 that any bonanza silver deposits attracted attention. These were at Leadville, Colo., where the lead sulphides and carbonates were found in imestone adjacent to porphyry. In places very rich silver ore was found and often associated with it was gold. Closely following this were the Butte, Mont., deposits, which were in granite that had been cut by intrusive dikes, forming fissures that were afterwards filled by solutions carrying copper sulphides, gold, and silver. The copper sulphides were weathered, leaving the gold and silver in great masses near the surface. The gangue in this instance is quartz, indicating that the mineral solutions came from below.

Following this discovery came the Mollie Gibson and Aspen silver deposits in Colorado. These mines were in limestone adjacent to porphyry, and like the Leadville mines, were contact deposits. Probably the next most noted silver deposit was found by a burro in the Couer d'Alene district at Wardner, Idaho. The silver-bearing galena seems to be as rich in the Bunker Hill and Sullivan Mine at a depth of 2,100 feet, as at the surface. The mine is said to have paid over $7,000,000 in dividends since its discovery in 1885. It is at present the richest silver mine in the United States, and other silver-lead deposits are being discovered in the same district almost every year. The deposits are in a mineralized zone, having quartzite foot wall and an impregnated hanging wall of brecciated quartzite. The rocks in this section are quartzite and schists that have been folded and otherwise distorted.

In the Cobalt district in Canada there are some exceedingly rich silver veins in diabase. The outcrop of these veins is colored pink by cobalt bloom, and if nickel be present a greenish tinge is observed. The silver in this district is almost native and is associated with calcite gangue showing that the ascending solutions carrying silver were met by descending solutions carrying carbonate of lime.

While silver is found in the older formations in quartz veins, and in the Cobalt district with calcite gangue, the largest deposits are found in limestone adjacent to porphyry. It seems remarkable at first that this should be the case until the same phenomenon is noticed in the case of copper sulphides and galena.

Both copper and galena when in sulphide form are associated almost invariably with silver. If they become weathered or taken in solution they leave the silver to be absorbed by some other solution, and this traveling along crevices in limestone eventually finds some mineral or solution which precipitates the silver.

For example, silver sulphate in solution could be precipitated by a salt solution forming insoluble silver chloride, known also as horn silver or cerargyrite. Large deposits of this mineral are rare, but it is found associated with other silver minerals. It is soluble in ammonia but not in nitric acid. Being soft and waxy it is readily melted, and will, when wet and placed on zinc, turn black, swell up, and show metallic luster if pressed with the point of a knife. It is usually found near the surface, but also in some depth in deposits formed from other minerals, being oxidized and taken into solution. Horn silver contains 75 per cent. silver and 25 per cent. chlorine. It is whitish with other shades of color at times.

Should the silver be in solution and meet another solution containing antimony, ruby silver would be formed. Ruby silver is a black mineral with a dark red tinge. It generally looks massive, but under the glass it is seen to be finely crystallized. It gives a dark red streak on porcelain; is easily melted, giving off sulphur fumes, and is soluble in nitric acid. It might be mistaken for proustite or light red silver, but to the prospector this makes little difference. Light red silver contains sulphur and arsenic instead of sulphur and antimony. It is soft, gives a bright red streak and has a bright red color. It is decomposed by nitric acid and melts easily. Both minerals are associated and at times carry considerable gold. Several other silver minerals are known, but usually are associated with other metals or non-metals to such an extent as to be unrecognizable, although at times they can be determined by tests.

Limestone is generally bluish-gray or drab, but cannot always be recognized with the eye; however, a drop of acid will cause it to froth. Silicious limestone will not effervesce, and in all probability silver deposits will not be found in it. Porphyry weathers more or less at the surface unless highly silicious, and is generally white or gray with crystals of some other minerals prominent in a fine mass. It is an intrusive rock that often forms great dikes. It is presumed that solutions bearing minerals accompany the intrusion, and these, finding their way into limestone, deposit their mineral constituents. Another reasonable supposition is that the mineral in porphyry weathers and is carried down by surface waters and is then deposited.

THE MEXICAN SITUATION

PEOPLE in the United States when asked to invest in Mexican enterprises, have stated that while under President Diaz their investments would be safe, there are a large number of malcontents who under less firm management would stir up internecine war. The educated and refined Mexicans, the men who have made their wealth by their brains, voice the same opinion, all of which reflects on the integrity of Mexico as a nation.

The answer to this has been, that so much foreign capital is now invested in Mexico that the United States under the Monroe Doctrine will be obliged to protect it.

While this is undoubtedly true, the uprising against United States citizens who have transgressed no law of the Republic, and the insult to the people of the United States as a whole, argues that the self-imposed patriots are plunging their country into trouble.

People in the United States desire to live peaceably, and to that end accept a certain amount of imposition, but when their neighbors become a nuisance hard feelings are engendered and ructions occur.

The people in the United States know that the citizens of Mexico did not encourage the half-baked students and political shysters to insult them by trampling on their flag, in fact the press as a whole, held the Mexican Government blameless, in a matter which no European country would tolerate.

In nearly every locality in Mexico there is a politician who imagines himself the government in his bailiwick. This species hates the gringo who invades his bastion and pays out real pesos that accomplish results, for the reason that his importance as the leading citizen is on the wane and his former constituents are climbing to an eminence which challenges his superiority.

The Germans have circulated scurrilous literature to foment this hatred and, as the politician has a certain following, progress toward improvement is slow. Bucolic and jealous, he is unable to realize that the foreign invasion adds to his country's wealth and enlightenment, and being ignorant of affairs he is unable to share in the general prosperity. He has a grouch because the foreigners do not place him in some position of importance which he is not able to occupy. The younger generation are in a better position and will occupy positions of trust and responsibility provided they take advantage of their opportunities to attend the schools and colleges in Mexico that make for progress. People who have invested in enterprises in Mexico would rather employ Mexicans than people from the States, for the latter are apt to leave at any time for home. The writer is sure of this for he left an excellent position in Mexico to be with his own people, and therefore from hearsay and knowledge there seems to be no question but that the educated Mexican will come into his own, always provided the "sour balls" can be subdued. There are certain states in the United States whose laws inflict death for ravishing women. As the

people make the law, they sometimes constitute themselves judge, jury, and inflictors of punishment.

If the man in Texas had not committed the crime he did, he would not have received the horrible death penalty. Even this was no excuse for mobbing inoffensive citizens whose only crime was that they were English-speaking Americans, and an abject apology is coming.

MINE PROMOTION LITERATURE

JULIAN HAWTHORNE claims that for the sake of the Hawthorne Mining Co., Ltd., whose properties are said to be in Canada somewhere, he has abandoned literature and journalism. The *Cobalt Nugget* says: "A perusal of the prospectus would seem to refute this, as he has not given up fiction and he still wields a fascinating pen."

The *Mining Investor* says: "Julian Hawthorne is a writer who has nobly overcome the handicap of a distinguished literary name." "In his pamphlet, 'The Secret of Solomon,' Mr. Hawthorne points out three well-known facts: First, that King Solomon was the wisest of men; second, that he was also the richest of men; and third, that he made his money from mining."

The mysterious veil which heretofore enveloped Solomon's title to supremacy in wisdom is now brushed aside—he was a mining engineer.

A poor man's riches consist in children, and as Solomon had a thousand wives who worked for him, and no children to speak of, he ought to have been as rich as Rockefeller at least. That he made his money from mining should be qualified to read, he obtained his money from mines. Some of the thought gems from Hawthorne's "Solomon" are the following:

"Unwrap from its napkin that talent in the safe-deposit drawer."

"Take the tide at its flood."

"Climb, and do not fall."

"Open the door to opportunity."

"Remember that Solomon looked before he leaped."

"Study the situation well."

"He that lingers till tomorrow buys dear what was cheap yesterday."

As a Recessional to those who hesitate to invest he furnishes this:

"He either fears his fate too much
Or his desert is small,
Who dares not put it to the touch
To win or lose it all."

EDUCATING THE ANTHRACITE MINER

COL. R. A. PHILLIPS, Superintendent of the Delaware, Lackawanna & Western Railroad Co.'s coal mining department, has reached the conclusion that it is easier to teach non-English speaking mine workers to protect themselves in the mine through their eyes than through their ears.

He is therefore having a series of about 80 subjects photographed showing the right and wrong method of doing things in mines.

Mr. Bunnell, the official photographer, takes these pictures inside the mines, thus making them realistic and difficult to be misunderstood.

Slides will be made of the photographs so that they may be projected on screens where all miners attending the monthly meetings of the Y. M. C. A. mining institute can see them.

The Y. M. C. A. is laboring faithfully to educate the foreign-speaking mine workers in order to reduce fatalities and injuries to a minimum.

Mine superintendents appreciate their endeavors and aid the representatives financially and in the practical way mentioned. Colonel Phillips proposes to supply a full set of slides to the anthracite committee of the Y. M. C. A. for each class of foreign miners.

HOW ABOUT THIS

BEFORE many years have passed the hard coal operators in Northeastern Pennsylvania will be confronted with a problem as serious as any that has occurred in anthracite mining. According to prevailing laws a man must work 2 years as a laborer, 5 years as a miner, and then pass a rigid examination as to his fitness to occupy the position of mine boss.

At present, with competent captains at the helm, the coal companies are sailing unruffled seas, but where are the master mariners' mates who will command the ships when nature asserts itself and the captains go over the side. Would it not be policy to import young educated English speaking miners from other coal fields; make it worth their while to work as laborers 2 years and miners 5, and at the same time tutor under the present mine foreman?

BOOK REVIEW

Smoley's Tables, sixth edition, has been issued by the Engineering News Publishing Co., price $3.50. Flexible leather, 4¾ in. × 7 in., 518 pages. The tables are combined in a way to obviate the tedious calculations in structural and other branches of engineering. Their convenience led to the immediate adoption of the early editions, and the work was soon regarded as indispensable to the designer.

In the later editions, tables of angles and logarithmic functions corresponding to any given bevel were added. Also a complete set of logarithmic and trigonometric tables were included. The present edition contains a complete table of natural trigonometric functions for every minute of the quadrant; a table of reciprocals, squares and square roots, cubes and cube roots, together with circumferences and areas of circles corresponding to diameters from 1 to 1,000. This latest table, by supplementing the tables of squares and logarithms of lengths in feet and inches, makes a desirable addition.

Compressed Air Plant, by Prof. Robert Peele, 502 pages, 8 vo., 209 figures. Price $3.50. This second edition is enlarged by 174 pages and 97 illustrations. The additions relative to

the construction and operation of rock drills, coal-cutting machines, and channeling machines occupy 90 pages. The theory of the compression of air is presented in greater detail and deductions from the more important formulas used to calculate the horsepower in single- and multiple-stage compression are given. Professor Peele has from time to time furnished articles on compressed air for Mines and Minerals and is therefore known to the older subscribers. However, for the newer subscribers it is stated that a more comprehensive and practical book on compressed air is not printed. Publishers, John Wiley & Sons, New York; Chapman & Hall, London.

Ore Mining Methods, by Prof. W. R. Crane, 8 vo., 219 pages, 60 illustrations; John Wiley & Sons, New York City, publishers. Price, bound in cloth, $3. In this book Professor Crane has not attempted to cover the machinery, tools, or other apparatus used in excavating ore. This elimination permits the concentration on the methods adopted in modern exploitation without digression; also it permits the author to discuss his theme connectedly without cross-references to subjects creeping into the text to distract the reader. The book forms a contrast to those usually put out on mining, and because of its valuable contents will appeal to ore miners. There is more on the methods of ore mining in this book than the number of pages would indicate for the reasons stated.

Practical Shaft Sinking, by Francis Donaldson, Chief Engineer of the Dravo Contracting Co.; 139 pages, 8 vo., 63 illustrations. Price $2. McGraw-Hill Book Co., New York City. This book is written by a practical man engaged in the business of shaft sinking, and covers the ground of modern shaft sinking from *a* to *z*. Chapter I includes contract agreement for excavation; the extra prices to be paid for excess of water pumped above 100 gallons per minute; and timbering specifications where shafts require to be lined. Chapter II covers the power plant required for sinking shafts to various depths; the disposal of excavated material; and an itemized cost of an entire sinking plant for a shaft 500 feet deep. Chapter III. In this chapter the author shows how to sink and support earth from the surface to rock; the various kinds of piling used, including steel; the use and construction of circular and oblong concrete caissons, with the construction of the shoes. Chapter IV covers the pneumatic process of sinking through soft ground; also the shield method practiced in Illinois. Chapter V covers rock excavations; the tools for drilling; placing holes for blasting; progress and probable cost per foot. Chapter VI. The processes followed abroad and the Poetsch-Sooysmith freezing process are described. Chapter VII describes the Kind-Chaudron process, and the cementation of water-bearing fissures. Chapter VIII is devoted entirely to lifting water during the progress of shaft sinking. Chapter IX deals with various kinds of shaft linings used abroad and in this country. Chapter X gives the cost per linear foot for rectangular, angular, elliptical, and quadrilateral cement-lined shafts.

CORRESPONDENCE

Rules for Mine Foremen

Editor Mines and Minerals:

SIR:—In my opinion the following rules should be carried out to make a successful mine foreman:

1. A mine foreman should be a man of good character, of cool disposition and sound in his judgment.
2. Should be courteous and discreet in hiring and handling men.
3. Should be able to gain the respect and confidence of his subordinates without sacrificing his individuality.
4. Always insisting on orders being obeyed.
5. Should be able to assert his personal, as well as his representative, rights when circumstances demand it.
6. Should be able and qualified to give instructions by example as well as by precept.
7. Always provide plenty of ventilation.
8. Always keep good roads for the transportation of coal.
9. When an order is given you by your superior, see that it is carried out.
10. Always keep in mind next thing to the protection of your men, the protection of the company's property.
11. Always give a man a civil answer.
12. Always use the company's money as if it were your own.

Carbondale, Pa. T. J. ASTON

Fernie Slack Bin Fire

A fire occurred at the Fernie slack bins, Fernie, B. C., recently. Mr. Ashworth writes "that he anticipated either a violent inflammation or explosion when the sides gave way and threw a large volume of coal dust into the air in close contact with the flaming woodwork, but no explosion took place." "If, as argued by some coal dust experts, a 'pioneering cloud' is necessary to originate a coal-dust explosion in a mine, he would like to ask why he did not have an explosion? With plenty of air, plenty of fine coal dust, and plenty of hot fire."

Miscellaneous Questions

Editor Mines and Minerals:

SIR:—1. What size of a box will it take to measure 1 ton of lignite coal?

2. For a 3-foot seam of lignite coal with only a moderate roof (area of coal 640 acres) what size of car would you prefer, and what size of car wheels and size of rails?

3. For a 4-foot seam of lignite coal with a very poor roof (area of coal to be taken out is 40 acres) what size and kind of coal car and size of rails would be preferred.

4. What is the horsepower of a boiler 42 inches in diameter and 42 feet long with two 12-inch flues?

5. What is the horsepower of a Cameron pump, diameter of the plunger 6 inches; length of stroke, 13 inches; size of steam cylinder, 10 inches in diameter; steam pressure at the boiler, 90 pounds?

6. What is the safe load for a 1-inch plow-steel rope, to haul up an incline 350 feet long; angle 35 degrees?

Bow Island, Lethbridge SCOTCHMAN

A DRY TIME IN SEWARD PENINSULA

All the placer camps were prosperous in 1909 except those of Seward Peninsula, where dry weather curtailed the output. In this region the methods of mining must evidently be adapted to meet the exigencies due to frequent seasons of low water. Important advances were made in dredging enterprises.

COMPETITION AMONG SMELTING COMPANIES

According to men who have arrangements with the International and allied smelting interests like the Amalgamated and Cole-Ryan people, the competition between the International and the American Smelting and Refining Co. is more bitter than the public has understood. With the erection of an International smelter in the Ely district of Nevada, as contemplated every field of the American Smelting and Refining Co. except Colorado will be invaded by the new company. Colorado is said not to be inviting for the Cole-Ryan people, as ore production has fallen off so greatly in that state that the Guggenheims can operate only three of their seven furnaces there. The International and its allied interests now have the smelters at Anaconda and Great Falls, Mont.; the plant at Tooele, Utah; the Calumet and Arizona smelter at Douglas, Ariz.; and the Cole-Ryan plant at Cananea, Mex., covering a large part of the field from which the American Smelting and Refining Co. draws its copper ores.

When the latter had a clear field its charges for ore treatment were so high as to allow a profit of $4 to $6 a ton. The excessive smelter charges made many enemies among Western miners, and the International interests have an advantage in that fact, while its smelting plants are new and modern. With these advantages the International will be satisfied with profits of $1 to $1.50 a ton and its purpose evidently is to prevent the American Smelting and Refining Co. from renewing any of its old and highly profitable contracts. The best contract the American Smelting and Refining Co. has is that of the Utah Copper Co., and it is said that the profits made by the smelting company on it are enormous.

The International interests expect to treat a normal tonnage of custom ore of about 5,000 tons a day. At a profit of only $1 a ton this would amount to $1,825,000 a year. It is expected that this will represent a tonnage that the American Smelting and Refining Co. will lose.—*New York Sun.*

REPORT OF AMERICAN ZINC, LEAD, AND SMELTING CO.

In the annual report of the American Zinc, Lead, and Smelting Co. for the year ending June, 1910, the net profits for the year amounted to $238,885.22. From this, dividends 6 and 7 amounting to $80,520 at 50 cents per share each were declared. The balance of the profits carried to surplus amounted to $103,365. $25,000 was added to a special reserve fund for further additions and betterments of the property.

The additions to the mines in Missouri consisted of the purchase of 16¾ acres of land adjoining the Davey properties, the installation of an air compressor and the completion of the equipment of the Vogey mill upon the December tract. The additions and betterments at the smelters consisted principally of new gas lands and leases acquired, development of gas lands and construction of pipe lines.

The property account is represented by 2,416 acres of mineral lands owned in fee in the Joplin district, and upon these lands six operating concentrating mills, two smelters at Caney and Dearing, Kans., gas lands and gas leases, and an ore separating plant at Platteville, Wis.

In mining operations during the year 11¼ acres were mined from the Davey tract, but this has been more than made up by developments and the purchase of the adjoining tract.

On the December tract operations during the fiscal year were not carried on at the full capacity of the plant. It is now being worked up to nearly its full capacity of 1,000 tons per day. At the Kansas smelters operations were carried on at the full capacity throughout the entire year. The operation of the Wisconsin properties has been unsatisfactory. The development of the Huff process has been steady. Progress is being made at Wisconsin, Utah, and elsewhere.

GEORGIA BROWN IRON-ORE WASHERIES

*Written for Mines and Minerals, by E. F. McCrossin**

Method of Handling the Ore and Cleaning It by Use of Log Washers Operated by Steam or Electricity

The brown iron ores in Georgia so far developed are in Polk, Bartow, and Floyd counties. In Bartow County the deposits are named as follows: The Eastern district, the Iron Hill district, and the Linwood district. Probably the most important of these three divisions is the Eastern district, which is confined to the eastern part of the county. The deposits in this part of the state begin about 2 miles south of Emerson and extend in a northerly direction to Sugar Hill, a distance of about 16 miles. Some of the most important brown ore mines in the state, such as Sugar Hill mines, are located in this district. The brown iron ores occur chiefly in the form of pockets in the residual clays and are quite variable in size. It is not uncommon to find the deposits extending over 5 or 6 acres, although the ore does not occur in equal abundance over the entire area. On the contrary it is often traversed and intersected by clay horses. The depth to which the ore extends is also variable. In some cases it is quite superficial, being only a few feet in thickness, while in other cases they appear to extend to more than 50 feet in depth. In some instances the deposits on the hill slope are found to extend into the valley below. The ore is found mostly in the form of boulders or pieces in the residual clays, and the proportion which the ore bears to the entire material varies greatly. In some of the most valuable deposits the ore will average 50 per cent. or more of the material mined, but generally it falls short of this average, and it becomes necessary to wash the deposits in order to concentrate the ore for transportation.

Fig. 1. Sugar Hill Iron Mine Plant

The ore, which evidently has had its origin from the weathering of pyrite, varies in phosphorus content from .363 to 1.583. The silica varies from 5.82 to 16.47.

Until recently it has been the policy of the larger corporations operating in the Alabama and Georgia brown iron-ore fields, to erect small instead of large plants, preferring to have two small washers rather than one large one. As is the case in all other iron-ore fields, the rapid exhaustion of the richer deposits has compelled the erection of larger and more efficient plants in order that the lower grade ore may be successfully handled.

The most elaborate and recent developments along this line have just been completed on the Bartow Division of the Georgia Steel Co. The division consists of about 1,300 acres in northwest Georgia. The company owns its own standard-gauge railroad running through the property and connecting with two interstate railroads. Along the railroad are located the four principal plants: the Sugar Hill, Big Springs, Bufford, and Guyton washers, situated in the order named, Sugar Hill being the terminus of the road.

The plant at the Sugar Hill Mine, shown in Fig. 1, consists of a steel six-log washer, equipped with overhead distributing screens, sand screens, and four picking belts, three of which are of the steel-pan type, the other a 30-inch canvas belt. On the sand screens the standard slotted sheets heretofore used have been replaced by perforated sheets with ⅞-inch circular perforations. The ore, after passing through the distributing screens and logs, reaches the sand screens, the oversize passing through and on to the picking belts and the undersize to the jig plant attached to the washer, where it goes through a concentration process; the silicious matter being discarded and the concentrate loaded into the bins, from which it is later loaded into cars with the ore from the picking belts. This washer has been in operation about 3 years and has a capacity of about 500 tons per day. The jig plant is a more recent addition and has a capacity of about 16 tons an hour.

The mines at Sugar Hill cover a very large area and have been worked more or less for a number of years. Ore was hauled from them in wagons to small stone furnaces in the western part of Bartow County, which were in blast long before the Civil War. The ore from the working faces is hauled to the washer with standard-gauge locomotives in 6-yard, side-dump cars, loaded direct by steam shovels, as shown in Fig. 2. A branch line from the railroad extends to a deposit about 2½ miles from the washer. On this line 12-yard side-dump cars are used with much success.

The ore is a high-grade brown hematite lying in large irregular deposits with a massive sandstone foot-wall. It is good all the way down until the local water level is struck, where, as a rule pyrite begins to show and causes the sulphur to exceed the limit allowed by the furnaces. It is possible that some time in the future even this ore will be extracted and roasted.

Seven miles from Sugar Hill, on the company's railroad, lies the town of Aubrey, where are located the division offices, the machine shop, forge shop, power house, and a number of residences for the officials and men. This is the nucleus of the division. The steam shovels, locomotives, cars, and all classes of equipment are brought here for repairs. The shops are fully equipped with lathes, drill presses, shapers, steam hammers, and all other tools necessary to repair and rebuild the mining machinery. All the shop machinery is driven by electric motors.

The power house is a modern brick building with steel trusses. The current to operate the shops, the Big Springs and Bufford washers, and the two 1,200-gallon-per-minute pumps for the washers, is generated by two direct-connected, 550-volt, 455-ampere, direct-current generators and one 350-ampere belted generator; all connected in parallel, so that any machine can assume the load from any line by simply alining the proper switches. One machine is always idle and held in reserve. The current is sent to the washers over heavy copper cables. Chestnut poles set 75-feet centers hold the cables. There are frequently heavy static discharges in this district, but so far there has been very little trouble from this source. A large bank of lightning arresters has been provided at the power house and at each plant a number are also scattered, along the transmission lines.

* Consulting Engineer, Cartersville, Georgia.

The Big Springs plant, shown in Fig. 3, consists of a wooden four-log washer and is situated 2 miles east of Aubrey on a branch line of the railroad. The logs and screens are driven by a 100-horsepower motor belted to a friction wheel, which in turn drives the line shaft. This is an innovation in this district and should the logs become overloaded or jammed, the entire washer can be stopped at an instant's notice, and then by

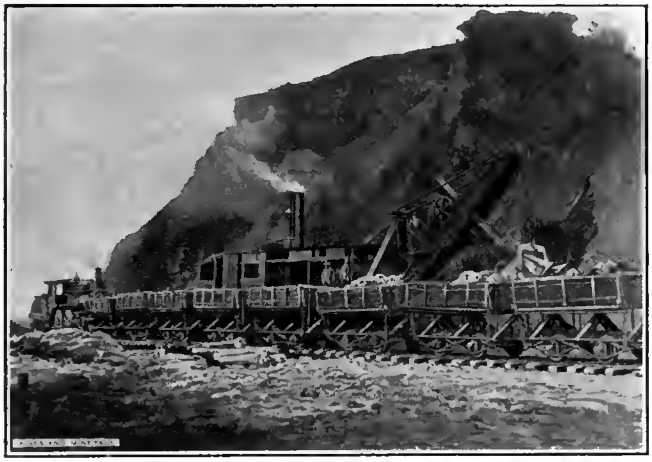

Fig. 2. Loading Iron Ore at Sugar Hill, Ga.

slowly applying the friction wheel to the shaft the logs can be relieved and loosened and gradually put up to their normal speed.

The ore is brought to this plant from the open cuts in narrow-gauge, 4-yard, side-dump cars, hauled by "dinky" locomotives. All the material is dumped into the hoppers on grates, the bars of which are set 6 inches apart The undersize from these grizzlies is flumed direct to the sizing screens. The oversize is separated, the foreign matter is thrown out and the heavy massive ore discharged into a No. 8 gyratory crusher from which it is flumed to the logs. The location of this plant is ideal and a minimum operative cost can be maintained.

The Bufford plant is not so favorably situated as the Big Springs washer. The slope of the hill upon which it was found necessary to erect the washer was so gradual that it necessitated the elevation of the mud-boxes, or hoppers, above the grade of the mine tracks. The mining conditions here are much the same as Sugar Hill, and the ore is brought to the washer in 6-yard side-dump cars. These cars are hoisted to the mud-boxes by a 70-horsepower electric hoist, and discharge direct into the hoppers. The crusher at this plant is elevated on timber bents to the level of the flume line, and the material follows the same course as it does at Big Springs. The washer is the same type as the one at Sugar Hill, except that it has four steel logs instead of six, and has no jigs.

Both of the washers have given very little trouble since their erection, and the cost of the operation of these washers and their pumps by electricity, compares most favorably with that of steam plants of equal capacity.

DRILLING IN THE UPPER PENINSULA

There has been a cessation of diamond drilling operations in all the iron fields of the upper peninsula.

Many drilling outfits have been transferred from the iron country to the Lake copper district, where exploration for new lodes is actively in progress. There will be much learned of Ontonagon County through the use of these drills, and many of them are being now employed in the district. Several promising discoveries have been made with the drill and the work is being supplemented with new borings to learn as much as possible concerning these deposits. Should one good copper deposit be proved it will well repay for all the carbons that have been used, because some day copper is to come into its own and find a market at a profit commensurate with the cost of getting it. Carbons at $85 per carat are pretty expensive agents for rock cutting, being about half the price of the ordinary-sized and ordinary-colored brilliant. There was a time when carbons used to sell at $6 to $10 per carat, but the demand has increased owing to the greater number of drills employed, and those who have the industry of carbon mining and selling in hand know how to conduct their affairs so as not to give their output away without proper compensation. At $85 per carat it is evident that the carbon men are reaping a rich harvest at this particular time.

Many substitutes have been tried for black diamonds, but up to this time none have been found worth mentioning. Bortz may be used if the ground is not too hard, and highly tempered steel has sometimes been employed. When it comes to boring the hard rocks of the Lake Superior country, however, the black diamonds are required, and it needs the best of these to cut the jaspers of the iron-bearing formations.

Much of the drill work in the lake region is done by contract with parties owning their drill equipments and having experienced men in charge. It stands to reason that with the high price of the black diamond a careless setter could easily waste a lot of money. The setter is a man of great importance. The runner also should know how to treat his bit of stones in the hole. He can easily destroy hundreds of dollars worth of stones in a single careless shift. The bit must be fed into the rock according to the hardness of the latter and it is only long practice that decides the proper handling of the machine by the operator. Good setters and machine men are always in demand and are well known to those using drills.

The diamond drill has been valuable in locating new iron ore deposits in the past few years. Probably there have been greater additions to the known iron-ore deposits through the use of the drill in this time than in any former similar period, this because they were being more used in new localities. It has been the practice, as it still is, for the mining companies to use drills in their mines, locating ore extensions and pockets on

Fig. 3. Iron Ore Washery, Big Springs, Ga.

the strike of the formation and contiguous to their underground operations. Nearly all the mining companies of the Lake Superior country own drills that are operated by their employes.

Shaft work will take the place of the drilling crews at many locations in the iron country, and it may be that the use of the drills in the Lake Superior copper country will be followed by new mines in that section already well known for its merit in a mineral way.

UTAH METALS COMPANY TUNNEL

Writen for Mines and Minerals, by Leroy A. Palmer

A Tunnel 11,000 feet long for Ore Transportation. Electric Driven Air Compressors

To reduce the cost of transportation to the Tooele smelter, a distance of 24 miles by rail, and only a few miles through the mountain the Utah Metals Co. is constructing a tunnel. This transportation project of the Utah Metals Co. starts in the property of the Bingham Central Standard Mine near the Utah Consolidated and pierces the mountain in a general westerly direction, coming out in Middle cañon at a point about 2,000 feet higher than the International smelter at Tooele, and 4 miles distant in a direct line, the topography being such that an aerial tram could be built without any great difficulty. The tunnel, when completed, will be 11,000 feet long with a grade of 3 to 4 inches in 100 feet. It will be 8 ft.×9 ft. in the clear with frequent passing tracks and, while the width of 9 feet would make it rather crowded, it could, if necessary, be double tracked without enlarging. It is being driven by compressed air generated by electricity in the company's hydroelectric plant. The water is drawn in two pipe lines, one from Middle Creek proper and the other from a fork of the creek just above the power house.

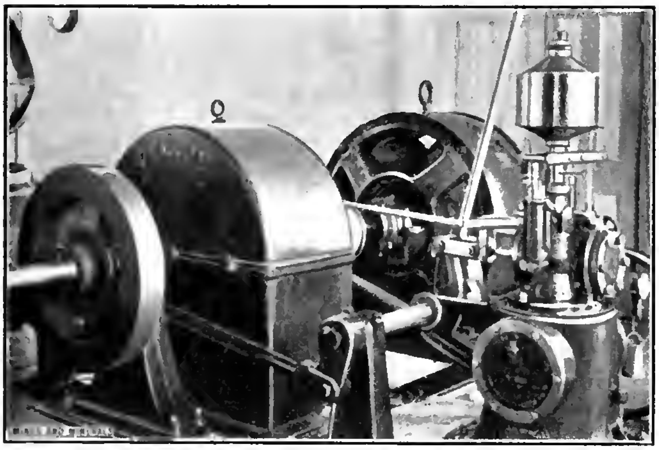

Fig. 1. Pelton Generating Unit, Utah Metals Co. Tunnel

The line from Middle Creek contains 5,600 feet of American spiral pipe; 2,400 feet of 12-inch, 3,000 feet of 10-inch, 100 feet of 8-inch, and, just before entering the power house, 75 feet of 5-inch. The water has a head of 750 feet that gives a static pressure of approximately 325 pounds per square inch, and the pipe is tested to four times this amount. The joints are of forged steel bolted type. A sleeve belled at each end is slipped over the pipe and a rubber gasket placed inside the bell. A flanged collar fits inside the bell against the gasket on which it is tightened by bolts through the flanges. This makes a joint which is tight under pressure and allows of some deflection without leakage. There is sufficient movement in the joints to take care of all expansion and contraction but they also call for very secure anchorage. This is secured by sinking a deadman 5 feet in the ground at every other joint. A clamp is put around the pipe and a bolt attached, the other end of the bolt being passed through the deadman.

The water from the fork is carried in a wrought-iron pipe 6,000 feet long, 1,420 feet of 12-inch, 1,078 feet of 8-inch, 1,807 feet of 6-inch, and 1,620 feet of 5-inch. The head is 800 feet, giving a pressure of approximately 400 pounds per square inch. This pipe has ordinary sleeve joints. It is buried for the greater part of its length which does away with part of expansion and contraction in length due to temperature and as it is on rather sharp curves such changes as do occur are taken up by lateral movements. The fact that it is buried relieves some of the necessity of anchoring, and the anchors, which are of the same style as these used on the spiral pipe, are placed only every 500 feet.

The spiral pipe discharges against a 30-inch Pelton wheel, Fig. 1, with deflecting nozzle and Pelton governor. This wheel is direct-connected to a 55-kilowatt direct-current generator making 875 revolutions per minute and generating at 5,550 volts and 10 amperes. The current is carried to the tunnel 1,100 feet distant where it is used for the haulage system and to drive a small fan.

The wrought-iron pipe line discharges against a 36-inch Pelton wheel belted to an Ingersoll-Sergeant two-stage compressor, 9½ in.×15 in.×10 in. which can be run at 140 revolutions per minute, thus giving a capacity of 400 cubic feet of free air per minute. The compressor works to 100 pounds. The air is carried in a 6-inch line to a point 200 feet within the portal of the tunnel where the line is reduced to 4 inches and carried to a receiver near the working face. From the receiver the machines are fed by a 2-inch line.

At this writing the tunnel is in 3,900 feet through quartzite with occasional belts of limestone. It is 8 ft.×9 ft. in the clear with a drain at the side in which is laid a flume 24 in.×24 in. The flow of water, 380 gallons per minute, is piped in a 5-inch line to the power house and directed against an 18-inch Pelton wheel direct-connected to a 3-kilowatt direct-current generator which supplies the lighting system. At present the company is getting more than sufficient power for its own use and no attempt is being made to utilize the tunnel water other than described, but when the work is completed this water can be led down the cañon to a point, still on Utah Metals ground, where sufficient head can be obtained to develop 500 horsepower.

Drilling is done by two Ingersoll-Sergeant 3¼-inch piston machines mounted on the same bar. The ordinary round consists of 12 holes, three cut holes with as much pitch as the ground will stand, three breast holes with a slight angle downwards, three uppers at a slight angle, and three lifters with just sufficient angle to carry water. This round is varied to suit the nature of the ground, and frequently three or four additional holes are drilled. The holes are charged with 40-per-cent. dynamite, 50 to 70 pounds to a round, and fired by hand. Three shifts are at work and each breaks a little over 4 feet in the regular sized drift.

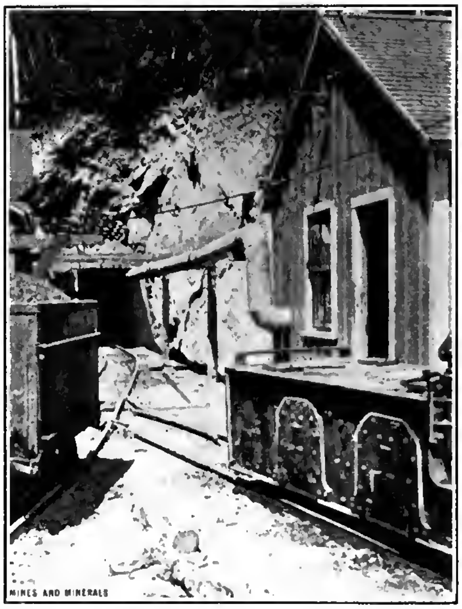

Fig. 2. Portal and Fan House, Utah Metals Co. Tunnel

The formation so far encountered is sufficiently firm to stand with little support. Whatever timbering is needed

consists of stulls or posts with head-boards and a few full drift sets. If bad ground is encountered, a drift set with the cap framed in three segments so as to form a rough arch will be used. The timbers, of which there is an abundance on the property, are undressed. The track is 24-inch gauge, of 30-pound rails on ties whose centers are 24 inches apart. The cars have a capacity of 42 cubic feet, with slope bottom, so that by throwing a catch one side is released and the rock slides out. They are hauled in trains of four by a Baldwin-Westinghouse locomotive. Ventilation is effected by a 48-inch Sirocco fan direct-connected to a 15-horsepower direct-current motor. It is used as a blower while the men are drilling and as an exhauster after blasting.

At first it was installed as shown in Fig. 2, but was changed and placed inside the tunnel 2,300 feet from the portal where it gives a much higher efficiency. The fan has a capacity of 5,300 cubic feet of air per minute and the object in changing its position was to balance to a certain degree the length of the intake and discharge pipes, and to use it as an exhaust fan all the time. The cost of driving 10½ feet in two shifts is as follows: Sixteen men at $3.50, $56; 90 pounds explosive at 16 cents, $14.40; two engineers, $7; blacksmithing, $7; superintendent and engineering, $10.67; total for 10.5 feet, $95.07, or $9.15 per foot.

The principal object of the tunnel is to afford transportation for the ores of the Utah Metals Co., which owns about 3,500 acres in Bingham, to the International smelter, but it will doubtless be used to handle the ores of other companies as well. It is about 50 miles from the upper Bingham mines to the Tooele smelter by rail. By the tunnel and an aerial tramway this distance will be cut to a little more than 6 miles. The water will develop a considerable amount of power which can be disposed of to advantage, and there is good reason to believe that mineral will be encountered. The formation is quartzite and lime which, on the other side of the range, frequently gives values on the contact and in the fissures in the lime, and the tunnel has encountered some mineralization in the lime but not of sufficient value to be classed as ore. No attempt is being made to follow up these indications, the company confining the work, at present, to getting the tunnel through the mountain as quickly as possible. At the present rate of progress the work should be completed in the next 18 months or 2 years and should prove a very convenient outlet for the Bingham ores which are to be treated at the Tooele plant.

The writer wishes to acknowledge the courtesy of those who have assisted in the preparation of this article, notably, S. H. Treloar, General Manager, and H. M. Hurst, Engineer of the Utah Metals Co.

LAKE SUPERIOR IRON ORE

That the Marquette range, from Ishpeming to Michigammee and beyond, will be tested with diamond drills during the next few years, is now certain. Some of the mining companies owning lands in that region have met with such success that continued and more extensive exploratory work is being planned. The Marquette range is the oldest of the Lake Superior iron districts, yet evidences multiply that it is far from the zenith of its development. Ore has been encountered in many drill holes.

It is expected that the Cleveland Cliffs Iron Co. will undertake the draining of North Lake, on the east shore of which the North Lake Mine is now being opened. This lake is 3 miles west of Ishpeming. In view of the fact that ore bodies also have been found on the west shore, it is believed that the deposits extend under the lake, which is three-quarters of a mile wide. Thus there is indicated an ore body of wide area, particularly since the diamond drilling has determined the deposit to be of considerable depth.

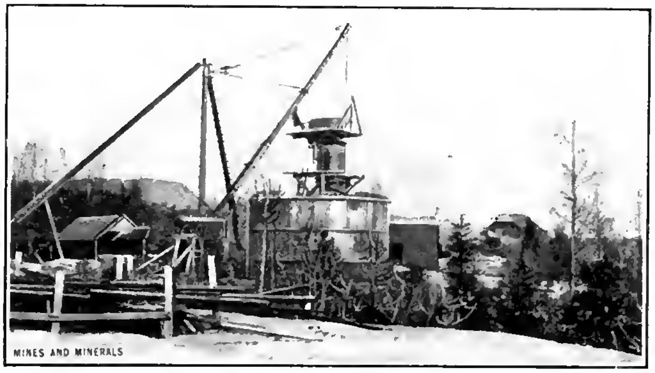
The district to the westward of Ishpeming promises to make good the loss of ore to which the older producing portions of the range have been subjected the past 60 years, during which many million gross tons have been sent to market.

The Cleveland Cliffs Co. was the first to begin a systematic exploration of the field. It mapped out the geology, beginning at the Cliffs shafts, Ishpeming, and with diamond drills it has tested the country westward for several miles. The discovery of the North Lake ore body was due to this carefully worked out plan. A large sum of money has been spent in exploring and equipping the property for the work of mining that soon is to be commenced. There is a concrete shaft to the ledge,* a fine plant of machinery in substantial buildings, and an attractive location of dwellings for employes.

Further west of North Lake, where the Cleveland Cliffs Co. is testing lands near the old Dexter hematite mine, a little village has been built and a shaft is well along toward the ore deposit. A steel head-frame and substantial buildings holding adequate machinery are also erected. This property, the Barnes, will soon be in condition to mine ore.

West of the Dexter Mine the next active property is the American Mine, where the Hanna interests are about ready to operate. The American Mine was operated years ago, but the ore bed was small and it was not worked advantageously.

The shaft at this mine has been deepened, new levels added, and the mine equipped with necessary machinery,



NORTH LAKE SHAFT, SHOWING LOCK FOR PNEUMATIC PROCESS OF SINKING

preparatory to mining. Exploration shows the ore deposits to have greater dimensions than supposed at any former time in the mine's history.

West of the American Mine, in a large swamp, George J. Maas, of Negaunee, and several associates, have been operating diamond drills for 2 years. A bed of hard ore and an immense deposit of soft hematite of commercial value has been found. There is also a large area of low-grade ore, which it is planned to concentrate.

The property which is to be developed by the North Range Mining Co. will be supplied with a shaft to be sunk at least 700 feet before the ore is sought by connecting drifts.

The Maas interests control a large acreage in the vicinity and intend doing work on other lands than those embraced within the corporation now being organized. It will take a year to get the shaft down to the high-grade deposits, which will be mined first.

The steel corporation is exploring west of the Maas holdings. It has two diamond drills in commission and intends to put down a series of deep holes.

From Ferdinand Schlesinger's Newport Mine, on the Gogebic range, more than 1,000,000 tons of ore will be shipped this year. The Newport is the largest producer on the Gogebic, as well as one of the most extensive underground mines in the Lake Superior iron region. Not infrequently, upward of 600 six-ton skips are hoisted to surface through a single shaft in the course of a 10-hour shift and that from a depth of 2,000 feet.

* See MINES AND MINERALS, Vol. XXX, page 217.

EVOLUTION OF HOISTING

Written for Mines and Minerals, by E. B. Wilson

(*Continued from November*)

In the November issue of Mines and Minerals, where balancing hoisting engines by different methods was discussed, the flat-rope reel was mentioned. It must be remembered that the greatest load comes on a hoisting engine when the cage, rope, and load are being moved from the bottom landing of the shaft, and to minimize this load the reel drum is made small in diameter.

Engines for Flat Hoisting Ropes. Koepe System, Poore System, Whiting System

The power which the engine must exert to move the load from this place is influenced by the diameter of the reel. Therefore, as the rope winds up and increases the diameter, the leverage becomes greater; at the same time the weight of

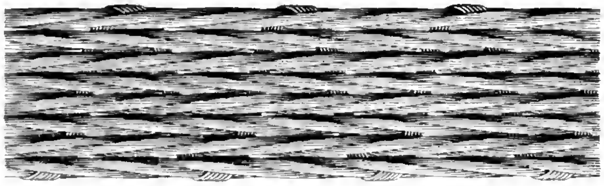


Fig. 26

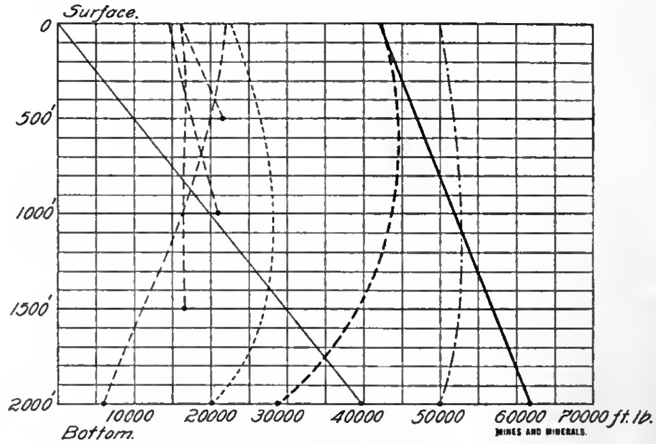
the rope becomes less. So the two factors in a measure balance and the engine runs comparatively steady.

Flat ropes consist of several strands of round rope sewed together with wire, as shown in Fig. 26. Ropes of this discription are made of iron, steel, crucible-steel, and plough-steel wire, the same as other wire ropes. They possess the advantage of being less rigid than round ropes of the same strength, and may be wound on smaller drums without so great injury. Flat wire ropes weigh more than round wire ropes of the same strength and add that much more weight for the engine to lift. They will last equally as long under favorable conditions as a round rope of the same strength, with this distinction, however, that the round rope will need no repairs, while the flat rope will probably need to be resewed several times before being discarded. One of the advantages to be derived from the use of flat wire rope is that the drum may be lined or centered with the head-frame sheave. This centering avoids the extra strain put on the pulley at that point and does away with the extra power the engine would require to overcome the friction due to the rope angling at the sheave. Owing to this favorable feature the hoist and shaft house might be under the same roof were not such an arrangement bad mining practice, that in case of fire involves the risk of smothering all miners below the surface unless there are two mine exits

Diagram of Static Moments for the Following Conditions:

Ore.......................................4,000 pounds
Cars, cage, and rope, from head gear to cage..........4,500 pounds
Round rope..................................$1\frac{1}{8}$ inch diameter
Flat Rope.......................................$4\frac{1}{2}$ in.$\times\frac{5}{8}$ in.
Straight drum........................9 feet $10\frac{1}{2}$ inches diameter
Conical drum.......................8 feet diameter at small end
Conical drum...............11 feet 9 inches diameter at large end..
Reel center ....4 feet diameter



Straight drum, hoisting singly, loaded
Conical drum, hoisting singly, loaded
Flat-rope reel, hoisting singly, loaded
Flat-rope reel, hoisting singly, empty to change levels
Straight drum, hoisting in balance, loaded from different levels
Flat-rope reel, hoisting in balance, loaded, from different levels

Fig. 27

Note.—The worst disaster in the history of anthracite mining occurred at Avondale, Pa. It was due to the shaft house, placed over the only exit from the mine, taking fire.

It is probable that the principal objection to the use of flat ropes comes from the necessity of making repairs; in more recent years, however, men have become skilled in binding together the round ropes that make the flat one, and this in a measure overcomes the objection.

In the United States, reels vary from 3 to 11 feet in diameter, and as the rope winds on itself, each turn increases the diameter of the reel by twice the thickness of the rope, so that at the finish the diameter of the reels may be from 8 to 20 feet, according to the length of the rope, its thickness, and the original diameter of the reel. In England, reels are made up to 16 feet in diameter, and increase up to 20 feet or more, depending on the length and thickness of the rope.

Large reels are naturally less wearing on the rope, although, in any case, as the rope winds on itself that factor has considerable to do with the life of the rope. In this country the common practice is to make the diameter of the reel as small as the rope will

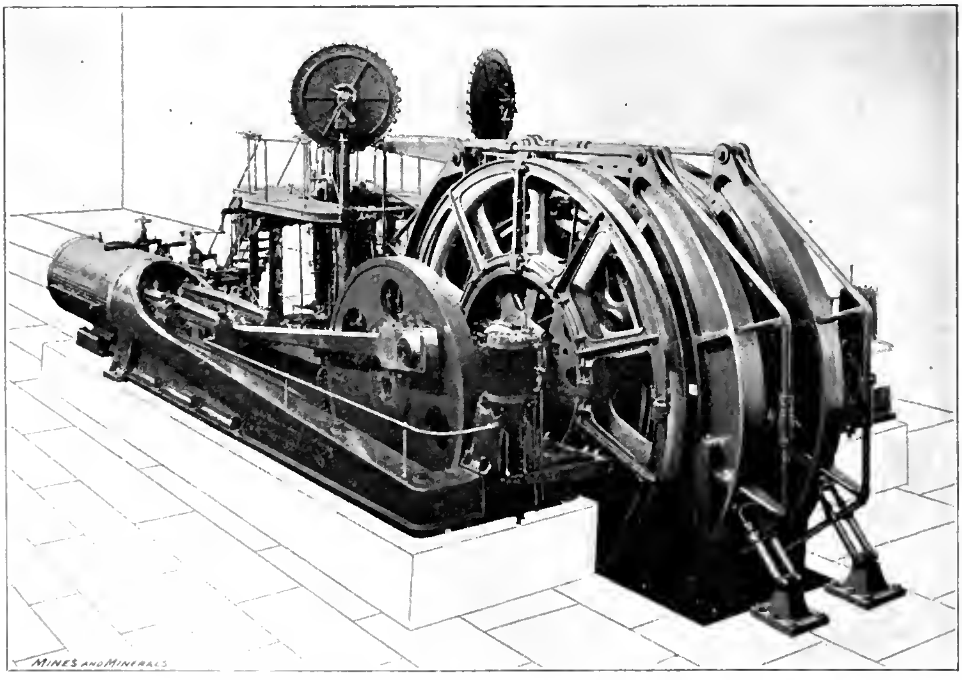


Fig. 28. Double Engine for Hoisting 3,000 Feet With Flat Rope

permit and so reduce the starting load. Assume the load to be that given for the diagram, Fig. 27, with the reel 4 feet in diameter and the rope 4½ in. × ⅜ in.

From Table 1, furnished by wire rope makers, such a rope would weigh about 50 per cent. more than a round rope of equal strength.

The diagram, Fig. 27, shows that the static moment for the whole lift of 2,000 feet varies from 28,000 pounds to 45,000

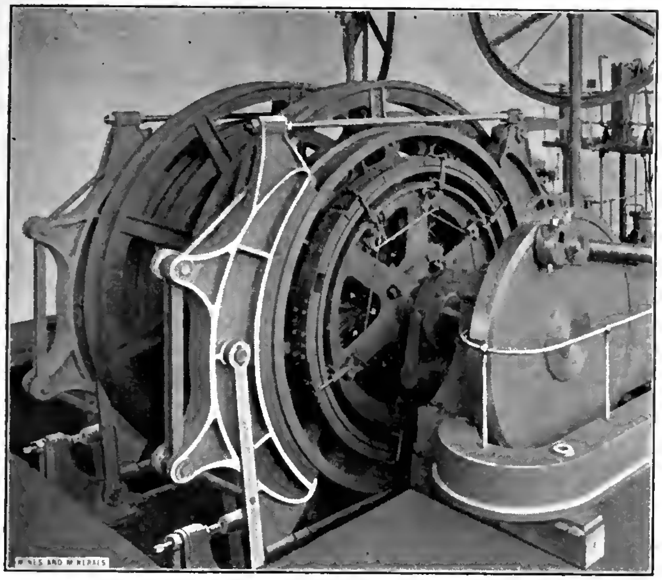

FIG. 29. HOIST WITH TWO LOOSE REELS AND FRICTION CLUTCH

pounds, and terminates at about 42,500 pounds. It will be noticed from the same diagram that these static moments are less than in the case of the cone and straight drums, and that the engine may have, therefore, smaller cylinders, in fact 2 inches less than the cone-drum engine and 4 inches less than

TABLE 1. COMPARATIVE WEIGHTS AND STRENGTHS OF CAST-STEEL ROPE

Size in Inches		Weight Per Foot-Pound		Approximate Breaking Stress, Tons of 2,000 Pounds	
Round	Flat	Round	Flat	Round	Flat
¾	2 × ⅜	.96	1.35	21	20.00
	2½ × ⅜		1.70		25.00
⅞	3 × ⅜	1.25	2.05	29	30.00
	3½ × ⅜		2.40		35.00
1	4 × ⅜	1.70	2.75	38	40.00

1¼	6 × ⅜	2.50	4.15	56	60.00
1	3 × ½	1.70	2.40	38	37.50
	3½ × ½		2.85		43.75
1⅛	4 × ½	2.15	3.30	47	50.00
	5 × ½		4.20		62.50
1⅜	6 × ½	3.17	5.10	69	75.00
1½	7 × ½	4.71	6.00	81	87.50
1¾	8 × ½	5.00	6.90	109	100.00

the straight-drum engine. While this looks as if there would be an economy in steam, the reverse is true, owing to the flat-rope engine making 90.8 revolutions, while the cone and straight-drum engines make but 64.4 revolutions. If it be assumed that the load is raised in 1 minute, the average horsepower of the cone and straight-drum engines would be 704, and that of the flat-rope engine would be 781.* It is evident from this that a waste of power occurs when hoisting out of balance with a flat rope and reel. However, the diagram shows that when hoisting in balance the horsepower needed for the flat rope is greatly reduced, in fact is 267 for a perfect balance.

Hoisting engines with flat ropes and reels, built so as to run either balanced or unbalanced, generally have two loose reels that are driven by clutches. Sederholm, in the article mentioned, says: "The general belief is that when running in balance the effect is good; however, except when hoisting from the most advantageous level, say the 1,500-foot, the static moments vary with every level, and with badly proportioned hoists the effect may be a negative quantity." Suppose for example a hoist is needed for the conditions assumed. In this case the descending cage with empty car materially assists in lifting the ascending car. If the relative positions of the reels are such that one cage is at the bottom when the other is at the top, then the line starting from the bottom of the diagram represents the static moments. If the reels are shifted from the 1,500-, 1,000-, and 500-foot levels the balancing effect is quite different. When hoisting from the 1,500-foot level the balancing effect is nearly perfect and the static moments practically constant. The diagram also shows that when hoisting from the shaft bottom, less effort is required to start the load, but that the effort increases all the way to the surface, so that the relative moments are as 1 to 3.67, and in addition a hoisting engine of this kind is expected to lift the loaded cage unbalanced, which operation requires an effort 7.4 times the minimum effort. Under such conditions good economy is out of the question; nevertheless a reel proportioned on these lines will give the best average results when hoisting must be done from different levels of a shaft. The double-reel hoist, shown in Fig. 28, was built for the Anaconda Mining Co., of Butte, Mont. It has first-motion engines with cylinders 30 in. × 72 in., constructed to hoist four-decked cages from a depth of 3,000 feet. Another reel hoist used at the Copper Queen Mine, Bisbee, Ariz., is shown in Fig. 29. This hoist has two loose reels which are thrown in and out of gear by the friction clutch shown on the crank-shaft.

The reel and flat rope are appreciated by metal miners owing to the hoister taking up comparatively little room in the engine house. The reel is much lighter than a drum, and where the machinery must be packed some distance over a rough country or into almost inaccessible mountain districts, this is also appreciated. The greatest depth to which flat ropes have been used in the United States is probably 3,000 feet, at the Anaconda copper mines. It is also probable that owing to the great weight of the rope, which will necessitate an increase in the size of the engine beyond 3,000 feet in depth, it will make

FIG. 30. WATT HOISTING ENGINE AND REEL FOR FLAT ROPE, USED IN CUBA

it more economical to use some other kind of hoister. Edgar G. Tuttle, E. M., who furnished Fig. 30, states that there is an old Watt engine with reel and 1,000 feet of flat rope wound on it at the Cobre copper mines in Cuba. These mines were put out of working order by Cuban insurgents about the year 1868.

Flat ropes are not a new invention, in fact one of the earliest hoisting engines, shown in Fig. 16 of this article, has a reel† and flat rope, probably hemp.

* E. T. Sederholm, Vol. XXIV, page 579, MINES AND MINERALS.

† MINES AND MINERALS, November, 1910.

When a rope winds off and on a drum it makes an angle with the groove in the head-sheave that creates considerable friction. To overcome this the engine is placed at considerable distance back from the head-frame, which position has a number of disadvantages. In order to overcome this angling, the inertia due to heavy drums driven at a high rate of speed, and to decrease the load on the engine, a system of hoisting was invented by Herr Koepe.

The system known as the Koepe, has been extensively adopted on the continent of Europe; to a limited extent in Great Britain; but not at all in the United States, except in a modified form. To replace the drum and obtain sufficient frictional resistance a large grooved wheel is placed on the engine crank-shaft. The rope passes half around this wheel and over two sheaves on the head-frame, thence to the top of the cages—one being at the bottom of the shaft and the other at the top landing. A balance rope is fastened underneath the platform of each cage. Ordinarily there is sufficient frictional resistance between the hoisting rope and the wheels, if the plant is designed properly, to hoist the loads, but in order to be on the safe side and furnish a good rope bearing, the driving wheel has been made of such size that the advantages in point of lightness have in a measure been lost. Owing also to the chances of the rope slipping on the driving wheel, the load must be started from the bottom gradually and not at full speed as with a drum.

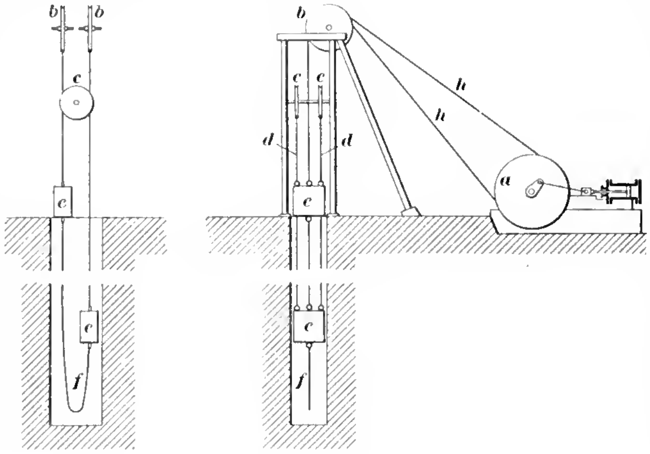

Fig. 31. Modification of the Koepe System

To overcome these objections, and possibly some others, flat ropes have been tried on the pulleys, as they offer more bearing surface; and double drums placed tandem, supplied with round ropes have also been introduced.

With flat ropes there is no overcoiling as in the case of reels, and as the stitching wires are not broken to such extent, less repairs are needed, besides the ropes last longer.

As flat ropes would be in balance in the Koepe system, their weight would not be objectionable after the load was in motion. However, the total weight of the mass to be set in motion may be so great as to favor the use of round ropes. Taken as a whole, the Koepe system of winding with flat-rope reels does not appear to offer advantages over the round-rope system with sheave wheels placed tandem to a double-grooved driving pulley. In the latter case the sheave wheel is mounted on a movable carriage, so weighted as to take up any stretch in the rope. One end of the rope is attached to one of the cages and passes over one of the head-sheaves to the underside of the grooved driving wheel and over one of the grooves on the idler sheave on the balance car, then back to the driving wheel where it passes under and over to the second head-sheave and hence down to the other cage. Fig. 32 shows the Koepe system of winding where two head-sheaves are placed side by side, Fig. 33 shows a method where the head-sheaves are arranged tandem. In the first case the head-sheaves are not in direct line with the driving pulley, while in the latter case they are in such a direct line that there is no side friction due to lateral movement between the moving rope and driving pulley.

One modified application to the system is shown in Fig. 31, in which *a* is the engine pulley, *b* the head-sheaves, *c* the pulley wheels for safety ropes, *d* the safety ropes, *e* the cages, *f* the balance rope, and *h* the hoisting rope. The object of placing the head-sheaves tandem and the pulley wheels *c* at right angles to the head-sheaves when placed side by side as in Fig. 31, is to keep the cages in line with the head-sheaves and prevent the hoisting and tail-ropes interfering. One objection to the Koepe system is that should the rope break both cages would fall, and the safety ropes *d* are connected with each cage to prevent this sort of accident. Where such additions are made the system loses its simplicity, the balance rope must be made heavier, and additional power is required to set the masses in motion.

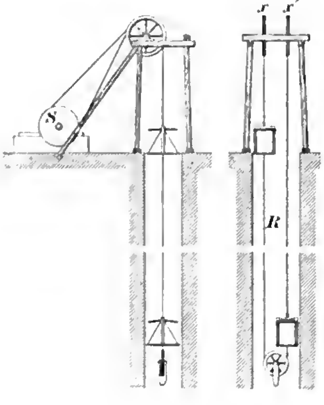

Fig. 32. Koepe System

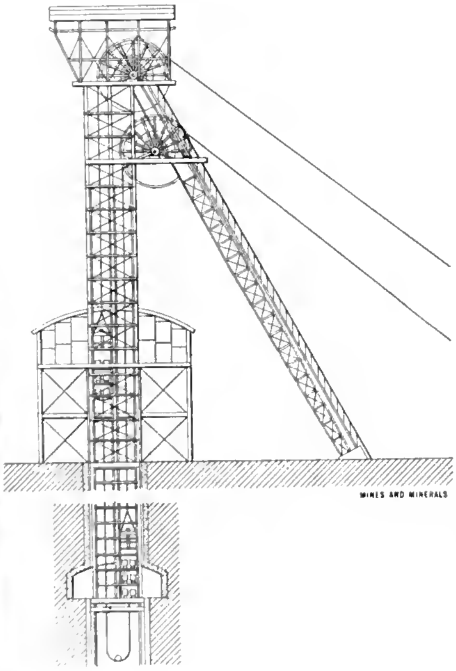

Fig. 33. Koepe System with Tandem Drums

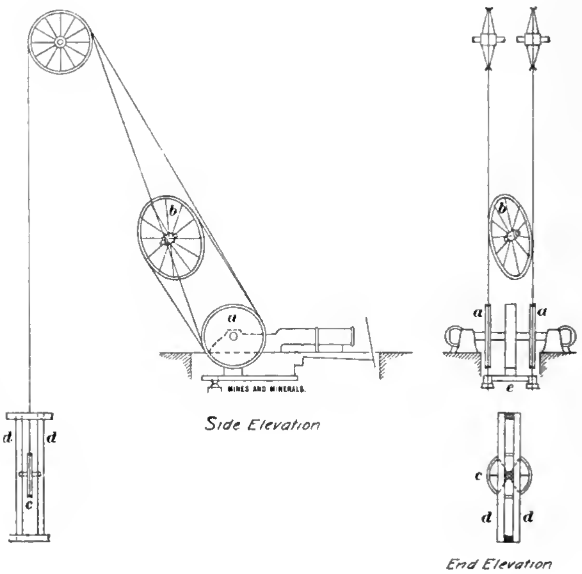

Fig. 34. The Poore System

The Poore system, adopted for a short time at the Pettibone shaft, near Wilkes-Barre, and at the Neilson shaft, near Shamokin, Pa., is a modification of the Koepe system, as shown in Fig. 34.

This system used two driving pulleys *a*, instead of one, on the engine shaft; a transfer wheel *b* so placed and mounted on a movable truck as to carry the rope from one driving wheel to the other in tangential lines; a tail-rope guide sheave *c* hanging in the bight of the rope and held in position by bearings which travel on guides *d*.

The Neilson shaft, at which the Poore system was installed, obtained most of its coal from the 900-foot level instead of the lowest, or 1,278-foot level,* and to hasten operations all loads were hoisted on one cage.

"Out of this developed the only defect of moment in the system, and this in fact was due to the engine always starting the load in the same direction, so that there was a tendency of the rope wheels to slip ahead before the inertia of the rope and loaded cage was overcome. This resulted in the indicator showing the cage as having reached the landing before it had done so. The amount of slip was quite variable with no apparent reason for the change in rate."

Ihlseng† states "that in a shaft 1,260 feet deep a saving of 11 per cent. in power is effected by the Koepe system." "With sheaves 8½ feet in diameter on an 8-inch axle; main rope 1.75 pounds per foot; tail-rope 1.55 pounds per foot; cage and car 2,100 pounds; load 2,750 pounds; depth of shaft 2,500 feet; and velocity of hoisting 2,500 feet per minute, 250 horsepower is saved over that required to operate the same loads by another system."

In 1862, S. B. Whiting, Chief Engineer of the Reading Coal and Iron Co., invented a system of hoisting applicable to deep shafts, but owing to the prejudice against adopting an unknown plan, it was many years before the system was acknowledged. When it became almost imperative to adopt some system which would economize in power at deep shafts, the Whiting system was resurrected and plants installed in three copper mines of Michigan, and two gold mines in South Africa. There is no fear of the rope slipping in the Whiting system and it is possible to arrange matters so that hoisting may be done from several levels, although an auxiliary hoist should be used for upper levels.

There is a very large hoisting plant of this kind at the Red Jacket Mine of the Calumet & Hecla Mining Co., at Keweenaw Point, Mich. This hoist has two hoisting drums 19 feet 1½ inches in diameter, capable of using a rope 2¼ inches in diameter. It is designed to hoist 10 tons from a depth of 4,900 feet. The cages and cars are in balance and a tail-rope of smaller size than the hoisting rope is in use. The plant installed at the Rand Mining Co., Ltd., South Africa, is shown in Fig. 35. The driving rods of this duplex, tandem-compound, Corliss engine are connected to the crank of the first drum, while the first and second drum cranks are joined with connecting-rods as shown in the illustration. The coupling of the engine to the drums is similar to the coupling of a locomotive piston to the driving wheels. The general arrangement of the Whiting system is shown in plan and elevation in Fig. 36.

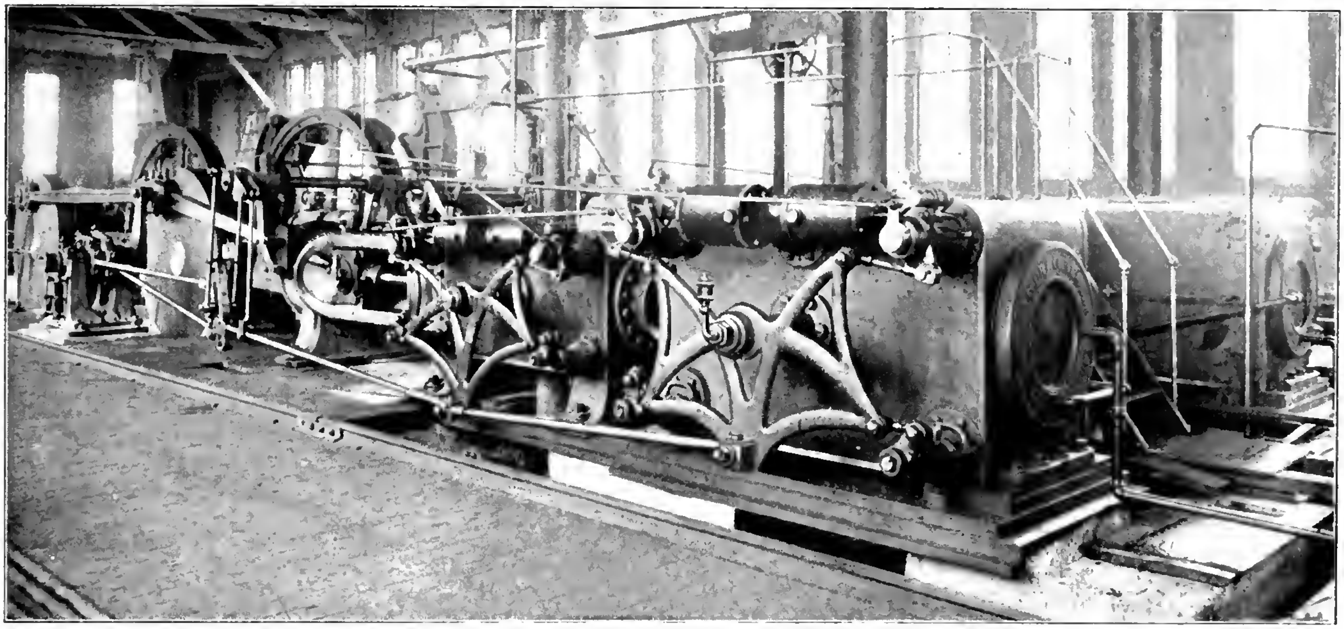

Fig. 35. Whiting Hoisting Engine at Rand Mine, Ltd.

Judging from this experience, the tendency to slip places the Poore system in the same class as the Koepe system, concerning which the following disadvantages are enumerated: In case the winding rope breaks, both cages fall down the shaft; difficulty is experienced in socketing the hoisting rope; extra strain comes on the rope fastenings, due to the weight of the balance rope; the danger of one rope fastening failing, with consequent accident to both cages, and this danger is increased by the lack of cage rests at the top landing. However, should cage rests be used at the surface the rope loses that amount of friction due to the weight of the cage and its balance rope, and may cause trouble when the latches are released. Koepe's system is not suitable for shallow quick winding, for if full steam be quickly put on the engine at the start, the driving wheel slips around like a locomotive wheel at starting; further, once the full speed of the engine is attained it cannot be stopped quickly without a tendency to slip. At the Neilson shaft the speed of hoisting is said to have reached 30 feet per second. However, the system is better adapted for hoisting heavy weights at slow speed from the bottom of deep shafts than where other conditions prevail.

The rope it will be noticed starts from the top of cage *A*, goes over the head-sheave *S*, down to the guide wheel *T*, from underneath which it goes to the under side of drum *M*, where it is given one-half turn to drum *F*. The rope is given three half turns over these drums, and passing off from underneath *F*, goes to the tension car *C*, then half around this, back to and under another guide pulley up to the second sheave on the head-frame and down to cage *B*.

* Arthur H. Storrs in Vol. 24, page 609, Mines and Minerals.

† Manual of Mining, page 147.

The drums M F would be on parallel shafts were it not that the drum F is given a slight inclination so that the rope shall run direct from the groove of one drum to that of the other without binding or friction. Special arrangements are made so that the connecting-rods to this drum shall run in line with the cranks of drum M.

The object of the tension car C, shown also in Fig. 37, is to permit hoisting from different levels. The first dotted circle represents one level, the second circle the present situation of the car another level, and the third circle another level. It is obvious that one cage goes down the shaft when the other is lifted, and that by changing the position of the tension car, one cage is raised or lowered without affecting the position of the other cage, because the length of rope on one cage has not been changed. Where there are a number of levels to be worked simultaneously, it is necessary to change the position of tension car with some haste, for which reason it is mounted on a track and moved by a strong engine of the geared type. When the car is in position it is clamped to the track. In using the Whiting system a tail-rope is useful both for balancing and safety, as it is a kind of guarantee that the cage or skip will move down the shaft whenever it is desired to lower it from the top landing. During sinking operations tail-ropes are impracticable and auxiliary hoists should be used to hoist at least to the lower level.

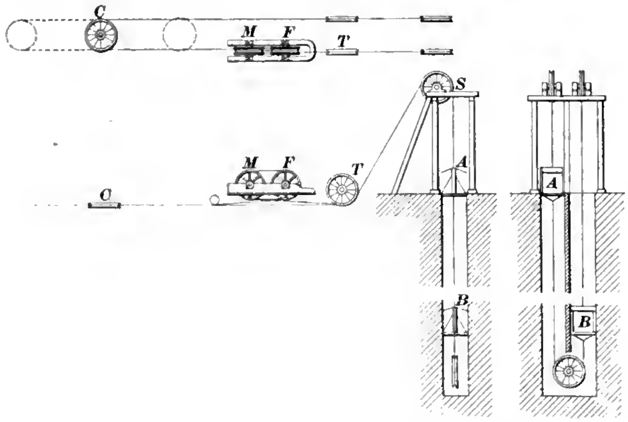

FIG. 36. PLAN AND ELEVATION OF WHITING SYSTEM

In either the Koepe or the Whiting systems, hoisting depends upon the frictional resistance, and this depends on the tension of the rope, the coefficient of friction, and arc of contact.

Let T_l = the tension on the loaded rope;

T_u = the tension on the unloaded rope;

f = coefficient of friction;

θ = arc of contact;

e = .434, the modulus of the common logarithm referred to 2.718, the base of the Naperian logarithm.

Then the relation of the various factors to each other may be expressed by the formula $\frac{T_l}{T_u} = e f \theta$, or $\log \frac{T_l}{T_u} = .434 f \theta$, if θ is in circular measure = degrees × .01745; or $\log \frac{T_l}{T_u} = .007578 f \theta$ if θ is in degrees. Take, for example, a load of 8,000 pounds to be raised from a depth of 5,000 feet, that needs a steel rope $1\frac{1}{2}$ inches in diameter. The rope will weigh 18,250 pounds and the skip it is assumed weighs 5,600, hence, $T_l = 31{,}850$ and $T_u = 23{,}850$. $\frac{T_l}{T_u} = \frac{31{,}850}{23{,}850} = 1.33$, and log 1.33 = .123852. Assuming the arc of contact to be 180 degrees, although this contact could only occur when the sheave were directly over the hoisting drum, 180° × .01745 = 3.14, and 3.14 × .434 = 1.36276. The coefficient required to prevent slipping will be, therefore,

$$f = \frac{.123852}{1.36276} = .09.$$

The coefficient of friction for a wire rope running on a cast-iron pulley may be taken as .1, and for a wire rope running on a grooved pulley lined with wood or leather, as .2. In order to obviate slipping $\frac{T_l}{T_2}$ must be less than the constants given, and where this condition is not fulfilled either the ratio $\frac{T_l}{T_2}$ must be

FIG. 37. TENSION CAR, WHITING SYSTEM

reduced by increasing the weights on one or both ropes hanging in the shaft, or the factors f or θ must be increased, usually the latter, as where in the Whiting system the rope is passed several times over the two pulleys. It may be noted here that flat ropes, owing to their greater weight, increase the friction on the pulley. In the Whiting case grooved pulleys are used and $\theta = \Phi n$ in which n = the number of grooves in the pulleys when both are driven and Φ the arc of contact of one groove, or 180 degrees.

If* it were attempted to hoist in balance on straight drums without a tail-rope, the engine would have to overcome both the weight of the ore and 18,250 pounds of rope, and the drums would be 18 feet in diameter in order to keep the length within reasonable bounds. The advantage of the Whiting system compared with conical drums is shown in Fig. 38.

DIAGRAM OF STATIC MOMENTS FOR THE FOLLOWING CONDITIONS

HYDROMETALLURGY OF COBALT ORES

Written for Mines and Minerals, by E. B. W.

Different Methods of Treatment As Illustrated by Flow Sheets of the Principal Mills

Probably the town of Cobalt shows to better advantage the benefits to be derived from the metal-mining industry than any other town in Canada east. What was a wilderness in the spring of 1903 is now a thriving place with most of the advantages found in cities. Indirectly this is due to the construction of a railway, and in this respect Cobalt was again fortunate, for usually a mining town must prove its worth prior to its receiving railway assistance. When grading for the construction of the Temiskaming and Northern Ontario Railway, silver, associated with cobalt, nickel, and arsenic, was discovered. The first application for a mining claim in this district was made in August, 1903, by J. H. McKinley and Earnest F. Darragh, who at that time were subcontractors on the Temiskaming railway.

The second application for a mining claim was made by Fred LaRose and was dated September 29, 1903. The third discovery was made by Tom Herbert, who on October 21, 1903, located the first vein of ore on the property now owned by the Nipissing Mining Co. In November, 1903, Neil King discovered what is known now as the O'Brien property. The principal factor in attracting outside capital to the Cobalt district was W. G. Trethewey's discovery of the Trethewey and Coniagas claims in May, 1904. Shortly afterwards Alexander Longwell located the Buffalo Mine. These continued rich finds gave credence to the number and stability of the deposits. Until the spring of 1905 little attention was given the Cobalt district and then the Tretheway shipment of approximately $208,000 from an 8-inch vein caused people to take notice, and in August, 1906, the real boom commenced, caused by the Nipissing declaring a 3-per-cent. quarterly dividend on a capitalization of $6,000,000. Up to January 15, 1910, this company has declared dividends equaling 64 per cent. on its capital stock. The Little Silver vein, located by Mr. Herbert, in 1903, is shown in Fig. 1.

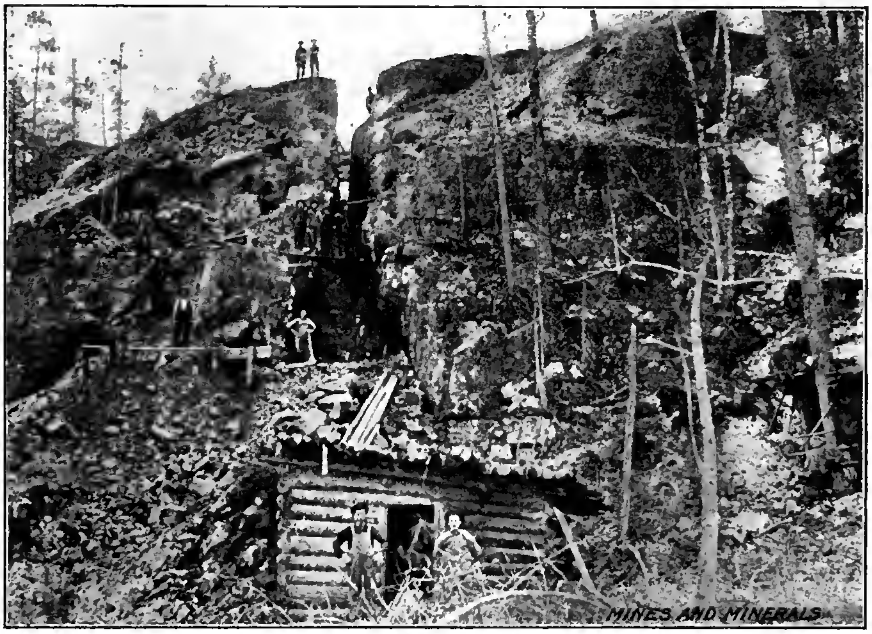

Fig. 1. The Little Silver Vein, Cobalt

The town of Cobalt is in Colman Township, in the province of Ontario, Canada, 10 miles from the Quebec line; 330 miles north of Toronto; and about 103 miles from North Bay Junction on the Canadian Pacific Railway.

For 200 years previous to the construction of the Temiskaming railway, white men have been traveling this country to and from Hudson Bay both by land and water. Lake Temiskaming, which is about 90 miles long, and from 1 to 5 miles wide, is but a short distance from Cobalt. It forms in part the division line between Quebec and Ontario, and Coleman Township, is on its western shore about half-way up the lake. Since the discovery of silver at Cobalt, the country for many miles around it has been prospected with an intelligence that has extended the known mineral area as far south as the Gilles Limit, and to Hudson Bay on the north. While all the ground has not been thoroughly covered, a number of silver, gold, lead, and copper deposits have been discovered.

The native silver in the Cobalt veins occurs in flat, thin sheets in vein rock, in nuggets, and occasionally in slabs up to 1 inch thick. In order to break the ore with as small waste as possible and at the same time work to advantage, an excavation about 4 feet wide is made on one side of the vein, and the ore broken down with light charges of powder placed in shallow holes. The best ore is assorted by hand, sacked inside the mine, and when sufficient has accumulated at the ore house on the surface, is shipped to some smelter. The remainder of the ore is hoisted in bulk, concentrated by hand cobbing, or by machinery and the concentrates shipped to the smelters. That ore which is third class and which may carry from 25 to 100 ounces of silver per ton is given hydrometallurgical treatment which reduces the bulk of ore to such an extent it carries up to 4,000 ounces of silver per ton. In the course of concentration an average of 12 per cent. of the silver is lost unless the cyanide process is introduced to treat the tailing. Cobalt ores, because of their complexity, are not easy to smelt economically, because unless carefully mixed they form matte, spiess, and accretions that must be retreated. In early days the ore was reduced to metal by spreading from 1,000 to 1,500 pounds over a lead bath. This volatilized some of the impurities although a large quantity of spiess was formed that had to be re-treated. At present the ore is roasted to volatilize the arsenic, antimony, and sulphur, after which it is smelted in the lead blast furnace.

To roast the ore so as to eliminate more than 10 per cent. of arsenic is not economical, as various complications and extra expense will follow, although the smelters as a rule penalize shippers for ore that carries over 5 per cent. arsenic. There are excellent reasons why they attach this penalty: first, they must oxidize the ore, which costs money, and, secondly, the arsenic in volatilizing in the furnace carries away part of the silver and other metals.

Those Cobalt ores which are too low grade to ship are hoisted from the mines and sorted on shaking tables which are sprayed with water to clean the ore. The coarsest of the ore is picked out by hand. In some cases the ore is screened and washed in a trommel and the fine material which settles out of the wash water is shipped to the smelter, as it carries from 200 to 500 ounces in silver. In concentrating by means of water there is a loss of from 10 per cent. to 20 per cent., making it advisable to keep the high-grade ore separated from the lower grades. The screenings from the picking tables, which are over 100 ounces of silver per ton, are shipped generally to the smelter, although recent practice has indicated the advisability of concentrating ore running as high as 125 ounces. All ore, however, which is considered too low in silver to ship, that is from 75 ounces down, is saved, and either a concentrating mill is constructed after enough such ore is accumulated to

warrant its construction, or else it is sent to a custom concentrating mill. Where there is a mill in connection with the mine, the ore is hoisted direct to the mill bins or crusher floor after cobbing in the mines. Some favor cobbing in the mines, but it is probably better to cob in daylight.

There are two distinct kinds of low-grade ore. One in which the silver mineral is disseminated through the rock, and

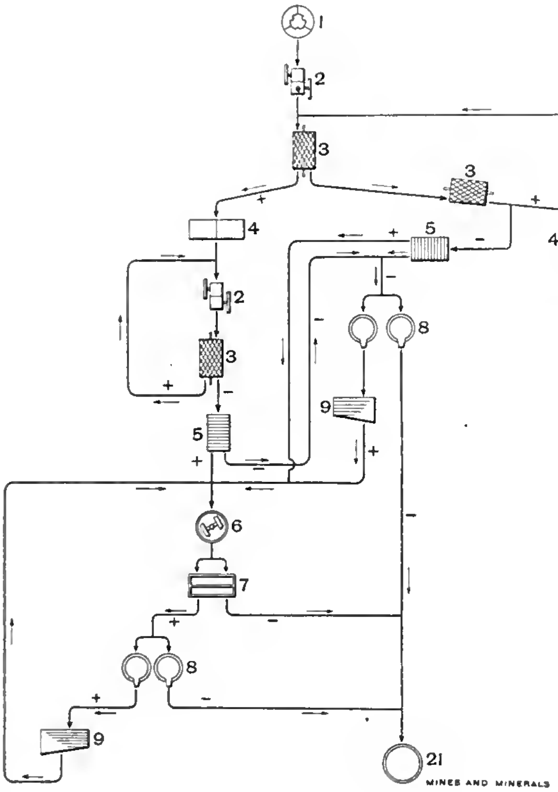

FIG. 2. BUFFALO MILL

the other in which the ore is mixed with vein material and wall rock. The silver in the wall rock is so irregular it makes a uniform low-grade ore impossible, a condition which adds somewhat to the difficulties of water concentration. The rock which contains the disseminated silver mineral demands fine crushing, while the mixed vein matter and wall rock are treated by coarse crushing and jigging. The calcite of the vein and the diabase walls adjacent to the vein usually contain wires of smaltite and native silver.

The object of concentrating low-grade ores is to reduce their bulk and separate the valuable from the worthless mineral. By this means it is possible to obtain a valuable ore for shipment to the smelter. There are 13 hydrometallurgical mills in the Cobalt district and the methods of treatment at the different mills are shown by the flow sheets appended, the legend for which is as follows: 1, crusher; 2, rolls; 3, trommel; 4, jigs; 5, impact screen; 6, Chilian mill; 7, settling box; 8, classifiers; 9, concentrating tables of various makes; 10, Hardinge conical mill; 11, stamp batteries; 12, pulp thickeners; 13, canvas tables; 14, dewatering trommel; 15, Frue vanners; 16, tube mill; 17, Spitzkasten; 18, shaking screen; 19, waste; 20, Richards jigs; 21, cyanide tank; 22, agitators; 23, precipitation tank; 24, filter press; 25, Moore filter.

Fig. 2 is a flow sheet of the Buffalo mill, which originally was of 60 tons daily capacity, was erected in September, 1907. A cyanide plant was installed later that went into operation in August, 1909. The average recovery with this concentrating mill was 86.4 per cent. of the silver in the ore, and with the cyanide process in operation, 91 per cent. The average value of the ore being treated is 45 ounces of silver per ton, and the ratio of concentration is 45 tons of ore to make one of concentrates. About 125 tons of ore are treated daily. From the flow sheet it will be noticed that this mill has three pairs of rolls 16 by 36 inches. The middling from the seven concentrating tables is reground with a Chilian mill, while the tailing from the classifiers is cyanided.

Fig. 3 is the flow sheet of the Cobalt Central mill, which treats about 100 tons of ore per day, and produces 75,000 ounces of silver in the form of concentrates in the course of a month. The recovery is said to be 88 per cent. with a concentration ratio of 50 to 1. The average value of the concentrates is 2,000 to 3,000 ounces per ton. It is stated that it is the intention of the company to install a cyanide plant. By reference to the flow sheet it will be seen that this mill has three pairs of rolls, one coarse jig and two fine jigs; two trommels, one with ½-inch mesh and the other with ⅛-inch mesh. All material passes through a classifier or Hardinge conical mill before going to the tables. The overflow from the last of the classifiers, which in this case are Callow settling tanks, goes to slime tables. In the Cobalt district concentration runs as high as 75 tons of material to one of concentrates and possibly higher, for which reason no side discharges are used on the plunger jigs. Once or twice, possibly oftener, in each shift the jig is skimmed by hand. The smaltite which is softer than the rock wears away rapidly and jig bed builds up slowly. Smaltite also breaks with sharp corners and causes trouble in fine plunger jigs owing to its clogging the screens, in fact it was so bad at one mill, the mill-

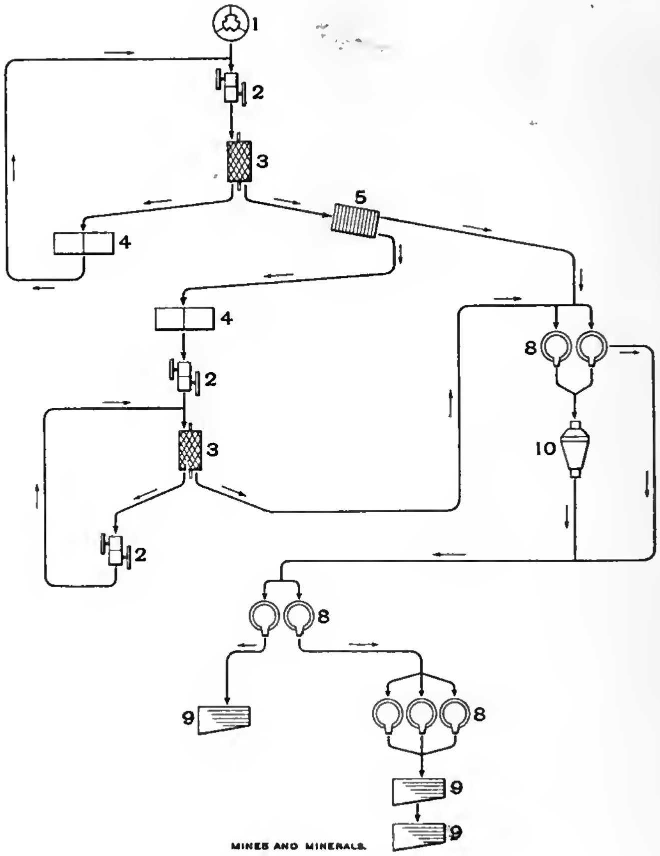

FIG. 3. COBALT CENTRAL MILL

man gave up trying to jig through ¼-inch or 12-mesh screen and sent the product directly to the regrinding machines, and hence to the tables. Pulsator jigs are liked in the Cobalt district, as the screen does not blind and the capacity of the jig is large for the screen surface, and permits the use of an automatic side discharge which results in less loss from smaltite tatrition.

Fig. 4 is a flow sheet of the Colonial mill which belongs to the Colonial Silver mines. This mill is of comparatively recent construction and not so much information is to be had concerning it. According to advices, this company has a large tonnage of low-grade ore and it was for the purpose of concentrating this ore that the mill was constructed. As will be observed, the fine material from the roll goes to classifiers, while the oversize from the jigs goes to the stamp mill and then to classifiers. The middling from the concentrating tables is reground in a tube mill. There are five concentrating tables and 10 stamps in this mill. In the Cobalt district there are three types of recrushing apparatus used for jig tailing. The stamp is most generally adopted, with the tube mill growing in favor as a recrusher. The Chilian mill is used but little and is not to be recommended for regrinding this particular ore. The middlings after leaving the concentrating tables are sent to tube mills. In some cases the material from the tube mills flows to classifiers and then to slime tables. In other cases it is cyanided.

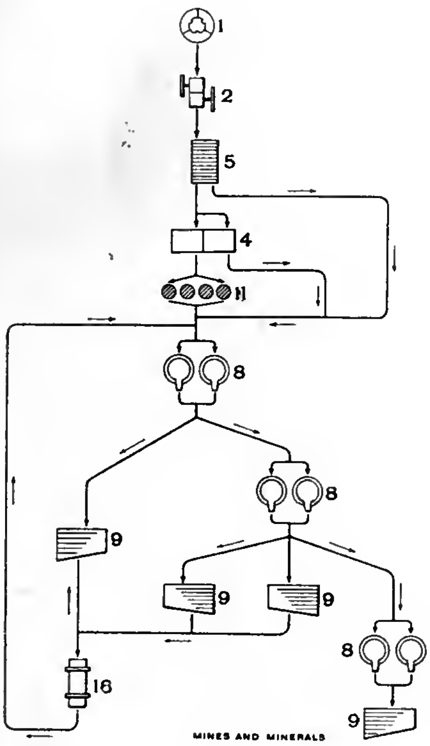

FIG. 4. FLOW SHEET COLONIAL MILL

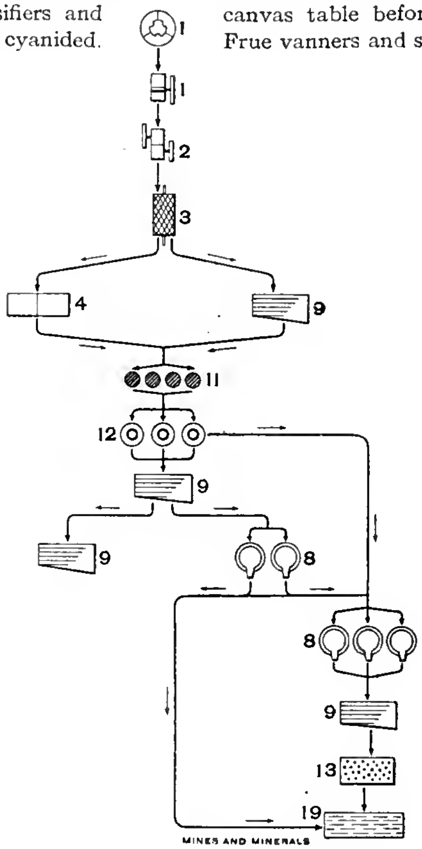

FIG. 5. CONIAGAS MILL

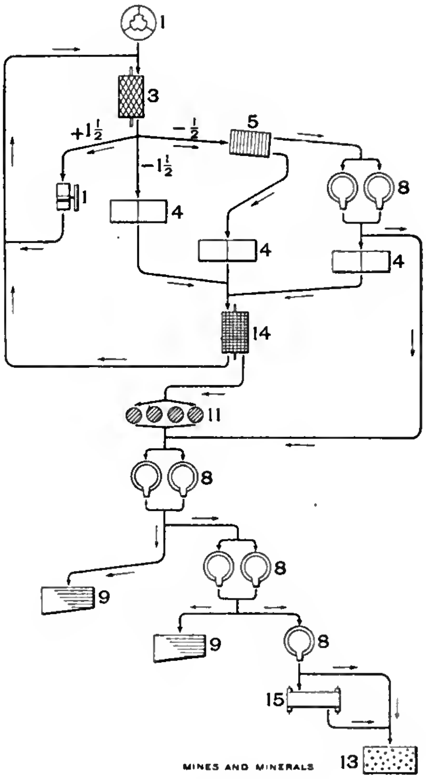

FIG. 6. KING EDWARD MILL

In a number of mills, after leaving the slime tables, the tailing flows over canvas tables before going to waste. In some of the mills the stamps are of California type and weigh 1,250 pounds; in other mills they are of the Nissen type with circular mortar and weigh 1,500 pounds.

Fig. 5 shows the Coniagas concentrating mill; the property of the Coniagas Mine Co., which also owns the issued stock of the Coniagas Reduction Co., Ltd. The smelters of this company, as previously stated, are at Thorold, where they handle the product of the mine and are producing refined silver, refined white arsenic, and expect to produce refined cobalt oxide and nickel oxide. The Coniagas mill has 30 stamps with a capacity of 80 to 90 tons of ore per day. Thirty additional stamps have probably been installed at this writing, which it is supposed will increase the capacity to 160 tons per day. The ore sent to the mill averages between 80 and 100 ounces of silver to the ton and a reduction of about 40 to 1 is made, and an extraction of 80 to 85 per cent. At this mill there is a 10″×16″ Blake crusher which delivers 4-inch diameter material to a gyratory crusher that further reduces the material to 1½-inch diameter. The rolls are 30 in.×30 in. and are said to crush to ¾-inch. The middling from the six jigs and one table goes to the stamps, and after the pulp has been thickened it goes to seven tables. The middling goes to classifiers which separate the slime from the sand. After settling the slime goes to slime tables; the tailing from these to canvas tables, and then to waste. While this mill is putting in canvas tables for slime treatment, it would seem that the more logical treatment would be cyaniding, for the reason that in the latter case the end product is bullion, where the table concentrate is low-grade and entails high smelting cost for treatment.

Fig. 6 is the King Edward Mill, which is one of the best arranged so far mentioned. The discard from the coarse jig is the only material returned for a second treatment. The remainder goes to the 10-stamp mill, and, after classifying, to its proper concentrator. The tailing from the Frue vanner flows to a canvas table before going to waste. The concentrates from Frue vanners and slime tables average about 900 ounces of silver to the ton, and so far without cyaniding it is probable that the average loss from milling is at least 12 per cent. of the silver in the ore.

Fig. 7 is a flow sheet of the McKinley-Darragh mill, which has a capacity of 120 tons per day, with a ratio of concentration of 30 to 1. The recovery is 82.71 per cent. of the silver. One of the two tube mills is 5 feet in diameter and 20 feet long; the other is an 8-foot Hardinge conical mill. There are 30 stamps, 13 slime tables and canvas tables before the tailing is wasted. The fine pulp from the first classifiers goes to four Frue vanners, but the recoveries are generally low and the concentrate of low-grade in these vanners.

Jig concentrates at Cobalt commonly carry from 1,000 to 4,000 ounces of silver per ton. The table concentrates from 1,000 to 1,800 ounces per ton. In some instances the tables concentrate 120 into 1, making 1,500 ounces of concentrate from a feed that carries less than 10 ounces of silver per ton.

No. 8 is the Nipissing reduction mill. This is a custom mill built on the Nipissing ground and has been concentrating

the low-grade ore in the Kendall dump. At this mill is introduced a shaking screen which makes two separations. Anything over 20 mesh goes to the jigs, all the discard from them going to Hardinge conical mill. All 20 mesh and under goes to classifiers, then to tables, the tailing going to waste and the middling to the Hardinge mill. By the arrangement of this mill no unnecessary material is rehandled. The capacity of the mill is said to be 80 tons per day. At the shafts of the Nipissing mines bumping tables separate the ore into three classes. The first class averages 2,000 ounces of silver to the ton; the screening averages about 100 ounces of silver to the ton; the discard averages from 15 to 20 ounces of silver to the ton. By the aid of recently improved tables the screenings are subdivided. The high-grade screenings that run over 100 ounces per ton are sacked and sent direct to the smelter. The discards and the low-grade screenings go to the custom mill for treatment. The is dried and sacked for shipment. The average assay of the ore treated is about 25 ounces of silver to the ton. The concentrates average about 1,000 ounces of silver to the ton, or a ratio reduction of 44 to 1. The mill averages an extraction of about 88 per cent. The tariff charged by this custom concentrator is about as follows:

On ore yielding less than 20 ounces of silver per ton crushed, 10 ounces of the silver are retained and the balance turned over to the mining company with 50 per cent. of other metals that can be sold. Ore running from 20 to 35 ounces of silver per ton pays 50 per cent. tariff; 35 to 50 ounces of silver pays 55 per cent. tariff; 50 to 70 ounces of silver pays 60 per cent. tariff; 70 to 90 ounces of silver pays 65 per cent. tariff; 90 to 110 ounces of silver pays 70 per cent. tariff; 110 to 125 ounces of silver pays 75 per cent. tariff.

Ore is also treated on the tonnage basis of $4 per ton

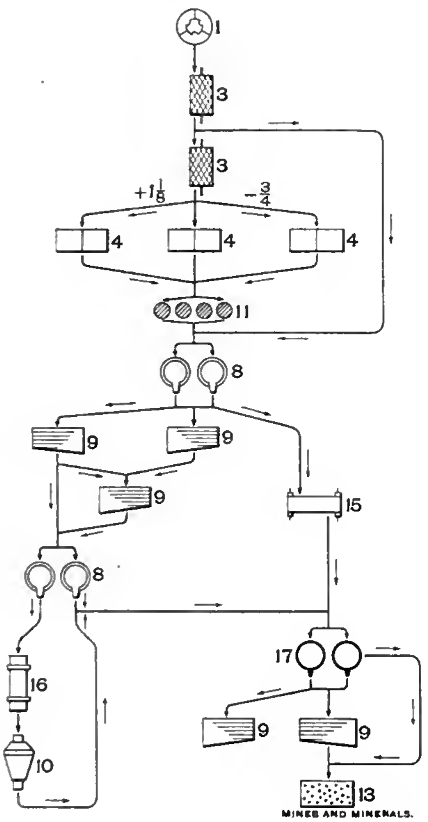

Fig. 7. McKinley-Darragh Mill

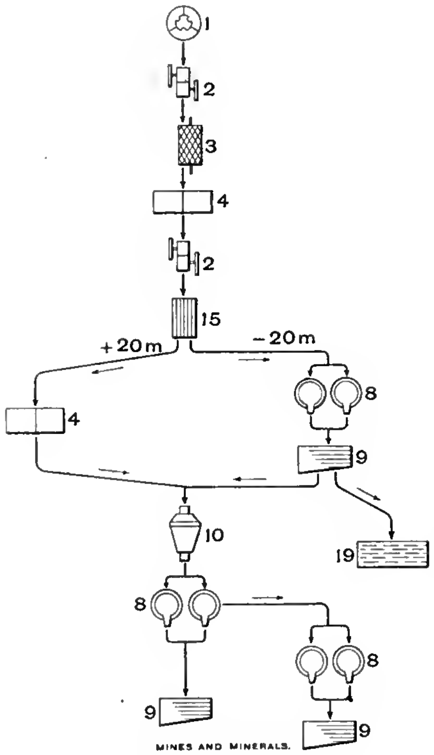

Fig. 8. Nipissing Customs Mill

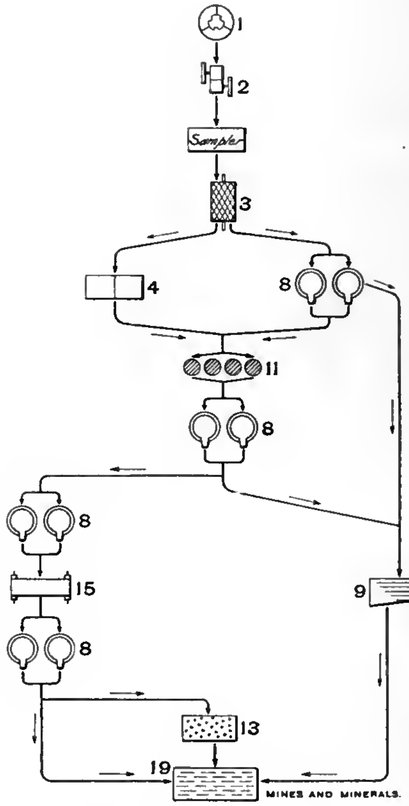

Fig. 9. Northern Customs Mill

actual cost of mining is a small part of the expense in connection with Cobalt operations. The cost of marketing ore alone amounts to 6.3 cents and the total cost of production amounts to 20.7 cents per ounce of silver.

The flow sheet shown in Fig. 9 is that of the Northern Customs Concentrating Co. The capacity of this mill is said to be 100 tons per day. The ore after passing the crusher in rolls is elevated to a Vezin sampler, where 10 per cent. is cut for a sample. The remainder goes through a trommel which screens out the fines, sending them to a hydraulic classifier, and the coarse or oversize to a 24″×40″ jig, where the metallic particles are sent to ore bins for sacking and shipment. The jig concentrate includes small pieces of high-grade ore and heavy silver. The tailing from the jigs and spigot product from the classifier go to the stamps which crush to 30-mesh. The pulp from the stamps is elevated to a Richards classifier and separated into two sizes; the spigot or coarse sand goes to the tables, the overflow to the vanners. The tables and vanners extract the loose particles of metallic silver and the heavy metallic minerals with more or less rock attached. This product delivered at the mill and the concentrate delivered to the owners is sacked, dried, and loaded on the cars. As an example, one milling rock contains 25 ounces of silver and one contains 100 ounces of silver, assume that 100 tons of each is to be milled. One hundred tons of 25-ounce silver would, if there were no loss, furnish 2,500 ounces of silver, but there is a loss of 12 per cent. in concentration or 300 ounces of silver, making 2,200 ounces of silver in $2\frac{1}{4}$ tons of concentrates. With silver at 50 cents an ounce this would be $1,100. The cost of concentrating 100 tons at $4 a ton would be $400, thus leaving balance in favor of the miner of $700, or $7 a ton.

In the second case 100 tons of 100-ounce silver would mean 10,000 ounces of silver. As there is a loss of 12 per cent. in concentrating there would be 8,800 ounces of silver available. This at 50 cents an ounce would amount to about $4,400. Less the cost of concentrating $400, thus netting the operator $4,000. The concentrates are now shipped to the smelter. Assuming it would pay for 94 per cent. of the silver contents, less a treatment charge of $10 per ton, plus $\frac{1}{2}$ cent on each ounce of silver contained. No smelter can afford to treat ore running

as low as 25 ounces, and the cost of freight on a ton of 25 ounces of ore would make the shipment prohibitory. On the other hand, by concentrating the miner obtains a fair return for his trouble. Different custom mills have different schedules but they are not far apart.

Fig. 10 shows the flow sheet of the O'Brien mill which is said to have a capacity of 125 tons per day. At this mill Richards jigs are introduced to work on material under ¾ inch in diameter. Also at this mill cyanide solution is introduced in part of the stamp-mill battery. The stamps are generally run in batteries of five, having separate cam-shafts, and part of them are run on clear water and send their pulp to tables, classifiers, slimers, and vanners. The pulp from the stamps, crushing in cyanide solution, is delivered to two Hardinge conical mills, which recrush the slime for the usual cyanide slime process, consisting of Dorr pulp thickener, Pachuca agitators, Moore filters, zinc precipitation tanks, and a filter press for the precipitate.

Fig. 11 is a flow sheet of the Nova Scotia mill, where there are 20 stamps which crush in cyanide solution, delivering the pulp to tables, then to classifiers and the spigot to tube mills. The overflow from the classifiers is given in cyanide treatment and the precipitates after filter pressing are refined into bullion. The Nova Scotia mill and the O'Brien mill seem to be the only two straight cyanide mills so far in the Cobalt district.

Fig. 12 is a flow sheet of the Silver Cliff concentrator. At this mill straight concentration will be practiced when it is finished. It is designed to handle 100 tons of ore per day. There are no stamps at this mill but there are two sets of 14″×42″ rolls and one 6-foot Chilian mill for a recrusher of the material coming from the jigs.

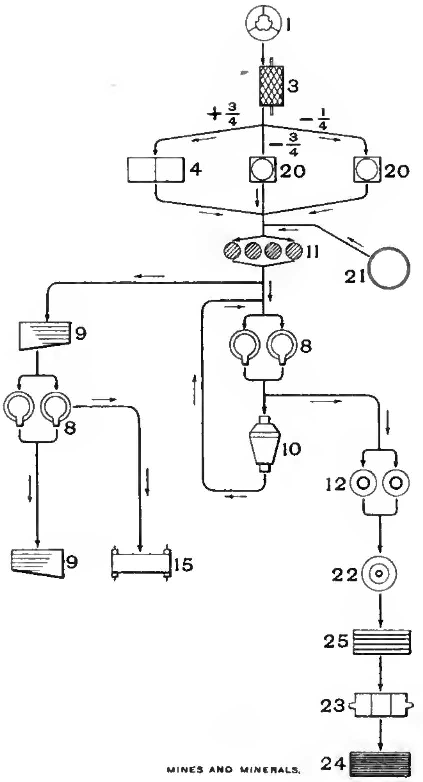

FIG. 10. O'BRIEN MILL

The flow sheet shown in Fig. 13 is that of the Temiskaming mill, designed for a capacity of 100 tons a day with 30 stamps. The mill is to work on ore carrying 50 ounces of silver to the ton and the management thinks that $15 per ton profit is not too much to be expected. It is stated that a Chilian mill will be used at this plant as a recrusher previous to cyaniding the tailing from slime tables.

Fig. 14 is that of the Trethewey mill. This mill has 30 stamps, the sand from which is to go to six tables, the middling to be reground in a tube mill, from which it goes to six slime tables. The capacity of this mill is reckoned at 100 tons with 30 stamps. No arrangements have been made for cyaniding. While the cost of power at Cobalt has been as high as from $150 to $180 per horsepower a year, the Cobalt electric plant on the Montreal River, 10 miles south of Cobalt, is now selling power for $50 per horsepower year. Compressed air is also delivered at Cobalt from the hydraulic air compressor at Ragged Chutes in the Montreal River. This is sold to the mines at about 25 cents per thousand feet, reckoned at atmospheric pressure.

The future of Cobalt, for a number of years to come, is firmly established by the quantity of low-grade ore and the reduction which is being made in the cost of treatment. New veins are being continually found in the district, and at some of the mines for every ton of ore mined 3 tons have been blocked out. By this means dividends are assured for some time to come.

TUNGSTEN ORE IN WASHINGTON

**By August Wolf*

H. E. Schleiff, M. E., of Berlin, Germany, a recognized authority on tungsten, vanadium, and uranium, who has just completed a thorough investigation of the deposits and development work in the three camps in Stevens County, Wash,. located from 40 to 75 miles north of Spokane, declares that within its confines is the largest and most promising tungsten field in the world. He said:

The tungsten district in Stevens County has a chance to overshadow Boulder County, Colo., in the next few years. Boulder County is the country's chief producer, having an output of from 3,000 to 4,000 tons of concentrates a year. There is sufficient ore in the Stevens County deposits to harden steel for all the war guns, all the battleships, and all commercial uses throughout the century, and the profits that will accrue from its production may equal the millions in gold taken from the foremost fields in the country.

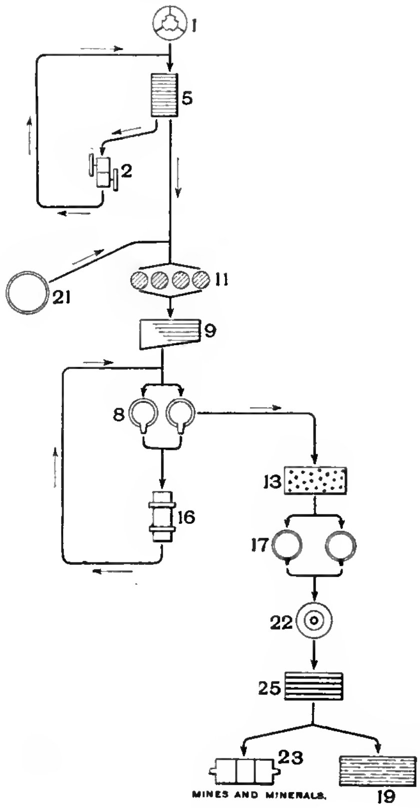

FIG. 11. NOVA SCOTIA MILL

Three camps are under development. One is the Germania in Cedar cañon, 30 miles north of Springdale; the Tungsten King, 8 miles north of Deer Park; and the Blue Grouse, a mile south of the Tungsten King and 8 miles from Loon Lake. Several tons of concentrates have been sent to the market. Prospecting is proceeding at many points in the field, embracing an area of 10 by 40 miles, and corporations are being formed for development on a broad scale.

The Germania, the oldest corporation in the district, has been operating the last 3 years. It has a property of large area on which the tungsten showing is large and promises greater. The country rocks throughout the district are feldspar and hornblende, containing small fragments of mica. The feldspar near Cedar cañon occurs in large pieces of the rock itself, differing in this characteristic from the granite structure in the Loon Lake–Deer Park district, where the feldspar is smaller and the granite contains more mica.

* 225 Hutton Building, Spokane, Wash.

Tunnels driven on one of the big veins in the Germania group have exposed a stoping area of 3,000 tons. Other veins of promise have been exposed by open cuts and short tunnels. Breaks in the main tunnel have caused some inconvenience in the process of development. The characteristic course of the cut-off is toward the foot-wall, pushing the vein 25 feet to the side, after which its regular course is resumed.

The crude ore in the lower levels contains from 3 to 4 per cent. tungstic acid and a little pyrite, while in the upper levels the percentage is from 4 to 6 per cent., with much pyrite. An examination of the dump and slimes suggested that more tungsten is being turned out of the mill than is being saved. The ore loses a great deal of the tungsten because of the imperfect treatment. The company intends to erect a 100-ton mill erect a mill next year and purposes making it the best on the continent.

The concentration of tungsten ore is accomplished with less difficulty in Stevens County than in Colorado. The tungsten ore in Boulder County occurs in fine seams in the quartz, or is impregnated in fine particles of quartz in the vein of the granite, and requires a fine grinding to extract the tungsten. In Stevens County the tungsten is of greater solidity and of higher percentage. It occurs in chunks of various sizes, sporadic in the vein of the granite, and, therefore, is not subject to fine grinding. Crushing the ore to a mesh of $\frac{3}{16}$ inch will produce less slime and make possible a higher saving.

The markets in the United States, Canada, England, Germany, France and other countries demand tungsten running

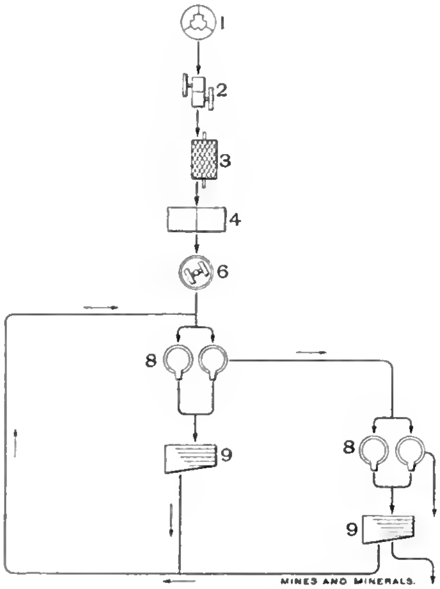

Fig. 12. Silver Cliff Mill

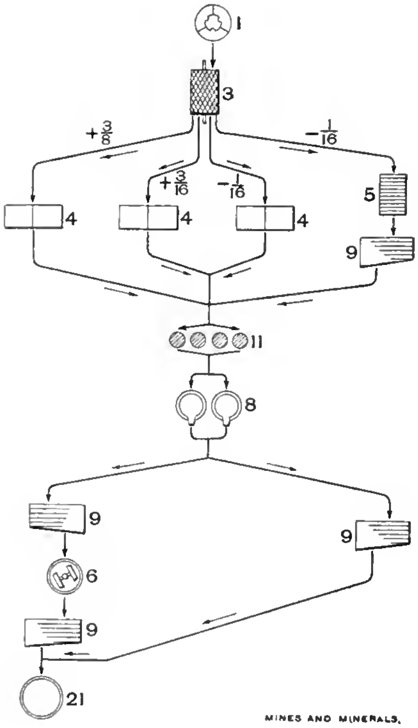

Fig. 13. Temiskaming Mill

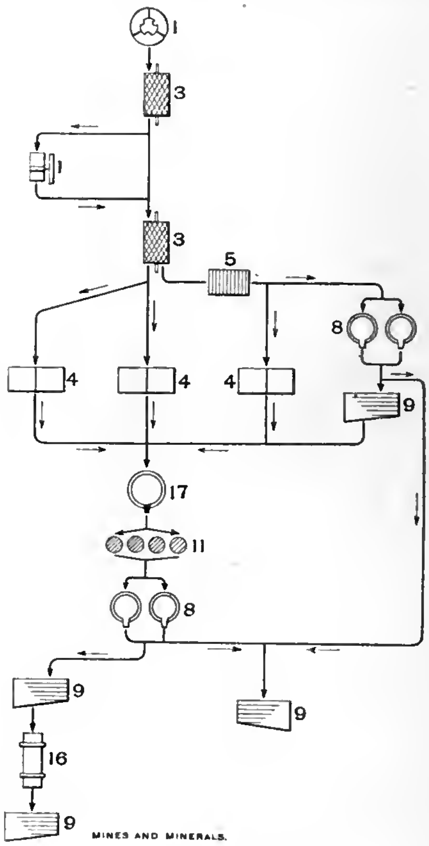

Fig. 14. Trethewey Mill

next year to replace the present 25-ton plant, with the expectation of saving 95 per cent. of the tungstic acid, which is easily possible with special machinery.

The Tungsten King obtains its ore through tunnels driven on several veins. It runs from 6 to 8 per cent., but about 50 per cent. of it is lost by poor treatment. No provision is made to save the slimes, which are bound to occur by grinding any kind of ore, especially tungsten. This part of the product must be saved by machinery constructed especially for that purpose.

A tunnel is being driven on the Blue Grouse property to reach the lead, which crosses the contact between granite and quartzite. The Blue Grouse occupies the granite side of the contact while the Tungsten King has the quartzite side. Enrichment appears to take place on the contact, the tungsten mineral metasomatically replacing the hornblende by the granite.

The Blue Grouse property is in the hands of W. A. Brockway, manager and superintendent, who is one of the few men in the country familiar with tungsten. He gained his knowledge of the metal in Boulder County, Colo. It is said that he will 60 per cent. tungstic acid (WO_3). The desire of many millmen to raise the concentrate to a percentage of from 70 to 72 is absurd. A high percentage of concentrate can be obtained only at the expense of the middle product, which, by the lower percentage of concentrate, can be saved. The experience with tungsten has been that the best results are obtained in an effort to make a 62-per-cent. product.

Because of the great ease and facility of transmission, the telephone has in the past couple of years been making rapid strides into favor among railroad managers. It performs the work formerly done by the telegraph in a more rapid and efficient manner, and the adoption of the telephone standard by a great many of the largest railroads in the country has caused a complete change in dispatching methods.

The smokeless-powder factory of the Mexican Government having been completed, will shortly be inaugurated. Its annual capacity is 110,000 pounds of powder of the best quality.

TIN SLUICING IN TASMANIA

*By Edward Edwards**

The tin fields of Northeastern Tasmania are in the ancient and present river beds tributary to the Ringarooma River. Much of the granite rock which predominates in the Ringarooma watershed is tin bearing, and from this rock the stanniferous alluvial deposits have been derived. The deposits have a length of 13 miles, a width of over a mile and in places at the northern end, have a depth of 230 feet.

Methods of Prospecting and Breaking Down the Ground. Arrangement of Sluices

Figs. 1 and 2 show the granite country rock, how it was eroded to form the ancient river channel, the alluvial drift that filled the channel and was later covered over by a volcanic overflow of basalt, likewise the sections of the present rivers relative to the Briseis and North Home mines. Tin is scattered as cassiterite SnO_2 throughout the alluvial drift, although as a rule, its great weight (specific gravity 6.5–7.1) compared with the other minerals in the granite has caused it to sink to bed rock wherever possible and become more or less concentrated.

The present river beds are worked by dredging; while the ancient river beds are worked by dredging or hydraulicking, and it is this latter class of deposits this paper describes.

For successful hydraulic mining there are five essentials; and neglect to investigate any one may cause failure:

1. The deposit must be capable of being broken down and sluiced by water.
2. There must be a sufficient quantity of water available for breaking down, transporting material, and for all other purposes.
